Acetaminophen is metabolized predominantly by a phase II reaction to innocuous sulfate and glucuronide metabolites; however, a small proportion is metabolized by a phase I reaction to a hepatotoxic metabolite formed from the parent compound by cytochrome P450 CYP2E1. This metabolite, *N*-acetyl-p-benzoquinone-imine (NAPQI), is detoxified by binding to "hepatoprotective" glutathione to become harmless, water-soluble mercapturic acid, which undergoes renal excretion. When excessive amounts of NAPQI are formed, or when glutathione levels are low, glutathione levels are depleted and overwhelmed, permitting covalent binding to nucleophilic hepatocyte macromolecules forming acetaminophen-protein "adducts." These adducts, which can be measured in serum by high-performance liquid chromatography, hold promise as diagnostic markers of acetaminophen hepatotoxicity, and a point-of-care assay for acetaminophen-Cys adducts is under development. The binding of acetaminophen to hepatocyte macromolecules is believed to lead to hepatocyte necrosis; the precise sequence and mechanism are unknown. Hepatic injury may be potentiated by prior administration of alcohol, phenobarbital, INH, or other drugs; by conditions that stimulate the mixed-function oxidase system; or by conditions such as starvation (including inability to maintain oral intake during severe febrile illnesses) that reduce hepatic glutathione levels. Alcohol induces cytochrome P450 CYP2E1; consequently, increased levels of the toxic metabolite NAPQI may be produced in chronic alcoholics after acetaminophen ingestion, but the role of alcohol in potentiating acute acetaminophen injury is still debated. Alcohol also suppresses hepatic glutathione production. Therefore, in chronic alcoholics, the toxic dose of acetaminophen may be as low as 2 g, and alcoholic patients should be warned specifically about the dangers of even standard doses of this commonly used drug. In a 2006 study, aminotransferase elevations were identified in 31–44% of normal subjects treated for 14 days with the maximal recommended dose of acetaminophen, 4 g daily (administered alone or as part of an acetaminophen-opioid combination); because these changes were transient and never associated with bilirubin elevation, the clinical relevance of these findings remains to be determined. Although underlying hepatitis C virus (HCV) infection was found to be associated with an increased risk of acute liver injury in patients hospitalized for acetaminophen overdose, generally, in patients with nonalcoholic liver disease, acetaminophen taken in recommended doses is well tolerated. Acetaminophen use in cirrhotic patients has not been associated with hepatic decompensation. On the other hand, because of the link between acetaminophen use and liver injury and because of the limited safety margin between safe and toxic doses, the FDA has recommended that the daily dose of acetaminophen be reduced from 4 g to 3 g (even lower for persons with chronic alcohol use), that all acetaminophen-containing products be labeled prominently as containing acetaminophen, and that the potential for liver injury be prominent in the packaging of acetaminophen and acetaminophen-containing products. Within opioid combination products, the limit for the acetaminophen component has been lowered to 325 mg per tablet.

TREATMENT

Acetaminophen Overdosage

Treatment includes gastric lavage, supportive measures, and oral administration of activated charcoal or cholestyramine to prevent absorption of residual drug. Neither charcoal nor cholestyramine appears to be effective if given >30 min after acetaminophen ingestion; if they are used, the stomach lavage should be done before other agents are administered orally. The chances of possible, probable, and high-risk hepatotoxicity can be derived from a nomogram plot **(Fig. 340-2)**, readily available in emergency departments, as a function of measuring acetaminophen plasma levels 4–8 h after ingestion. In patients with high acetaminophen blood levels (>200 μg/mL measured at 4 h or >100 μg/mL at 8 h after ingestion), the administration of *N*-acetylcysteine reduces markedly the severity of hepatic necrosis. This agent provides sulfhydryl donor groups to replete glutathione, which is required to render harmless toxic metabolites that would otherwise bind covalently via sulfhydryl linkages to cell proteins, resulting in the formation of drug metabolite-protein adducts. Therapy should be begun within 8 h of ingestion but may be at least partially effective when given as late as 24–36 h after overdose. Routine use of *N*-acetylcysteine has substantially reduced the occurrence of fatal acetaminophen hepatotoxicity. *N*-acetylcysteine may be given orally but is more commonly used as an IV solution, with a loading dose of 140 mg/kg over 1 h, followed by 70 mg/kg every 4 h for 15–20 doses. Whenever a patient with potential acetaminophen hepatotoxicity is encountered, a local poison control center should be contacted. Treatment can be

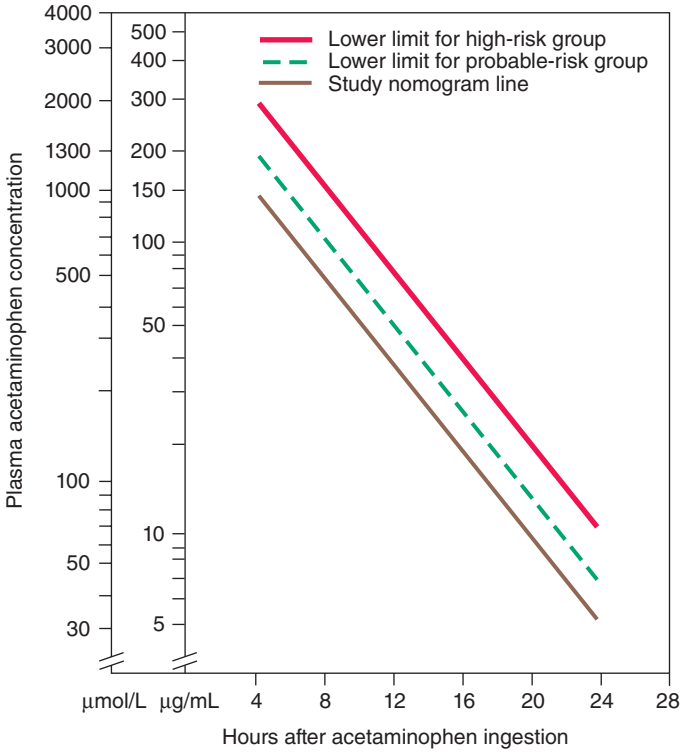

FIGURE 340-2 Nomogram to define risk of acetaminophen hepatotoxicity according to initial plasma acetaminophen concentration. *(Reproduced with permission from Pediatrics, 55:871. Copyright © 1975 by the AAP.)*

stopped when plasma acetaminophen levels indicate that the risk of liver damage is low. If signs of hepatic failure (e.g., progressive jaundice, coagulopathy, confusion) occur despite *N*-acetylcysteine therapy for acetaminophen hepatotoxicity, liver transplantation may be the only option. Early arterial blood lactate levels among such patients with acute liver failure may distinguish patients highly likely to require liver transplantation (lactate levels >3.5 mmol/L) from those likely to survive without liver replacement. Acute renal injury occurs in nearly 75% of patients with severe acetaminophen injury but is virtually always self-limited.

Survivors of acute acetaminophen overdose rarely, if ever, have ongoing liver injury or sequela but may be subject to repeat overdosing.

ISONIAZID HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION)

INH remains central to most antituberculous prophylactic and therapeutic regimens, despite its long-standing recognition as a hepatotoxin. In 10% of patients treated with INH, elevated serum aminotransferase levels develop during the first few weeks of therapy; however, these elevations in most cases are self-limited, are mild (values for ALT <200 IU/L), and resolve despite continued drug use. This adaptive response allows continuation of the agent if symptoms and progressive enzyme elevations do not follow the initial elevations. Acute hepatocellular DILI secondary to INH is evident with a variable latency period up to 6 months and is more frequent in alcoholics and patients taking certain other medications, such as barbiturates, rifampin, and pyrazinamide. If the clinical threshold of encephalopathy is reached, severe hepatic injury is likely to be fatal or to require liver transplantation. Liver biopsy reveals morphologic changes similar to those of viral hepatitis or bridging hepatic necrosis. Substantial liver injury appears to be age-related, increasing substantially after age 35; the highest frequency is in patients over age 50, and the lowest is in patients under the age of 20. Even for patients >50 years of age monitored carefully during therapy, hepatotoxicity occurs in only ~2%, well below the risk estimate derived from earlier experiences. Fever, rash, eosinophilia, and other manifestations of drug allergy are distinctly unusual. Antibodies to INH have been detected in INH recipients, but a link to causality of liver injury remains unclear. A clinical picture resembling chronic hepatitis has been observed in a few patients. Many public health programs that require INH prophylaxis for a positive tuberculin skin test or blood test (Quantiferon or T-Spot) include monthly monitoring of aminotransferase levels, although this practice has been called into question. Even more effective in limiting serious outcomes may be encouraging patients to be alert for symptoms such as nausea, fatigue, or jaundice, because most fatalities occur in the setting of continued INH use despite clinically apparent illness. The incidence of severe INH toxicity may be declining as a result of less frequent use and/or better management.

SODIUM VALPROATE HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION)

Sodium valproate, an anticonvulsant useful in the treatment of petit mal and other seizure disorders, has been associated with the development of severe hepatic toxicity and, rarely, fatalities, predominantly in children but also in adults. Among children listed as candidates for liver transplantation, valproate is the most common antiepileptic drug implicated. Asymptomatic elevations of serum aminotransferase levels have been recognized in as many as 45% of treated patients. These "adaptive" changes, however, appear to have no clinical importance, because major hepatotoxicity is not seen in the majority of patients despite continuation of drug therapy. In the rare patients in whom jaundice, encephalopathy, and evidence of hepatic failure are found, examination of liver tissue reveals microvesicular fat and bridging hepatic necrosis, predominantly in the centrilobular zone. Bile duct injury may also be apparent. Most likely, sodium valproate is not directly hepatotoxic, but its metabolite, 4-pentenoic acid, may be responsible for hepatic injury. Valproate hepatotoxicity is more common in persons with mitochondrial enzyme deficiencies and may be ameliorated by IV administration of carnitine, which valproate therapy can deplete. Valproate toxicity has been linked to HLA haplotypes (*DR4* and *B*1502*) and to mutations in mitochondrial DNA polymerase gamma 1.

NITROFURANTOIN HEPATOTOXICITY (IDIOSYNCRATIC REACTION)

This commonly used antibiotic for urinary tract infections may cause an acute hepatitis leading to fatal outcome or, more frequently, chronic hepatitis of varying severity but indistinguishable from autoimmune hepatitis. These two scenarios may reflect the frequent use and reuse of the drug for treatment of recurrent cystitis in women. Although most toxic agents manifest injury within 6 months of first ingestion, nitrofurantoin may have a longer latency period, in part perhaps because of its intermittent, recurrent use. Autoantibodies to nuclear components, smooth muscle, and mitochondria are seen and may subside after resolution of injury; however, glucocorticoid or other immunosuppressive medication may be necessary to resolve the autoimmune injury, and cirrhosis may be seen in cases that are not recognized quickly. Interstitial pulmonary fibrosis presenting as chronic cough and dyspnea may be present and resolve slowly with medication withdrawal. Histologic findings are identical to those of autoimmune hepatitis. A similar disease pattern can be observed with minocycline, which is used repeatedly for the treatment of acne in teenagers, as well as with hydralazine and α-methyldopa.

AMOXICILLIN-CLAVULANATE HEPATOTOXICITY (IDIOSYNCRATIC MIXED REACTION)

Currently, the most common agent implicated as causing DILI in the United States and in Europe is amoxicillin-clavulanate (most frequent brand name: Augmentin). This medication causes a very specific syndrome of mixed or primarily cholestatic injury. Because hepatotoxicity may follow amoxicillin-clavulanate therapy after a relatively long latency period, the liver injury may begin to manifest after the drug has been withdrawn. The high prevalence of hepatotoxicity reflects in part the very frequent use of this drug for respiratory tract infections, including community-acquired pneumonia. The mechanism of

hepatotoxicity is unclear, but the liver injury is thought to be caused by amoxicillin toxicity that is potentiated in some way by clavulanate, which itself appears not to be toxic. Symptoms include nausea, anorexia, fatigue, and jaundice—which may be prolonged—with pruritus. Rash is quite uncommon. On occasion, amoxicillin-clavulanate, like other cholestatic hepatotoxic drugs, causes permanent injury to small bile ducts, leading to the so-called "vanishing bile duct syndrome." In vanishing bile duct syndrome, initially, liver injury is minimal except for severe cholestasis; however, over time, histologic evidence of bile duct abnormalities is replaced by a paucity and eventual absence of discernible ducts on subsequent biopsies.

AMIODARONE HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION)

Therapy with this potent antiarrhythmic drug is accompanied in 15–50% of patients by modest elevations of serum aminotransferase levels that may remain stable or diminish despite continuation of the drug. Such abnormalities may appear days to many months after beginning therapy. A proportion of those with elevated aminotransferase levels have detectable hepatomegaly, and clinically important liver disease develops in <5% of patients. Features that represent a direct effect of the drug on the liver and that are common to the majority of long-term recipients are ultrastructural phospholipidosis, unaccompanied by clinical liver disease, and interference with hepatic mixed-function oxidase metabolism of other drugs. The cationic amphiphilic drug and its major metabolite desethylamiodarone accumulate in hepatocyte lysosomes and mitochondria and in bile duct epithelium. The relatively common elevations in aminotransferase levels are also considered a predictable, dose-dependent, direct hepatotoxic effect. On the other hand, in the rare patient with clinically apparent, symptomatic liver disease, liver injury resembling that seen in alcoholic liver disease is observed. The so-called pseudoalcoholic liver injury can range from steatosis, to alcoholic hepatitis–like neutrophilic infiltration and Mallory's hyaline, to cirrhosis. Electron-microscopic demonstration of phospholipid-laden lysosomal lamellar bodies can help to distinguish amiodarone hepatotoxicity from typical alcoholic hepatitis. This category of liver injury appears to be a metabolic idiosyncrasy that allows hepatotoxic metabolites to be generated. Rarely, an acute idiosyncratic hepatocellular injury resembling viral hepatitis or cholestatic hepatitis occurs. Hepatic granulomas have occasionally been observed. Because amiodarone has a long half-life, liver injury may persist for months after the drug is stopped.

ANABOLIC STEROIDS (CHOLESTATIC REACTION)

The most common form of liver injury caused by CAMs is the profound cholestasis associated with anabolic steroids used by body builders. Unregulated agents sold in gyms and health food stores as diet supplements, which are taken by athletes to improve their performance, may contain anabolic steroids. In a young male, jaundice that is accompanied by a cholestatic, rather than a hepatitic, laboratory profile almost invariably will turn out to be caused by the use of one of a variety of androgen congeners. Such agents have the potential to injure bile transport pumps and to cause intense cholestasis; the time to onset is variable, and resolution, which is the rule, may require many weeks to months. Initially, anorexia, nausea, and malaise may occur, followed by pruritus in some but not all patients. Serum aminotransferase levels are usually <100 IU/L, and serum alkaline phosphatase levels are generally moderately elevated with bilirubin levels frequently exceeding 342 μmol/L (20 mg/dL). Examination of liver tissue reveals cholestasis without substantial inflammation or necrosis. Anabolic steroids have also been used by prescription to treat bone marrow failure. In this setting, hepatic centrizonal sinusoidal dilatation and peliosis hepatis have been reported in rare patients, as have hepatic adenomas and hepatocellular carcinoma. Recently, a large series of cases with a uniform phenotype has been described. Unfortunately, no genomic signature has become evident despite the unique features of the injury. No permanent sequelae are evident besides prolonged jaundice, lasting frequently 10 weeks or more.

TRIMETHOPRIM-SULFAMETHOXAZOLE HEPATOTOXICITY (IDIOSYNCRATIC REACTION)

This antibiotic combination is used routinely for urinary tract infections in immunocompetent persons and for prophylaxis against and therapy of *Pneumocystis jirovecii* pneumonia in immunosuppressed persons (transplant recipients, patients with AIDS). With its increasing use, its occasional hepatotoxicity is being recognized with growing frequency. Its likelihood is unpredictable, but when it occurs, trimethoprim-sulfamethoxazole hepatotoxicity follows a relatively uniform latency period of several weeks and is often accompanied by eosinophilia, rash, and other features of a hypersensitivity reaction, including the drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome. Biochemically and histologically, acute hepatocellular necrosis predominates, but cholestatic features are quite frequent. Occasionally, cholestasis without necrosis occurs, and very rarely, a severe cholangiolytic pattern of liver injury is observed. In most cases, liver injury is self-limited, but rare fatalities have been recorded. The hepatotoxicity is attributable to the sulfamethoxazole component of the drug and is similar in features to that seen with other sulfonamides; tissue eosinophilia and granulomas may be seen. The risk of trimethoprim-sulfamethoxazole hepatotoxicity is increased in persons with HIV infection. In a recent study, unique HLA associations in European Americans and in African Americans have been identified.

HMG-COA REDUCTASE INHIBITORS (STATINS) (IDIOSYNCRATIC MIXED HEPATOCELLULAR AND CHOLESTATIC REACTION)

Between 1 and 2% of patients taking lovastatin, simvastatin, pravastatin, fluvastatin, or one of the newer statin drugs for the treatment of hypercholesterolemia experience asymptomatic, reversible elevations (greater than threefold) of aminotransferase activity. Acute hepatitis-like histologic changes, centrilobular necrosis, and centrilobular cholestasis have been described in a very small number of cases. In a larger proportion, minor aminotransferase elevations appear during the first several weeks of therapy. Careful laboratory monitoring can distinguish between patients with minor, transitory changes, who may continue therapy, and those with more profound and sustained abnormalities, who should discontinue therapy. Because clinically meaningful aminotransferase elevations are so rare after statin use and do not differ in meta-analyses from the frequency of such laboratory abnormalities in placebo recipients, a panel of liver experts recommended to the National Lipid Association's Safety Task Force that liver test monitoring was not necessary in patients treated with statins and that statin therapy need not be discontinued in patients found to have asymptomatic isolated aminotransferase elevations during therapy. Statin hepatotoxicity is not increased in patients with chronic hepatitis C, hepatic steatosis, or other underlying liver diseases, and statins can be used safely in these patients.

ALTERNATIVE AND COMPLEMENTARY MEDICINES (IDIOSYNCRATIC HEPATITIS, STEATOSIS)

Herbal medications that are of scientifically unproven efficacy and that lack prospective safety oversight by regulatory agencies account currently for >20% of DILI in the United States. Besides anabolic steroids, the most common category of dietary or herbal products is weight loss agents. Included among the herbal remedies associated with toxic hepatitis are Jin Bu Huan, xiao-chai-hu-tang, germander, chaparral, senna, mistletoe, skullcap, gentian, comfrey (containing pyrrolizidine alkaloids), ma huang, bee pollen, valerian root, pennyroyal oil, kava, celandine, Impila (*Callilepis laureola*), LipoKinetix, Hydroxycut, OxyElite Pro, Herbalife, herbal nutritional supplements, and herbal teas containing *Camellia sinensis* (green tea extract). Well characterized are the acute hepatitis-like histologic lesions following Jin Bu Huan use: focal hepatocellular necrosis, mixed mononuclear portal tract infiltration, coagulative necrosis, apoptotic hepatocyte degeneration, tissue eosinophilia, and microvesicular steatosis. Megadoses of vitamin A can injure the liver, as can pyrrolizidine alkaloids, which often contaminate Chinese herbal preparations and can cause a

veno-occlusive injury leading to sinusoidal hepatic vein obstruction. Because some alternative medicines induce toxicity via active metabolites, alcohol and drugs that stimulate cytochrome P450 enzymes may enhance the toxicity of some of these products. Conversely, some alternative medicines also stimulate cytochrome P450 and may result in or amplify the toxicity of recognized drug hepatotoxins. In many instances, herbal and dietary supplements actually contain chemicals rather than only leaves, roots, and bark. Antirheumatic "herbs" have been found to contain a nonsteroidal anti-inflammatory drug (NSAID) such as diclofenac, for example. Given the widespread use of such poorly defined herbal preparations, hepatotoxicity is likely to be encountered with increasing frequency; therefore, a drug history in patients with acute and chronic liver disease should include use of "alternative medicines" and other nonprescription preparations sold in so-called health food stores.

CHECKPOINT INHIBITOR AND OTHER IMMUNOTHERAPIES FOR CANCER

The introduction of a new class of immunotherapeutic agents for melanoma and other cancers has ushered in a new kind of hepatotoxicity, that associated with activation of the immune response. The three classes of immune-active molecules are cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4), programmed cell death receptor 1 (PD-1), and programmed cell death receptor ligand 1 (PD-L1). Within weeks of beginning treatment with any one of several agents, including ipilimumab (CTLA-4), pembrolizumab (PD-1), or nivolumab (PD-1), an active hepatitis evolves that is associated with positive ANAs and appears to respond to glucocorticoid therapy. Histologically, liver histology does not resemble autoimmune hepatitis but, instead, a nonspecific hepatic injury, assumed to result from the release of host modulation of anti-self-immune responses. Immune-mediated injury to thyroid, muscle, and colon is also commonly seen. Few deaths have been reported related to these immunotherapies; while these novel agents may need to be halted temporarily, in many cases, they can be restarted (and are tolerated better on retreatment) if patients are showing a favorable antitumor response.

HIGHLY ACTIVE ANTIRETROVIRAL THERAPY FOR HIV INFECTION (MITOCHONDRIAL TOXIC, IDIOSYNCRATIC, STEATOSIS; HEPATOCELLULAR, CHOLESTATIC, AND MIXED)

The recognition of drug hepatotoxicity in persons with HIV infection is complicated in this population by the many alternative causes of liver injury (chronic viral hepatitis, fatty infiltration, infiltrative disorders, mycobacterial infection, etc.), but drug hepatotoxicity associated with highly active antiretroviral therapy (HAART) was a common type of liver injury in HIV-infected persons in the early days of HIV therapy; however, it is less frequent now **(Chap. 202)**. Implicated most frequently are combinations including the nucleoside analogue reverse transcriptase inhibitors zidovudine, didanosine, and, to a lesser extent, stavudine; the protease inhibitors ritonavir and indinavir (and amprenavir when used together with ritonavir), as well as tipranavir; and the nonnucleoside reverse transcriptase inhibitors nevirapine and, to a lesser extent, efavirenz. Distinguishing the impact of HAART hepatotoxicity in patients with HIV and hepatitis virus co-infection is made challenging by the following: (1) both chronic hepatitis B and hepatitis C can affect the natural history of HIV infection and the response to HAART, and (2) HAART can have an impact on chronic viral hepatitis. For example, immunologic reconstitution with HAART can result in immunologically mediated liver-cell injury in patients with chronic hepatitis B co-infection if treatment with an antiviral agent for hepatitis B (e.g., nucleoside analogues such as tenofovir) is withdrawn. Infection with HIV, especially with low CD4+ T-cell counts, has been reported to increase the rate of hepatic fibrosis associated with chronic hepatitis C, and HAART therapy can increase levels of serum aminotransferases and HCV RNA in patients with hepatitis C co-infection. Didanosine or stavudine should not be used with ribavirin in patients with HIV/HCV co-infection because of an increased risk of severe mitochondrial toxicity and lactic acidosis.

341 Chronic Hepatitis

Jules L. Dienstag

Chronic hepatitis represents a series of liver disorders of varying causes and severity in which hepatic inflammation and necrosis continue for at least 6 months. Milder forms are nonprogressive or only slowly progressive, while more severe forms may be associated with scarring and architectural reorganization, which, when advanced, lead ultimately to cirrhosis. Several categories of chronic hepatitis have been recognized. These include chronic viral hepatitis, drug-induced chronic hepatitis **(Chap. 340)**, and autoimmune chronic hepatitis. In many cases, clinical and laboratory features are insufficient to allow assignment into one of these three categories; these "idiopathic" cases are also believed to represent autoimmune chronic hepatitis. Finally, clinical and laboratory features of chronic hepatitis are observed occasionally in patients with such hereditary/metabolic disorders as Wilson's disease (copper overload), α_1 antitrypsin deficiency **(Chaps. 344 and 415)**, and nonalcoholic fatty liver disease **(Chap. 343)** and even occasionally in patients with alcoholic liver injury **(Chap. 342)**. Although all types of chronic hepatitis share certain clinical, laboratory, and histopathologic features, chronic viral and chronic autoimmune hepatitis are sufficiently distinct to merit separate discussions. **For discussion of acute hepatitis, see Chap. 339.**

CLASSIFICATION OF CHRONIC HEPATITIS

Common to all forms of chronic hepatitis are histopathologic distinctions based on localization and extent of liver injury. These vary from the milder forms, previously labeled *chronic persistent hepatitis* and *chronic lobular hepatitis*, to the more severe form, formerly called *chronic active hepatitis*. When first defined, these

designations were believed to have prognostic implications, which were not corroborated by subsequent observations. Categorization of chronic hepatitis based primarily on histopathologic features has been replaced by a more informative classification based on a combination of clinical, serologic, and histologic variables. Classification of chronic hepatitis is based on (1) its *cause*; (2) its histologic activity, or *grade*; and (3) its degree of progression based on level of fibrosis, or *stage*. Thus, neither clinical features alone nor histologic features—requiring liver biopsy or noninvasive markers of fibrosis—alone are sufficient to characterize and distinguish among the several categories of chronic hepatitis.

CLASSIFICATION BY CAUSE

Clinical and serologic features allow the establishment of a diagnosis of *chronic viral hepatitis*, caused by hepatitis B, hepatitis B plus D, or hepatitis C; *autoimmune hepatitis*, including several subcategories, I and II, based on serologic distinctions; *drug-associated chronic hepatitis*; and a category of unknown cause, or *cryptogenic chronic hepatitis* **(Table 341-1)**. These are addressed in more detail below.

CLASSIFICATION BY GRADE

Grade, a histologic assessment of necroinflammatory activity, is based on examination of the liver biopsy. An assessment of important histologic features includes the degree of *periportal necrosis* and the disruption of the limiting plate of periportal hepatocytes by inflammatory cells (so-called *piecemeal necrosis* or *interface hepatitis*); the degree of confluent necrosis that links or forms bridges between vascular structures—between portal tract and portal tract or even more important bridges between portal tract and central vein—referred to as *bridging necrosis*; the degree of hepatocyte degeneration and focal necrosis within the lobule; and the degree of *portal inflammation*. Several scoring systems that take these histologic features into account have been devised, and the most popular are the histologic activity index (HAI), used commonly in the United States, and the METAVIR score, used in Europe **(Table 341-2)**. Based on the presence and degree of these features of histologic activity, chronic hepatitis can be graded as mild, moderate, or severe.

CLASSIFICATION BY STAGE

The stage of chronic hepatitis, which reflects the level of progression of the disease, is based on the degree of hepatic fibrosis. When fibrosis is so extensive that fibrous septa surround parenchymal nodules and alter the normal architecture of the liver lobule, the histologic lesion is defined as *cirrhosis*. Staging is based on the degree of fibrosis as categorized on a numerical scale 0–6 (HAI) or 0–4 (METAVIR) (Table 341-2). Several noninvasive approaches have been introduced to provide approximations of hepatic histologic stage, including serum biomarkers of fibrosis; fibrosis scores such as FIB-4, a validated algorithm based on such routine lab tests as aspartate and alanine aminotransferase (AST and ALT) levels and platelet counts (PLT) (age [years] × AST/PLT × $ALT^{1/2}$); and imaging determinations of liver elasticity.

CHRONIC VIRAL HEPATITIS

Both of the enterically transmitted forms of viral hepatitis, hepatitis A and E, are self-limited and do not cause chronic hepatitis (rare reports notwithstanding in which acute hepatitis A serves as a trigger for the onset of autoimmune hepatitis in genetically susceptible patients or in which hepatitis E **[Chap. 339]** can cause chronic liver disease in immunosuppressed hosts, for example, after liver transplantation). In contrast, the entire clinicopathologic spectrum of chronic hepatitis occurs in patients with chronic viral hepatitis B and C as well as in patients with chronic hepatitis D superimposed on chronic hepatitis B.

CHRONIC HEPATITIS B

The likelihood of chronicity after acute hepatitis B varies as a function of age. Infection at birth is associated with clinically silent acute infection but a 90% chance of chronic infection, whereas infection in young adulthood in immunocompetent persons is typically associated with clinically apparent acute hepatitis but a risk of chronicity of only ~1%. Most cases of chronic hepatitis B among adults, however, are recognized in patients who never had a recognized episode of clinically apparent acute viral hepatitis. The degree of liver injury (grade) in patients with chronic hepatitis B is variable, ranging from none in inactive carriers to mild to moderate to severe. Among adults with chronic hepatitis B, histologic features are of prognostic importance. In one long-term study of patients with chronic hepatitis B, investigators found a 5-year survival rate of 97% for patients with mild chronic hepatitis, 86% for patients with moderate to severe chronic hepatitis, and only 55% for patients with chronic hepatitis and postnecrotic cirrhosis. The 15-year survival in these cohorts was 77%, 66%, and 40%, respectively. On the other hand, more recent observations do not allow us to be so sanguine about the prognosis in patients with mild chronic hepatitis; among such patients followed for 1–13 years, progression to more severe chronic hepatitis and cirrhosis has been observed in more than a quarter of cases.

More important to consider than histology alone in patients with chronic hepatitis B is the degree of hepatitis B virus (HBV) replication. As reviewed in **Chap. 339,** chronic HBV infection can occur in the presence or absence of serum hepatitis B e antigen (HBeAg), and

TABLE 341-1 Clinical and Laboratory Features of Chronic Hepatitis

TYPE OF HEPATITIS	DIAGNOSTIC TEST(S)	AUTOANTIBODIES	THERAPY
Chronic hepatitis B	HBsAg, IgG anti-HBc, HBeAg, HBV DNA	Uncommon	IFN-α, PEG IFN-α Oral agents: First-line: entecavir, tenofovir Second-line: lamivudine, adefovir, telbivudine
Chronic hepatitis C	Anti-HCV, HCV RNA	Anti-LKM1[a]	PEG IFN-α plus ribavirin[b] Direct-acting oral agents: sofosbuvir, ledipasvir, velpatasvir ritonavir-boosted paritaprevir, ombitasvir, dasabuvir, elbasvir, grazoprevir, daclatasvir, simeprevir
Chronic hepatitis D	Anti-HDV, HDV RNA, HBsAg, IgG anti-HBc	Anti-LKM3	IFN-α, PEG IFN-α[c]
Autoimmune hepatitis	ANA[d] (homogeneous), anti-LKM1 (±) Hyperglobulinemia	ANA, anti-LKM1 anti-SLA[e]	Prednisone, azathioprine
Drug-associated	—	Uncommon	Withdraw drug
Cryptogenic	All negative	None	Prednisone (?), azathioprine (?)

[a]Antibodies to liver-kidney microsomes type 1 (autoimmune hepatitis type II and some cases of hepatitis C). [b]Supplanted in almost all cases by combinations of the direct-acting antiviral agents listed (see *www.hcvguidelines.org*). [c]Early clinical trials suggested benefit of IFN-α therapy; PEG IFN-α is as effective, if not more so, and has supplanted standard IFN-α. [d]Antinuclear antibody (autoimmune hepatitis type I). [e]Antibodies to soluble liver antigen (autoimmune hepatitis type III).

Abbreviations: HBc, hepatitis B core; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; IFN-α, interferon α; IgG, immunoglobulin G; LKM, liver-kidney microsome; PEG IFN-α, pegylated interferon α; SLA, soluble liver antigen.

[a]Ishak K, Baptista A, Bianchi L, et al: Histologic grading and staging of chronic hepatitis. J Hepatol 22:696, 1995. [b]Bedossa P, Poynard T, French METAVIR Cooperative Study Group: An algorithm for grading activity in chronic hepatitis C. Hepatology 24:289, 1996. [c]Necroinflammatory grade: A0 = none; A1 = mild; A2 = moderate; A3 = severe.

generally, for both HBeAg-reactive and HBeAg-negative chronic hepatitis B, the level of HBV DNA correlates with the level of liver injury and risk of progression. In *HBeAg-reactive chronic hepatitis B*, two phases have been recognized based on the relative level of HBV replication. The relatively *replicative phase* is characterized by the presence in the serum of HBeAg and HBV DNA levels well in excess of 10^3–10^4 IU/mL, sometimes exceeding 10^9 IU/mL; by the presence in the liver of detectable intrahepatocyte nucleocapsid antigens (primarily hepatitis B core antigen [HBcAg]); by high infectivity; and by accompanying liver injury. In contrast, the relatively *nonreplicative phase* is characterized by the absence of the conventional serum marker of HBV replication (HBeAg), the appearance of anti-HBe, levels of HBV DNA below a threshold of ~10^3 IU/mL, the absence of intrahepatocytic HBcAg, limited infectivity, and minimal liver injury. Patients in the relatively replicative phase tend to have more severe chronic hepatitis, whereas those in the relatively nonreplicative phase tend to have minimal or mild chronic hepatitis or to be inactive hepatitis B carriers. The likelihood in a patient with HBeAg-reactive chronic hepatitis B of converting spontaneously from relatively replicative to nonreplicative infection is ~10% per year. Distinctions in HBV replication and in histologic category, however, do not always coincide. In patients with HBeAg-reactive chronic HBV infection, especially when acquired at birth or in early childhood, as recognized commonly in Asian countries, a dichotomy is common between very high levels of HBV replication during the early decades of life (when the level of apparent host immunologic tolerance of HBV is relatively high) and negligible levels of liver injury; during this phase of chronic hepatitis B, the level of viral replication does not correlate with liver injury or late complications. Yet despite the relatively immediate, apparently benign nature of liver disease for many decades in this population, in the middle decades, activation of liver injury emerges as what appears to be the relative tolerance of the host to HBV declines, and these patients with childhood-acquired HBV infection are ultimately at increased risk later in life for cirrhosis, hepatocellular carcinoma (HCC) **(Chap. 82)**, and liver-related death; the link between high-level HBV replication and these late liver complications has been demonstrated convincingly in, and confined mostly to, persons in their middle decades, especially age ≥40. **A discussion of the pathogenesis of liver injury in patients with chronic hepatitis B appears in Chap. 339.**

HBeAg-negative chronic hepatitis B (i.e., chronic HBV infection with active virus replication and readily detectable HBV DNA but without HBeAg [anti-HBe-reactive]) is more common than HBeAg-reactive chronic hepatitis B in Mediterranean and European countries and in Asia (and, correspondingly, in HBV genotypes other than A). Compared to patients with HBeAg-reactive chronic hepatitis B, patients with HBeAg-negative chronic hepatitis B have HBV DNA levels several orders of magnitude lower (usually no more than 10^5–10^6 IU/mL) than those observed in the HBeAg-reactive subset. Most such cases represent precore or core-promoter mutations acquired late in the natural history of the disease (mostly early-life onset; age range 40–55 years, older than that for HBeAg-reactive chronic hepatitis B); these mutations prevent translation of HBeAg from the precore component of the HBV genome (precore mutants) or are characterized by downregulated transcription of precore mRNA (core-promoter mutants; **Chap. 339**). Although their levels of HBV DNA tend to be lower than among patients with HBeAg-reactive chronic hepatitis B, patients with HBeAg-negative chronic hepatitis B can have progressive liver injury (complicated by cirrhosis and HCC) and experience episodic reactivation of liver disease reflected in fluctuating levels of aminotransferase activity ("flares"). The biochemical and histologic activity of HBeAg-negative disease tends to correlate closely with levels of HBV replication, unlike the case mentioned above of Asian patients with HBeAg-reactive chronic hepatitis B during the early decades of their HBV infection. Worth reiterating, the level of HBV replication is the most important risk factor for the ultimate development of cirrhosis and HCC in both HBeAg-reactive (beyond the early decades of "relatively nonreplicative" infection) and HBeAg-negative patients. Although levels of HBV DNA are lower and more readily suppressed by therapy to undetectable levels in HBeAg-negative (compared to HBeAg-reactive) chronic hepatitis B, achieving sustained responses that permit discontinuation of antiviral therapy is less likely in HBeAg-negative patients (see below). Inactive carriers are patients

with circulating hepatitis B surface antigen (HBsAg), normal serum aminotransferase levels, minimal or no histologic evidence of liver injury, undetectable HBeAg, and levels of HBV DNA that are either undetectable or present at a threshold of $\leq 10^3$ IU/mL. This serologic profile occurs not only in inactive carriers but also in patients with HBeAg-negative chronic hepatitis B during periods of relative inactivity; distinguishing between the two requires sequential biochemical and virologic monitoring over many months.

The spectrum of *clinical features* of chronic hepatitis B is broad, ranging from asymptomatic infection to debilitating disease or even end-stage, fatal hepatic failure. As noted above, the onset of the disease tends to be insidious in most patients, apart from the very few in whom chronic disease follows failure of resolution of clinically apparent acute hepatitis B. **The clinical and laboratory features associated with progression from acute to chronic hepatitis B are discussed in Chap. 339.**

Fatigue is a common symptom, and persistent or intermittent *jaundice* is a common feature in severe or advanced cases. Intermittent deepening of jaundice and recurrence of malaise and anorexia, as well as worsening fatigue, are reminiscent of acute hepatitis; such exacerbations may occur spontaneously, often coinciding with evidence of virologic reactivation; may lead to progressive liver injury; and, when superimposed on well-established cirrhosis, may cause hepatic decompensation. Complications of cirrhosis occur in end-stage chronic hepatitis and include ascites, edema, bleeding gastroesophageal varices, hepatic encephalopathy, coagulopathy, and hypersplenism. Occasionally, these complications bring the patient to initial clinical attention. Extrahepatic complications of chronic hepatitis B, similar to those seen during the prodromal phase of acute hepatitis B, are associated with tissue deposition of circulating hepatitis B antigen–antibody immune complexes. These include arthralgias and arthritis, which are common, and the rarer purpuric cutaneous lesions (leukocytoclastic vasculitis), immune-complex glomerulonephritis, and generalized vasculitis (polyarteritis nodosa) **(Chap. 363)**.

Laboratory features of chronic hepatitis B do not distinguish adequately between histologically mild and severe hepatitis. Aminotransferase elevations tend to be modest for chronic hepatitis B but may fluctuate in the range of 100–1000 units. As is true for acute viral hepatitis B, ALT tends to be more elevated than AST; however, once cirrhosis is established, AST tends to exceed ALT. Levels of alkaline phosphatase activity tend to be normal or only marginally elevated. In severe cases, moderate elevations in serum bilirubin (51.3–171 μmol/L [3–10 mg/dL]) occur. Hypoalbuminemia and prolongation of the prothrombin time occur in severe or end-stage cases. Hyperglobulinemia and detectable circulating autoantibodies are distinctly absent in chronic hepatitis B (in contrast to autoimmune hepatitis). **Viral markers of chronic HBV infection are discussed in Chap. 339**.

TREATMENT

Chronic Hepatitis B

Although progression to cirrhosis is more likely in severe than in mild or moderate chronic hepatitis B, all forms of chronic hepatitis B can be progressive, and progression occurs primarily in patients with active HBV replication. Moreover, in populations of patients with chronic hepatitis B who are at risk for HCC **(Chap. 82)**, the risk is highest for those with continued, high-level HBV replication and lower for persons in whom initially high-level HBV DNA falls spontaneously over time. Therefore, management of chronic hepatitis B is directed at suppressing the level of virus replication. Although clinical trials tend to focus on clinical endpoints achieved over 1–2 years (e.g., suppression of HBV DNA to undetectable levels, loss of HBeAg/HBsAg, improvement in histology, normalization of ALT), these short-term gains translate into reductions in the risk of clinical progression, hepatic decompensation, HCC, liver transplantation, and death; regression of cirrhosis and of esophageal varices has been documented to follow long-term pharmacologic suppression of HBV replication. In addition, restoration of impaired HBV-specific T-cell function has been shown following successful suppression of HBV replication with antiviral therapy. To date, eight drugs have been approved for treatment of chronic hepatitis B: injectable interferon (IFN) α and pegylated interferon (long-acting IFN bound to polyethylene glycol, PEG [PEG IFN]) and the oral agents lamivudine, adefovir dipivoxil, entecavir, telbivudine, tenofovir disoproxil fumarate (TDF), and tenofovir alafenamide (TAF).

Antiviral therapy for hepatitis B has evolved rapidly since the mid-1990s, as has the sensitivity of tests for HBV DNA. When IFN and the first oral antiviral lamivudine were evaluated in clinical trials, HBV DNA was measured by insensitive hybridization assays with detection thresholds of 10^5–10^6 virions/mL; when subsequent treatments were studied in clinical trials, HBV DNA was measured by sensitive amplification assays (polymerase chain reaction [PCR]) with detection thresholds of 10^1–10^3 viral copies/mL or IU/mL. Recognition of these distinctions is helpful when comparing results of clinical trials that established the efficacy of these therapies (reviewed below in chronologic order of publication of these efficacy trials). Of the eight approved treatments, PEG IFN, entecavir, and the two tenofovir preparations (TDF and TAF) are recommended as first-line agents, and generally, the oral agents are favored over injectable PEG IFN.

INTERFERON

IFN-α was the first approved therapy (1992) for chronic hepatitis B. Although it is no longer used to treat hepatitis B, standard IFN is important historically, having provided important lessons about antiviral therapy in general. For immunocompetent adults with *HBeAg-reactive chronic hepatitis B* (who tend to have high-level HBV DNA [$>10^5$–10^6 virions/mL] and histologic evidence of chronic hepatitis on liver biopsy), a 16-week course of subcutaneous IFN, 5 million units daily or 10 million units thrice weekly, resulted in a loss of HBeAg and hybridization-detectable HBV DNA (i.e., a reduction to levels below 10^5–10^6 virions/mL) in ~30% of patients, with a concomitant improvement in liver histology. Seroconversion from HBeAg to anti-HBe occurred in ~20%, and, in early trials, ~8% lost HBsAg. Successful IFN therapy and seroconversion were often accompanied by an acute hepatitis-like elevation in aminotransferase activity, postulated to result from enhanced cytolytic T-cell clearance of HBV-infected hepatocytes. Relapse after successful therapy was rare (1 or 2%). Responsiveness to IFN was higher in patients with low-level HBV DNA and substantial ALT elevations. Therapy with IFN was not effective in immunosuppressed persons, persons with neonatal acquisition of infection and minimal-to-mild ALT elevations, or patients with decompensated chronic hepatitis B (in whom such therapy was actually detrimental, sometimes precipitating decompensation, often associated with severe adverse effects). After HBeAg loss during IFN therapy, 80% experienced eventual loss of HBsAg and ALT normalization over the ensuing decade. In addition, improved long-term and complication-free survival as well as a reduction in the frequency of HCC were documented among IFN responders, supporting the conclusion that successful antiviral therapy improves the natural history of chronic hepatitis B.

Brief-duration IFN therapy in patients with *HBeAg-negative chronic hepatitis B* was disappointing, suppressing HBV replication transiently during therapy but almost never resulting in sustained antiviral responses; however, more protracted courses for up to 1.5 years resulted in sustained virologic/biochemical remissions documented to last for several years in ~20%.

Complications of IFN therapy include systemic "flu-like" symptoms; marrow suppression; emotional lability (irritability, depression, anxiety); autoimmune reactions (especially autoimmune thyroiditis); and miscellaneous side effects such as alopecia, rashes, diarrhea, and numbness and tingling of the extremities. With the possible exception of autoimmune thyroiditis, all these side effects are reversible upon dose lowering or cessation of therapy.

Although no longer competitive with the newer generation of antivirals, IFN did represent the first successful antiviral approach, set a standard against which to measure efficacy of subsequent drugs, and demonstrated the benefit of antiviral therapy on the natural history of chronic hepatitis B. Standard IFN has been supplanted by long-acting PEG IFN (see below), and IFN nonresponders are now treated with one of the newer oral nucleoside analogues.

LAMIVUDINE

The first of the nucleoside analogues to be approved (in 1998) for hepatitis B, the dideoxynucleoside lamivudine inhibits reverse transcriptase activity of both HIV and HBV and is an effective agent for chronic hepatitis B; however, it is now superseded by newer, more potent, less resistance-prone agents. For a summary of its virologic, serologic, biochemical, and histologic efficacy, as well as its resistance profile, please refer to **Table 341-3**. In clinical trials, lamivudine therapy at daily doses of 100 mg for 48–52 weeks suppressed HBV DNA, as measured by sensitive PCR amplification assays, by a median of ~5.5 $\log_{10}$ copies/mL in HBeAg-positive chronic hepatitis B and ~4.5 $\log_{10}$ copies/mL in HBeAg-negative chronic hepatitis B (baseline HBV DNA levels

[a]Generally, these comparisons are based on data on each drug tested individually versus placebo in registration clinical trials; with rare exception, these comparisons are not based on head-to-head testing of these drugs. In addition, the sensitivity of HBV DNA assays increased in sensitivity over the two decades between the introduction of the earliest and latest of these approved drugs. Therefore, relative advantages and disadvantages should be interpreted cautiously. [b]Although standard interferon α administered daily or three times a week is approved as therapy for chronic hepatitis B, it has been supplanted by PEG IFN, which is administered once a week and is more effective. Standard interferon has no advantages over PEG IFN. [c]Duration of therapy in clinical efficacy trials; use in clinical practice may vary. [d]Because of a computer-generated randomization error that resulted in misallocation of drug versus placebo during the second year of clinical trial treatment, the frequency of HBeAg seroconversion beyond the first year is an estimate (Kaplan-Meier analysis) based on the small subset in whom adefovir was administered correctly. [e]7% during a year of therapy (43% at year 4) in lamivudine-resistant patients. [f]Despite its category C designation, lamivudine has an extensive pregnancy safety record in women with HIV/AIDS.

Abbreviations: ALT, alanine aminotransferase; HAI, histologic activity index; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; NA, not applicable; PEG IFN, pegylated interferon; PCR, polymerase chain reaction; Rx, therapy; yr, year; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate.

are lower in HBeAg-negative than in HBeAg-positive chronic hepatitis B) and to undetectable levels in ~40% and ~70%, respectively. Lamivudine, which was shown to improve histology, retard hepatic fibrosis, and prevent progression to cirrhosis, was effective in patients resistant to IFN (e.g., those with high-level HBV DNA) or who had failed prior IFN therapy. As was true for IFN therapy of chronic hepatitis B, lamivudine-associated HBeAg seroconversion occurred in ~20%; patients with near-normal ALT activity tended not to experience HBeAg responses (despite suppression of HBV DNA), while patients with ALT levels ≥5× the upper limit of normal could expect 1-year HBeAg seroconversion rates of 50–60%. Generally, HBeAg seroconversions were confined to patients who achieved suppression of HBV DNA to $<10^4$ copies/mL (equivalent to ~10^3 IU/mL). Lamivudine-associated HBeAg responses were accompanied by a delayed posttreatment HBsAg seroconversion rate comparable to that seen after IFN. Among Western patients who experienced HBeAg responses during a year-long course of therapy and in whom the response was sustained for 4–6 months after cessation of therapy, the response was durable thereafter in the vast majority (>80%); therefore, the achievement of an HBeAg response represented a viable stopping point in therapy. Reduced durability, however, was reported in Asian patients; therefore, to support the durability of HBeAg responses, a period of consolidation therapy of ≥6 months in Western patients and ≥1 year in Asian patients was recommended after HBeAg seroconversion (see treatment guidelines below; a full 12-month consolidation period is recommended currently for treatment extension after oral-agent-induced HBeAg seroconversion). Close posttreatment monitoring was recommended to identify HBV reactivation promptly and to resume therapy. If HBeAg was unaffected by lamivudine therapy, lamivudine was continued until an HBeAg response occurred, but long-term therapy was required to suppress HBV replication and, in turn, limit liver injury; HBeAg seroconversions increased to a level of 50% after 5 years of therapy. After a cumulative course of 3 years of lamivudine therapy, necroinflammatory activity was reduced in the majority of patients, and even cirrhosis was shown to regress to precirrhotic stages in as many as three-quarters of patients.

Losses of HBsAg were few during the first year of lamivudine therapy, and this observation had been cited as an advantage of IFN-based therapy over lamivudine therapy; however, in head-to-head comparisons between standard IFN and lamivudine monotherapy, HBsAg losses were rare in both groups. Trials in which lamivudine and IFN were administered in combination failed to show a benefit of combination therapy over lamivudine monotherapy for either treatment-naïve patients or prior IFN nonresponders.

Patients with *HBeAg-negative chronic hepatitis B* (i.e., in those with precore and core-promoter HBV mutations and who lack HBeAg) cannot achieve an HBeAg response to nucleoside analogue therapy—a stopping point in HBeAg-reactive patients; almost invariably, when therapy was discontinued, reactivation was the rule. Therefore, these patients required long-term lamivudine therapy.

Clinical and laboratory side effects of lamivudine were negligible and indistinguishable from those observed in placebo recipients; however, lamivudine doses were reduced in patients with reduced creatinine clearance. During lamivudine therapy, transient ALT elevations, resembling those seen during IFN therapy and during spontaneous HBeAg-to-anti-HBe seroconversions, occurred in one-fourth of patients. These ALT elevations may result from restored cytolytic T-cell activation permitted by suppression of HBV replication. Similar ALT elevations, however, occurred at an identical frequency in placebo recipients; however, ALT elevations associated temporally with HBeAg seroconversion in clinical trials were confined to lamivudine-treated patients. When therapy was stopped after a year of therapy, two- to threefold ALT elevations occurred in 20–30% of lamivudine-treated patients, representing renewed liver-cell injury as HBV replication returned. Although these posttreatment flares were almost always transient and mild, rare severe exacerbations, especially in cirrhotic patients, were observed, mandating close and careful clinical and virologic monitoring after discontinuation of treatment. Many authorities cautioned against discontinuing therapy in patients with cirrhosis, in whom posttreatment flares could precipitate decompensation.

Long-term monotherapy with lamivudine was associated with methionine-to-valine (M204V) or methionine-to-isoleucine (M204I) mutations, primarily at amino acid 204 in the tyrosine-methionine-aspartate-aspartate (YMDD) motif of the C domain of HBV DNA polymerase, analogous to mutations that occur in HIV-infected patients treated with this drug. During a year of therapy, YMDD mutations occurred in 15–30% of patients; the frequency increased with each year of therapy, reaching 70% at year 5. Ultimately, patients with YMDD mutants experienced degradation of clinical, biochemical, and histologic responses; therefore, if treatment was begun with lamivudine monotherapy, the emergence of lamivudine resistance, reflected clinically by a breakthrough from suppressed levels of HBV DNA and ALT, was managed by adding another antiviral to which YMDD variants are sensitive (e.g., adefovir, tenofovir; see below).

Currently, lamivudine has been eclipsed by more potent antivirals that have superior resistance profiles (see below); it is no longer recommended as first-line therapy. Still, as the first successful oral antiviral agent for use in hepatitis B, lamivudine provided proof of principle that polymerase inhibitors can achieve virologic, serologic, biochemical, and histologic benefits, including retardation and reversal of fibrosis and even of cirrhosis. In addition, lamivudine was shown to be effective in the treatment of patients with decompensated hepatitis B (for whom IFN is contraindicated), in some of whom decompensation can be reversed. Moreover, among patients with cirrhosis or advanced fibrosis, lamivudine was shown to be effective in reducing the risk of progression to hepatic decompensation and, based on subsequent population studies, the risk of HCC. In the half decade following the introduction in the United States of lamivudine therapy for hepatitis B, referral of patients with HBV-associated end-stage liver disease for liver transplantation fell by ~30%, supporting further the beneficial impact of oral antiviral therapy on the natural history of chronic hepatitis B.

Because lamivudine monotherapy in persons with HIV infection can result universally in the rapid emergence of YMDD variants, testing for HIV infection was recommended for all patients with chronic hepatitis B prior to lamivudine therapy; if HIV infection was identified, lamivudine monotherapy at the HBV daily dose of 100 mg was contraindicated. These patients require treatment for both HIV and HBV with an HIV drug regimen that includes or is supplemented by at least two drugs active against HBV; antiretroviral therapy (ART) often contains two drugs with antiviral activity against HBV (e.g., tenofovir and emtricitabine), but if lamivudine was part of the regimen, the 300-mg daily dose was required **(Chap. 202)**. The safety of lamivudine during pregnancy has not been established; however, the drug is not teratogenic in rodents and has been used safely in pregnant women with HIV infection and with HBV infection. As shown for subsequent nucleoside analogues, administration of lamivudine during the last months of pregnancy to mothers with high-level hepatitis B viremia reduced the likelihood of perinatal transmission of hepatitis B.

ADEFOVIR DIPIVOXIL

At an oral daily dose of 10 mg, the acyclic nucleotide analogue adefovir dipivoxil, the prodrug of adefovir (approved for hepatitis B in 2002), reduces HBV DNA by ~3.5–4 $\log_{10}$ copies/mL, i.e., it is less potent than lamivudine or any of the newer antiviral agents. For a summary of its virologic, serologic, biochemical, and histologic efficacy, as well as its resistance profile, please refer to Table 341-3. Like IFN and lamivudine, adefovir dipivoxil is more likely to achieve an HBeAg response in patients with high baseline ALT; HBeAg responses to it are highly durable and can be relied upon as a treatment stopping point, after a period of consolidation therapy; and biochemical, serologic, and virologic outcomes improve over time with continued therapy.

In HBeAg-negative chronic hepatitis B, as was true for lamivudine, because HBeAg responses—a potential stopping point—cannot be achieved, reactivation is the rule when adefovir therapy is discontinued, and indefinite, long-term therapy is required. Reported attempts to stop adefovir after 5 years were followed by a period of maintained suppression of HBV DNA and ALT; however, most such patients had persistent hepatitis B viremia, and most HBeAg-negative patients were treated indefinitely unless HBsAg loss, albeit very rare, was achieved.

Adefovir contains a flexible acyclic linker instead of the L-nucleoside ring of lamivudine, avoiding steric hindrance by mutated amino acids. In addition, the molecular structure of phosphorylated adefovir is very similar to that of its natural substrate; therefore, mutations to adefovir would also affect binding of the natural substrate, dATP. Thus, resistance to adefovir was much less likely than resistance to lamivudine, and no resistance was encountered in 1 year of clinical trial therapy. In subsequent years, however, adefovir resistance began to emerge (asparagine to threonine at amino acid 236 [N236T] and alanine to valine or threonine at amino acid 181 [A181V/T], primarily), occurring in 2.5% after 2 years but in 29% after 5 years of therapy (reported in HBeAg-negative patients). The primary contribution of adefovir, its effectiveness in lamivudine-resistant, YMDD-mutant HBV, led to its adoption for lamivudine-resistant hepatitis B. When lamivudine resistance occurred, adding adefovir (i.e., maintaining lamivudine to preempt the emergence of adefovir resistance) was superior to switching to adefovir. Almost invariably, patients with adefovir-induced HBV mutations respond to lamivudine (or newer agents, such as entecavir, see below). When, in the past, adefovir had been evaluated as therapy for HIV infection, doses of 60–120 mg were required to suppress HIV, and, at these doses, the drug was nephrotoxic. Even at 30 mg/d, creatinine elevations of 44 μmol/L (0.5 mg/dL) occurred in 10% of patients; however, at the HBV-effective dose of 10 mg, such creatinine elevations were encountered rarely and hardly ever before 6–8 months of therapy. Although renal tubular injury was a rare potential side effect, and although creatinine monitoring was recommended during treatment, the therapeutic index of adefovir dipivoxil was high, and the nephrotoxicity observed in clinical trials at higher doses was reversible. For patients with underlying renal disease, frequency of administration of adefovir had to be reduced, and it could be given only once a week for patients undergoing hemodialysis. Adefovir was very well tolerated, and ALT elevations during and after withdrawal of therapy were similar to those observed and described above in clinical trials of lamivudine. An advantage of adefovir was its relatively favorable resistance profile; however, it was not as potent as the other approved oral agents, it did not suppress HBV DNA as rapidly or as uniformly as the others, it was the least likely of all agents to result in HBeAg seroconversion, and 20–50% of patients failed to suppress HBV DNA by 2 $\log_{10}$ ("primary nonresponders"). For these reasons, adefovir, which has been supplanted in both treatment-naïve and lamivudine-resistant patients by the more potent, less resistance-prone tenofovir (see below), is no longer recommended as first-line therapy.

PEGYLATED IFN

After long-acting PEG IFN was shown to be effective in the treatment of hepatitis C (see below), this more convenient IFN preparation was evaluated in the treatment of chronic hepatitis B. Once-a-week PEG IFN is more effective than the more frequently administered, standard IFN, and several large-scale trials of PEG IFN versus oral lamivudine were conducted in patients with chronic hepatitis B.

In HBeAg-reactive chronic hepatitis B, two large-scale studies were done. In one study, PEG IFN-α2b (100 μg weekly for 32 weeks, then 50 μg weekly for another 20 weeks for a total of 52 weeks) was evaluated against a comparison arm of combination PEG IFN with oral lamivudine in 307 subjects. The other study involved PEG IFN-α2a (180 μg weekly for 48 weeks) in 814 primarily Asian patients, three-fourths of whom had ALT ≥2× the upper limit of normal, with comparison arms of lamivudine monotherapy and combination PEG IFN plus lamivudine. At the end of therapy (48–52 weeks) in the PEG IFN monotherapy arms, HBeAg loss occurred in ~30%, HBeAg seroconversion in 22–27%, undetectable HBV DNA (<400 copies/mL by PCR) in 10–25%, and normal ALT in 34–39%, and a mean reduction in HBV DNA of 2 $\log_{10}$ copies/mL (PEG IFN-α2b) to 4.5 $\log_{10}$ copies/mL (PEG IFN-α2a) was seen. Six months after completing PEG IFN monotherapy in these trials, HBeAg losses were present in ~35%, HBeAg seroconversion in ~30%, undetectable HBV DNA in 7–14%, and normal ALT in 32–41%, and the mean reduction in HBV DNA was 2–2.4 $\log_{10}$ copies/mL. Although the combination of PEG IFN and lamivudine was superior at the end of therapy in one or more serologic, virologic, or biochemical outcomes, neither the combination arm (in both studies) nor the lamivudine monotherapy arm (in the PEG IFN-α2a trial) demonstrated any benefit compared to the PEG IFN monotherapy arms 6 months after therapy. Moreover, HBsAg seroconversion occurred in 3–7% of PEG IFN recipients (with or without lamivudine); some of these seroconversions were identified by the end of therapy, but many were identified during the posttreatment follow-up period. The likelihood of HBeAg loss in PEG IFN–treated HBeAg-reactive patients was associated with HBV genotype A > B > C > D (shown for PEG IFN-α2b but not for PEG IFN-α2a). PEG IFN-α2a was approved in the United States for hepatitis B in 2005; PEG IFN-α2b, which is not approved for hepatitis B in the United States, is used in other countries.

Based on these results, some authorities concluded that PEG IFN monotherapy should be the first-line therapy of choice in HBeAg-reactive chronic hepatitis B; however, this conclusion has been challenged. Although a finite, 1-year course of PEG IFN results in a higher rate of sustained response (6 months after treatment) than is achieved with oral nucleoside/nucleotide analogue therapy, the comparison is confounded by the fact that oral agents are not discontinued at the end of 1 year. Instead, taken orally and free of side effects, therapy with oral agents is extended indefinitely or until after the occurrence of an HBeAg response. The rate of HBeAg responses after 2 years of oral-agent nucleoside analogue therapy is at least as high as, if not higher than, that achieved with PEG IFN after 1 year; favoring oral agents is the absence of injections, difficult-to-tolerate side effects, and laboratory monitoring as well as lower direct and indirect medical care costs and inconvenience. The association of HBsAg responses with PEG IFN therapy occurs in such a small proportion of patients that subjecting everyone to PEG IFN for the marginal gain of HBsAg responses during or immediately after therapy in such a very small minority is questionable. Moreover, HBsAg responses occur in a comparable proportion of patients treated with early-generation nucleoside/nucleotide analogues in the years *after* therapy, and, with the newer, more potent nucleoside analogues, the frequency of HBsAg loss during the first year of therapy equals that of PEG IFN and is exceeded during year 2 and beyond (see below). Of course, resistance is not an issue during PEG IFN therapy, but the risk of resistance is much lower with new agents (≤1% up to 3–8 years in previously treatment-naïve, entecavir-treated patients and 0% in tenofovir-treated patients; see below). Finally, the level of HBV DNA inhibition that can be achieved with the newer agents, and even with lamivudine, exceeds that achieved with PEG IFN, in some cases by several orders of magnitude.

In HBeAg-negative chronic hepatitis B, a trial of PEG IFN-α2a (180 μg weekly for 48 weeks vs comparison arms of lamivudine monotherapy and of combination therapy) in 564 patients showed that PEG IFN monotherapy resulted at the end of therapy in suppression of HBV DNA by a mean of 4.1 $\log_{10}$ copies/mL, undetectable HBV DNA (<400 copies/mL by PCR) in 63%, normal ALT in 38%, and loss of HBsAg in 4%. Although lamivudine monotherapy and combination lamivudine–PEG IFN therapy were both superior to PEG IFN at the end of therapy, no advantage of lamivudine monotherapy or combination therapy was apparent over PEG IFN monotherapy 6 months after therapy—suppression of HBV DNA by a mean of 2.3 $\log_{10}$ copies/mL, undetectable HBV DNA in 19%,

and normal ALT in 59%. In patients involved in this trial followed for up to 5 years, among the two-thirds followed who had been treated initially with PEG IFN, 17% maintained HBV DNA suppression to <400 copies/mL, but ALT remained normal in only 22%; HBsAg loss increased gradually to 12%. Among the half followed who had been treated initially with lamivudine monotherapy, HBV DNA remained <400 copies/mL in 7% and ALT normal in 16%; by year 5, 3.5% had lost HBsAg. As was the case for standard IFN therapy in HBeAg-negative patients, only a small proportion maintained responsiveness after completion of PEG IFN therapy, raising questions about the relative value of a finite period of PEG IFN versus a longer course with a potent, low-resistance oral nucleoside analogue in these patients. Moreover, the value of PEG IFN for HBeAg-negative chronic hepatitis B has not been confirmed. In the only other controlled clinical trial of PEG IFN for HBeAg-negative chronic hepatitis B, the hepatitis C regimen of PEG IFN plus ribavirin was compared to PEG IFN monotherapy. In this trial, HBV DNA suppression (<400 copies/mL) occurred in only 7.5% of the two groups combined, and no study subject lost HBsAg.

In patients treated with PEG IFN, HBeAg and HBsAg responses have been associated with *IL28B* (now renamed IFN lambda-3, *IFNL3*) genotype CC, the favorable genotype identified in trials of PEG IFN for chronic hepatitis C. Also, reductions in quantitative HBsAg levels have been shown to correlate with and to be predictive of responsiveness to PEG IFN in chronic hepatitis B. If HBsAg levels fail to fall within the first 12–24 weeks or to reach <20,000 IU/mL by week 24, PEG IFN therapy is unlikely to be effective and should be discontinued. (Similar observations of HBsAg levels in oral-agent-treated patients are of interest but of limited clinical relevance, given the very high likelihood of virologic responses during such therapy.) While PEG IFN remains one of the recommended first-line agents for hepatitis B, subsequent-generation, injection-free, very-well-tolerated, high-barrier-to-resistance, oral agents are used much more widely.

ENTECAVIR

Entecavir, an oral cyclopentyl guanosine analogue polymerase inhibitor (approved in 2005), appears to be the most potent of the HBV antivirals and is just as well tolerated as lamivudine. In a 709-subject clinical trial among HBeAg-reactive patients, oral entecavir, 0.5 mg daily, was compared to lamivudine, 100 mg daily. At 48 weeks, entecavir was superior to lamivudine in suppression of HBV DNA (mean 6.9 vs 5.5 $\log_{10}$ copies/mL), percentage with undetectable HBV DNA (<300 copies/mL by PCR; 67 vs 36%), histologic improvement (≥2-point improvement in necroinflammatory HAI score; 72 vs 62%), and normal ALT (68 vs 60%). The two treatments were indistinguishable in percentage with HBeAg loss (22 vs 20%) and seroconversion (21 vs 18%). Among patients treated with entecavir for 96 weeks, HBV DNA was undetectable cumulatively in 80% (vs 39% for lamivudine), and HBeAg seroconversions had occurred in 31% (vs 26% for lamivudine). After 3–6 years of entecavir, HBeAg seroconversions were observed in 39–44% and HBsAg loss in 5–6%. Similarly, in a 638-subject clinical trial among HBeAg-negative patients, at week 48, oral entecavir, 0.5 mg daily, was superior to lamivudine, 100 mg daily, in suppression of HBV DNA (mean 5.0 vs 4.5 $\log_{10}$ copies/mL) and in percentage with undetectable HBV DNA (90 vs 72%), histologic improvement (70 vs 61%), and normal ALT (78 vs 71%). No resistance mutations were encountered in previously treatment-naïve, entecavir-treated patients during 96 weeks of therapy, and in a cohort of subjects treated for up to 6 years, resistance emerged in only 1.2%. Entecavir-induced HBeAg seroconversions are as durable as those achieved with other antivirals. Its high barrier to resistance coupled with its high potency renders entecavir a first-line drug for patients with chronic hepatitis B.

Entecavir is also effective against lamivudine-resistant HBV infection. In a trial of 286 lamivudine-resistant patients, entecavir, at a higher daily dose of 1 mg, was superior to lamivudine, as measured at week 48, in achieving suppression of HBV DNA (mean 5.1 vs 0.48 $\log_{10}$ copies/mL), undetectable HBV DNA (72 vs 19%), normal ALT (61 vs 15%), HBeAg loss (10 vs 3%), and HBeAg seroconversion (8 vs 3%). In this population of lamivudine-experienced patients, however, entecavir resistance emerged in 7% at 48 weeks. Although entecavir resistance requires both a YMDD mutation and a second mutation at one of several other sites (e.g., T184A, S202G/I, or M250V), resistance to entecavir in lamivudine-resistant chronic hepatitis B was reported to increase progressively to 43% at 4 years and 57% at 6 years; therefore, entecavir is not as attractive a choice (and is not recommended, despite its approval for this indication) as adefovir was or as tenofovir is for patients with lamivudine-resistant hepatitis B.

In clinical trials, entecavir had an excellent safety profile. In addition, on-treatment and posttreatment ALT flares are relatively uncommon and relatively mild in entecavir-treated patients. Doses should be reduced for patients with reduced creatinine clearance. Entecavir does have low-level antiviral activity against HIV and cannot be used as monotherapy to treat HBV infection in HIV/HBV co-infected persons.

TELBIVUDINE

Telbivudine, a cytosine analogue (approved in 2006), is similar in efficacy to entecavir but slightly less potent in suppressing HBV DNA (a slightly less profound median 6.4 $\log_{10}$ reduction in HBeAg-reactive disease and a similar 5.2 $\log_{10}$ reduction in HBeAg-negative disease). In its registration trial, telbivudine at an oral daily dose of 600 mg suppressed HBV DNA to <300 copies/mL in 60% of HBeAg-positive and 88% of HBeAg-negative patients, reduced ALT to normal in 77% of HBeAg-positive and 74% of HBeAg-negative patients, and improved histology in 65% of HBeAg-positive and 67% of HBeAg-negative patients. Although resistance to telbivudine (M204I, not M204V, mutations) was less frequent than resistance to lamivudine at the end of 1 year, resistance mutations after 2 years of treatment occurred in up to 22%. Generally well tolerated, telbivudine was associated with a low frequency of asymptomatic creatine kinase elevations and with a very low frequency of peripheral neuropathy; frequency of administration had to be reduced for patients with impaired creatinine clearance. Its excellent potency notwithstanding, the inferior resistance and safety profile of telbivudine limited its appeal; telbivudine is neither recommended as first-line therapy nor widely used.

TENOFOVIR

Tenofovir disoproxil fumarate (TDF), an acyclic nucleotide analogue and potent antiretroviral agent used to treat HIV infection (approved for hepatitis B in 2008), is similar to adefovir but more potent in suppressing HBV DNA and inducing HBeAg responses; it is highly active against both wild-type and lamivudine-resistant HBV and active in patients whose response to adefovir is slow and/or limited. At an oral once-daily dose of 300 mg for 48 weeks, tenofovir suppressed HBV DNA by 6.2 $\log_{10}$ (to undetectable levels [<400 copies/mL] in 76%) in HBeAg-positive patients and by 4.6 $\log_{10}$ (to undetectable levels in 93%) in HBeAg-negative patients; reduced ALT to normal in 68% of HBeAg-positive and 76% of HBeAg-negative patients; and improved histology in 74% of HBeAg-positive and 72% of HBeAg-negative patients. In HBeAg-positive patients, HBeAg seroconversions occurred in 21% by the end of year 1, 27% by year 2, 34% by year 3, and 40% by year 5 of tenofovir treatment; HBsAg loss occurred in 3% by the end of year 1, 6% at year 2, and 8% by year 5. After 5 years of tenofovir therapy, 87% of patients experienced histologic improvement, including reduction in fibrosis score (51%) and regression of cirrhosis (71%). The 5-year safety (negligible renal toxicity, in 1%, and mild reduction in bone density, in ~0.5%) and resistance profiles (none recorded through 8 years) of tenofovir are very favorable as well; therefore, tenofovir has supplanted adefovir both as first-line therapy for chronic hepatitis B and as rescue therapy for lamivudine-resistant chronic hepatitis B. Studies of tenofovir and entecavir reviewed in 2015 showed no difference in long-term risks of renal and bone

toxicity; however, among patients treated with tenofovir, instances of acute renal failure and of low blood phosphate levels have been reported. Thus, in patients receiving tenofovir, monitoring bone density is not recommended, but periodic (at least annual) monitoring for renal injury is recommended (serum creatinine and phosphate, urine glucose and protein). Frequency of tenofovir administration should be reduced for patients with impaired creatinine clearance.

Tenofovir alafenamide (TAF), a second-generation tenofovir approved in 2016, is a prodrug of tenofovir that requires activation to tenofovir in hepatocytes. This targeted delivery to hepatocytes allows a lower dose to suffice and reduces systemic exposure by 90%, thereby minimizing TDF-associated proximal tubular renal injury, its associated phosphate wasting, and the potential consequent loss of bone mineral density. The dose of TAF is 25 mg, which is equivalent in antiviral potency to 300 mg of TDF; both formulations have the same high barrier to resistance, and clinical resistance has not been encountered. Randomized, controlled, double-blind, phase 3 noninferiority trials, one in HBeAg-positive patients and the other in HBeAg-negative patients, provided the safety and efficacy data to support TAF approval.

In 873 *HBeAg-positive* patients treated for 48 weeks, TAF versus TDF achieved (1) HBV DNA reductions to <29 IU/mL in 64% versus 67%; (2) ALT normalization in 72% versus 67% (an unexplained TAF biochemical advantage confirmed in other trials); (3) HBeAg loss in 14% versus 12%; (4) HBeAg seroconversion in 10% versus 8%; and (5) a negligible loss of HBsAg in 1% versus 0.3%. Compared to TDF, TAF was associated with reduced impairment of renal function (median reduction in estimated glomerular filtration rate of −0.6 mL/min for TAF vs −5.4 mL/min for TDF) and of bone density (in hip measurements, mean reduction of −0.10% for TAF vs −1.72% for TDF; adjusted difference, 1.62%).

In the parallel trial among 426 *HBeAg-negative* patients treated for 48 weeks, reductions in HBV DNA to <29 IU/mL occurred in 94% versus 93% of individuals treated with TAF versus TDF, respectively; normalization of ALT occurred in 83% versus 75%, but no HBsAg loss occurred in either group. Similar TAF advantages in maintaining renal function and bone density were reported: reduction in median estimated glomerular filtration rate (−1.8 mL/min for TAF vs −4.8 mL/min for TDF) and in median bone density (in hip measurements, mean reduction of −0.29% for TAF vs −2.16% for TDF; adjusted percentage difference, 1.87%).

At week 96, TAF and TDF HBV DNA and ALT reductions (including the TAF advantage observed at 48 weeks) were maintained. In the original TDF group, when TDF was switched to TAF after week 96, all differences observed during the first 96 weeks (in normalization of ALT and reductions in renal function and bone density) had resolved at week 120. Resistance did not emerge to either TAF or TDF throughout the trial.

Based on these trial outcomes, TAF joined the list of recommended first-line antiviral agents for chronic hepatitis B. This drug is recommended over TDF by the American Association for the Study of Liver Diseases (AASLD) and the European Association for the Study of the Liver (EASL) for patients with reduced renal function (creatinine clearance <50 mL/min), reduced bone density, and risk factors for renal injury (including, according to EASL guidelines, decompensated cirrhosis, creatinine clearance <60 mL/min, poorly controlled hypertension or diabetes, proteinuria, active glomerulonephritis, concomitant nephrotoxic medications, or solid-organ transplantation); the EASL recommendation extends to persons >60 years, who are at increased risk of TDF nephrotoxicity. In patients with creatinine clearances <15 mL/min, neither TDF nor TAF is recommended.

A comparison of antiviral therapies for chronic hepatitis B appears in Table 341-3; their relative potencies in suppressing HBV DNA are shown in Fig. 341-1.

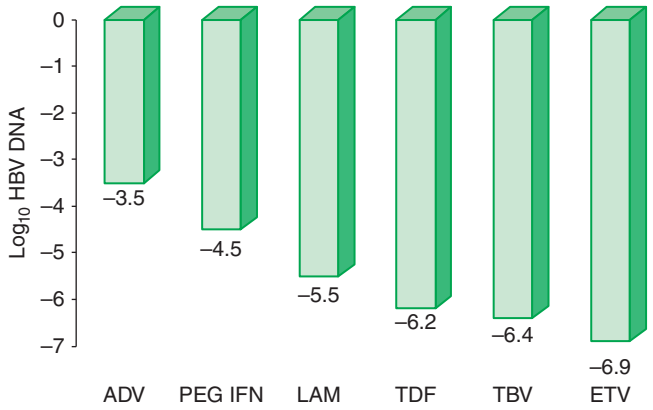

FIGURE 341-1 Relative potency of antiviral drugs for hepatitis B, as reflected by median $\log_{10}$ hepatitis B virus (HBV) DNA reduction in HBeAg-positive chronic hepatitis B. These data are from individual reports of large, randomized controlled registration trials that were the basis for approval of the drugs. In most instances, these data do not represent direct comparisons among the drugs, because study populations were different, baseline patient variables were not always uniform, and the sensitivity and dynamic range of the HBV DNA assays used in the trials varied. ADV, adefovir dipivoxil; ETV, entecavir; LAM, lamivudine; PEG IFN, pegylated interferon α2a; TBV, telbivudine; TDF, tenofovir disoproxil fumarate. Because of potency and a high barrier to resistance, ETV and tenofovir (either TDF or the second-generation tenofovir alafenamide) are recommended as first-line therapy. While PEG IFN remains a first-line agent, the oral agents developed earlier, LAM, ADV, and TBV, are no longer preferred agents.

COMBINATION THERAPY

Although the combination of lamivudine and PEG IFN suppresses HBV DNA more profoundly during therapy than does monotherapy with either drug alone (and is much less likely to be associated with lamivudine resistance), this combination used for a year is no better than a year of PEG IFN in achieving sustained responses. To date, combinations of oral nucleoside/nucleotide agents have not achieved an enhancement in virologic, serologic, or biochemical efficacy over that achieved by the more potent of the combined drugs given individually. In a 2-year trial of combination entecavir and tenofovir versus entecavir monotherapy, for a small subgroup of patients with very high HBV DNA levels ($\geq 10^8$ IU/mL), a reduction in HBV DNA to <50 IU/mL was higher in the combination group (79 vs 62%); however, no differences in HBeAg responses or any other endpoint were observed between the combination-therapy and monotherapy groups, even in the high-HBV DNA subgroup. For resistance to lamivudine or adefovir, adding a second, non-cross-resistant agent was the chosen approach. Whereas, initially, in clinical studies of adefovir as rescue therapy for lamivudine resistance, *adding* adefovir to lamivudine (combination therapy) was considered a better strategy than replacing lamivudine with adefovir monotherapy (to minimize ALT flares and to avoid adefovir resistance), according to current treatment recommendations of the AASLD and the EASL, *switching* from the resistant drug to the new drug is preferred. Because the current generation of antivirals is so potent and has such a high barrier to resistance, monotherapy with the rescue drug (e.g., tenofovir for lamivudine resistance) is as effective (as demonstrated in observational reports for up to 5 years) in maintaining viral suppression without the emergence of resistance as combination therapy with the resistant drug and the rescue drug. Generally, in patients treated with entecavir and tenofovir preparations, antiviral drug resistance is no longer encountered. For currently rare patients who already have acquired multidrug resistance (to both nucleoside analogues [lamivudine, entecavir, telbivudine] and nucleotide analogues [adefovir, tenofovir]), treatment with a combination of entecavir and tenofovir has been shown to be highly effective in suppressing HBV DNA and overcoming drug resistance.

NOVEL ANTIVIRALS AND STRATEGIES

In addition to the eight approved antiviral drugs for hepatitis B, emtricitabine, a fluorinated cytosine analogue very similar to lamivudine in structure, efficacy, and resistance profile, offers no advantage over lamivudine. A combination of emtricitabine and tenofovir is approved for the treatment of HIV infection and is

an appealing combination therapy for hepatitis B, especially for lamivudine-resistant disease; however, neither emtricitabine nor the combination is approved for hepatitis B. Several initially promising antiviral agents have been abandoned because of toxicity (e.g., clevudine, which was linked to myopathy during its clinical development). The current generation of oral antivirals have been very successful in the management of chronic hepatitis B; however, most patients require long-duration, usually indefinite, therapy. Ideally, an approach to achieving "cure" (eradication of HBV infection) with finite-duration therapy would be welcome. Currently, innovative approaches being investigated focus on viral-targeting strategies or immunomodulatory strategies. The direct viral approaches include viral entry inhibitors, nucleocapsid assembly inhibitors, HBV secretion (HBsAg release) inhibitors, covalently closed circular (ccc) DNA silencing/inhibition/cleavage, RNA interference, HBx inhibitors, and CRISPR/Cas9 gene editing. Immunomodulators being studied have included Toll receptor agonists, T-cell vaccines, programmed cell death 1 (PD-1) blockade, reconstitution of innate and adaptive immune responses, and HBV mRNA recognition and activation of innate immune signaling by retinoic acid–inducible gene-I (RIG-I). While data supporting several of these unconventional approaches have begun to appear, some have been abandoned for lack of efficacy or for toxicity (e.g., RIG-I and some of the capsid inhibitors). Even after almost a decade of early clinical trials, none has been shown to "cure" hepatitis B, and none is likely to be competitive, unless it can be shown to go beyond current antivirals in achieving recovery (HBsAg seroconversion) from HBV infection.

TREATMENT RECOMMENDATIONS

Several learned societies and groups of expert physicians have issued treatment recommendations for patients with chronic hepatitis B; the most authoritative and updated are those of the AASLD and the EASL. Although the recommendations differ slightly, a consensus has emerged on most of the important points **(Table 341-4)**. No treatment is recommended or available for inactive "nonreplicative" hepatitis B carriers (undetectable HBeAg with normal ALT and HBV DNA ≤10^3 IU/mL documented serially over time). In patients with detectable HBeAg and HBV DNA levels >2 × 10^4 IU/mL, treatment is recommended by the AASLD for those with ALT levels >2× the upper limit of normal. (The EASL recommends treatment in HBeAg-positive patients for HBV DNA levels >2 × 10^3 IU/mL and ALT above the upper limit of normal.) For HBeAg-positive patients with ALT ≤2× the upper limit of normal, in whom sustained responses are not likely and who would require multiyear therapy, antiviral therapy is not recommended currently. This pattern is common during the early decades of life among Asian patients infected at birth; even in this group, therapy would be considered for those >40 years of age, patients with extrahepatic manifestations of HBV infection, patients with a family history of cirrhosis or HCC, if the liver biopsy or noninvasive testing shows moderate to severe necroinflammatory activity or fibrosis, or if the patient has a history of previous treatment. In this group, when, eventually, ALT becomes elevated later in life, antiviral therapy should be instituted. For patients with HBeAg-negative chronic hepatitis B, ALT >2× the upper limit of normal (above the upper limit of normal according to EASL), and HBV DNA >2 × 10^3 IU/mL, antiviral therapy is recommended. If HBV DNA is >2 × 10^3 IU/mL and ALT is 1 to >2× the upper limit of normal, the same considerations apply as for HBeAg-positive patients with borderline ALT levels—for those >40 years of age, patients with extrahepatic manifestations of HBV infection, patients with a family history of cirrhosis or HCC, if the liver biopsy or noninvasive testing shows moderate to severe necroinflammatory activity or fibrosis, or if the patient has a history of previous treatment (treatment in this subset would be

TABLE 341-4 Recommendations for Treatment of Chronic Hepatitis B[a]

HBeAg STATUS	CLINICAL	HBV DNA (IU/mL)	ALT	RECOMMENDATION
HBeAg-reactive	[b]	>2 × 10^4	≤2 × ULN[c,d]	No treatment; monitor, except in patients >40, with family history of cirrhosis or hepatocellular carcinoma, with extrahepatic manifestations, with a history of previous treatment, and/or with liver biopsy (or noninvasive fibrosis determination) evidence for moderate to severe inflammation or fibrosis
	Chronic hepatitis	>2 × 10^4[d]	>2 × ULN[d]	Treat[e]
	Cirrhosis compensated	>2 × 10^3	< or > ULN	Treat[e] with oral agents, not PEG IFN
		<2 × 10^3	>ULN	Treatment suggested[f]
	Cirrhosis decompensated	Detectable	< or > ULN	Treat[e] with oral agents[g], not PEG IFN; refer for liver transplantation
		Undetectable	< or > ULN	Observe; refer for liver transplantation
HBeAg-negative	[b]	≤2 × 10^3	≤ULN	Inactive carrier; treatment not necessary
	Chronic hepatitis	>2 × 10^3	1 to >2 × ULN[d]	No treatment; monitor, except in patients >40, with family history of cirrhosis or hepatocellular carcinoma, with extrahepatic manifestations, with a history of previous treatment, and/or with liver biopsy (or noninvasive fibrosis determination) evidence for moderate to severe inflammation or fibrosis
	Chronic hepatitis	>2 × 10^3	>2 × ULN[d]	Treat[h,i]
	Cirrhosis compensated	>2 × 10^3	< or > ULN	Treat[e] with oral agents, not PEG IFN
		<2 × 10^3	>ULN	Treatment suggested[f]
	Cirrhosis decompensated	Detectable	< or > ULN	Treat[h] with oral agents[g], not PEG IFN; refer for liver transplantation
		Undetectable	< or > ULN	Observe; refer for liver transplantation

[a]Based on practice guidelines of the American Association for the Study of Liver Diseases (AASLD). Except as indicated in footnotes, these guidelines are similar to those issued by the European Association for the Study of the Liver (EASL). [b]Liver disease tends to be mild or inactive clinically; most such patients do not undergo liver biopsy. [c]This pattern is common during early decades of life in Asian patients infected at birth. [d]According to the EASL guidelines, treat if HBV DNA is >2 × 10^3 IU/mL and ALT >ULN. [e]One of the potent oral drugs with a high barrier to resistance (entecavir or tenofovir) or PEG IFN can be used as first-line therapy (see text). These oral agents, but not PEG IFN, should be used for interferon-refractory/intolerant and immunocompromised patients. PEG IFN is administered weekly by subcutaneous injection for a year; the oral agents are administered daily for at least a year and continued indefinitely or until at least 6 months after HBeAg seroconversion. [f]According to EASL guidelines, patients with compensated cirrhosis and detectable HBV DNA at any level, even with normal ALT, are candidates for therapy. Most authorities would treat indefinitely, even in HBeAg-positive disease after HBeAg seroconversion. [g]Because the emergence of resistance can lead to loss of antiviral benefit and further deterioration in decompensated cirrhosis, a low-resistance regimen is recommended—entecavir or tenofovir monotherapy or combination therapy with the more resistance-prone lamivudine (or telbivudine) plus adefovir. Therapy should be instituted urgently. [h]Because HBeAg seroconversion is not an option, the goal of therapy is to suppress HBV DNA and maintain a normal ALT. PEG IFN is administered by subcutaneous injection weekly for a year; caution is warranted in relying on a 6-month posttreatment interval to define a sustained response, because the majority of such responses are lost thereafter. Oral agents, entecavir or tenofovir, are administered daily, usually indefinitely or until, as very rarely occurs, virologic and biochemical responses are accompanied by HBsAg seroconversion. [i]For older patients and those with advanced fibrosis, consider lowering the HBV DNA threshold to >2 × 10^3 IU/mL.

Abbreviations: ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; PEG IFN, pegylated interferon; ULN, upper limit of normal.

recommended according to EASL guidelines, because ALT is elevated). Per current AASLD recommendations, antiviral treatment with oral agents can be stopped after HBeAg seroconversion in noncirrhotics, and the suggested period of consolidation therapy is 12 months with close monitoring for recurrent viremia (monthly × 6, then every 3 months for the rest of a year) after cessation of therapy. For patients with HBeAg-negative chronic hepatitis, the current recommendation with oral agents is for indefinite therapy; stopping therapy in this group can be considered after HBsAg loss.

The potential for stopping antiviral therapy in noncirrhotic HBeAg-negative patients after protracted (≥2–5 years) antiviral therapy has been the subject of several studies. After such prolonged courses of entecavir or tenofovir, in one study (DARING-B), 18-month virologic relapse rates (HBV DNA >2000 IU/mL) in 57 patients were high (in 72%), but only 26% met study criteria for resumption of therapy (ALT >10× upper limit of normal, ALT >5× upper limit of normal with bilirubin >2 mg/mL, ALT >3× upper limit of normal with HBV DNA $>10^5$ IU/mL, or ALT >2× upper limit of normal and HBV DNA $>2 \times 10^3$ IU/mL on three sequential visits). Moreover, 25% underwent HBsAg loss. In a similar study (FINITE), virologic relapse rates were high, but 62% did not meet criteria for retreatment, and 19% lost HBsAg. In contrast, in a study among Asian patients, only ~30% had sustained responses for which resumption of therapy was not introduced, and HBsAg responses were negligible. In other reports, including on patients with 8 years of TDF treatment prior to stopping, only 35–60% had sustained treatment-free outcomes, and only 5–13% lost HBsAg. In the only randomized, controlled trial of stopping therapy versus continuing therapy in HBeAg-negative patients after prolonged antiviral therapy (Toronto STOP study), only 33% had sustained responses after cessation of therapy, and HBsAg loss occurred with equal, small frequencies in both the stop-treatment group (4%) and the continue-treatment group (5%). Generally, then, although HBsAg loss can be achieved in a small fraction and although a subgroup may not require reintroduction of therapy in the short run, enthusiasm for this approach is limited, and for most HBeAg-negative patients, recommendations support indefinite treatment, unless they experience HBsAg loss.

For patients with compensated cirrhosis, because antiviral therapy has been shown to retard clinical progression, treatment is recommended regardless of HBeAg status and ALT as long as HBV DNA is detectable at $>2 \times 10^3$ IU/mL (detectable at any level according to the EASL); therapy is suggested, however, even for those with HBV DNA $<2 \times 10^3$ IU/mL, regardless of ALT level. For patients with decompensated cirrhosis, treatment is recommended regardless of serologic and biochemical status, as long as HBV DNA is detectable. Patients with decompensated cirrhosis should be evaluated as candidates for liver transplantation. Cirrhotics should be treated indefinitely (see considerations for stopping antiviral therapy in noncirrhotics, above).

Among the eight available drugs for hepatitis B, PEG IFN has supplanted standard IFN, entecavir has supplanted lamivudine, and tenofovir has supplanted adefovir. PEG IFN, entecavir, or tenofovir (TDF or TAF) is recommended as first-line therapy (Table 341-3). PEG IFN requires finite-duration therapy, achieves the highest rate of HBeAg responses after a year of therapy, and does not support viral mutations, but it requires subcutaneous injections and is associated with inconvenience, more intensive clinical and laboratory monitoring, and intolerability. Oral nucleoside analogues require long-term therapy in most patients, and when used alone, lamivudine and telbivudine foster the emergence of viral mutations, adefovir somewhat less so, and entecavir (except in lamivudine-experienced patients) and tenofovir rarely at all. Oral agents do not require injections or cumbersome laboratory monitoring, are very well tolerated, lead to improved histology in 50–90% of patients, suppress HBV DNA more profoundly than PEG IFN, and are effective even in patients who fail to respond to IFN-based therapy. Although oral agents are less likely to result in HBeAg responses during the first year of therapy, as compared to PEG IFN, treatment with oral agents is usually extended beyond the first year and, by the end of the second year (of the current generation of potent agents entecavir and tenofovir), yields HBeAg responses (and even HBsAg responses) comparable in frequency to those achieved after 1 year of PEG IFN (and without the associated side effects) **(Table 341-5)**. In a 2016 systematic review of 1716 patients involved in 25 clinical trials, responses after oral-agent therapy were found to be durable. Among patients with HBeAg-reactive chronic hepatitis B, the pooled rates of durable HBeAg seroconversions maintained after cessation of nucleoside/nucleotide analogue therapy (including all the oral agents) were 92% and 88% at posttreatment months 12 and 24, respectively, unaffected by the duration of post-HBeAg-response consolidation therapy (>6 months in all studies evaluated); the pooled rate of durable biochemical remission after therapy in this population was 76%. Even for HBeAg-negative chronic hepatitis B, for which most authorities recommend indefinite therapy, pooled rates of virologic remissions maintained after cessation of oral-agent therapy were 44%, 31%, and 30% at posttreatment months 12, 24, and 36, and the pooled rate of durable biochemical remission in this population was 57%.

Although adefovir and tenofovir (TDF) are safe, renal monitoring (e.g., serum creatinine and phosphate, urine glucose and protein) is recommended (not for TAF). Substantial experience with lamivudine during pregnancy (see above) has identified no teratogenicity; although widely used during pregnancy, lamivudine remains classified as pregnancy category C. Although IFNs do not

TABLE 341-5 Pegylated Interferon Versus Oral Nucleoside Analogues for the Treatment of Chronic Hepatitis B

	PEG IFN	NUCLEOSIDE ANALOGUES
Administration	Weekly injection	Daily, orally
Tolerability	Poorly tolerated, intensive monitoring	Well tolerated, limited monitoring
Duration of therapy	Finite 48 weeks	≥1 year, indefinite in most patients
Maximum mean HBV DNA suppression	4.5 $\log_{10}$	6.9 $\log_{10}$
Effective in high-level HBV DNA ($\geq 10^9$ IU/mL)	No	Yes
HBeAg seroconversion During 1 year of therapy During >1 year of therapy	~30% Not applicable	~20% 30% (year 2) to up to 50% (year 5)
HBeAg-negative posttreatment HBV DNA suppression	17% at 5 years	7% at 4 years (lamivudine)
HBsAg loss During 1 year of therapy During >1 year of therapy After 1 year of therapy–HBeAg-negative	3–4% Not applicable 12% at 5 years	0–3% 3–8% at 5 years of therapy 3.5% at 5 years
Antiviral resistance	None	Lamivudine: ~30% year 1, ~70% year 5 Adefovir: 0% year 1, ~30% year 5 Telbivudine: up to 4% year 1, 22% year 2 Entecavir: ≤1.2% through year 6 Tenofovir: 0% through year 8
Use in cirrhosis, transplantation, immunosuppressed	No	Yes
Cost, 1 year of therapy	++++	+ to ++

Abbreviations: HBV, hepatitis B virus; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; PEG IFN, pegylated interferon.

appear to cause congenital anomalies, these have antiproliferative properties and should be avoided during pregnancy. Adefovir during pregnancy has not been associated with birth defects; however, the risk of spontaneous abortion may be increased, and adefovir is categorized as pregnancy category C. Data on the safety of entecavir during pregnancy have not been published (pregnancy category C). Sufficient data in animals and limited data in humans suggest that telbivudine and tenofovir (both pregnancy category B) can be used safely during pregnancy; however, telbivudine is not an acceptable first-line drug. In general, then, except for lamivudine and tenofovir, and until additional data become available, the other antivirals for hepatitis B should be avoided or used with extreme caution during pregnancy. Tenofovir is the current drug of choice in pregnancy.

For children aged 2 to <18 years old with HBeAg-reactive hepatitis B (most children will be HBeAg-reactive; no studies have been done in children with HBeAg-negative chronic hepatitis B), treatment is recommended if HBV DNA is detectable and ALT levels are elevated, but not if ALT levels are normal. Each of the available drugs, except telbivudine, is approved for different childhood age groups (standard IFN α2b age ≥1 year; PEG IFN α2a age ≥5 years [approved for hepatitis C, not B, but can be used in hepatitis B]; lamivudine and entecavir age ≥2 years; adefovir and tenofovir age ≥12 years). Package inserts should be consulted for childhood doses.

As noted above, some physicians prefer to begin with PEG IFN, while other physicians and patients prefer oral agents as first-line therapy. For patients with decompensated cirrhosis, the emergence of resistance can result in further deterioration and loss of antiviral effectiveness. Therefore, in this patient subset, therapy with a very favorable resistance profile (e.g., entecavir or tenofovir) should be used. PEG IFN should not be used in patients with compensated or decompensated cirrhosis.

Several observational studies have suggested that TDF is superior to entecavir in reducing the risk of HCC. Such studies, however, sophisticated statistical analyses notwithstanding, are subject to confounding influences that could favor TDF; in addition, while several studies confirm a differential effect of TDF on long-term HCC risk, many others do not. Therefore, currently, the preponderance of data is insufficient to support this benefit of TDF over entecavir.

For patients with end-stage chronic hepatitis B who undergo liver transplantation, reinfection of the new liver is almost universal in the absence of antiviral therapy. The majority of patients become high-level viremic carriers with minimal liver injury. Before the availability of antiviral therapy, an unpredictable proportion experienced severe hepatitis B–related liver injury, sometimes a fulminant-like hepatitis and sometimes a rapid recapitulation of the original severe chronic hepatitis B **(Chap. 339)**. Currently, however, prevention of recurrent hepatitis B after liver transplantation has been achieved definitively by *combining* short-term (5–7 days) intravenous hepatitis B immune globulin (HBIG) with lifelong low-resistance oral entecavir or TDF or TAF **(Chap. 345)**; in some patients, especially those with a low risk for recurrence, the newer, more potent, and less resistance-prone oral agents may be used instead of HBIG for posttransplantation therapy. For patients at high risk for recurrence and progressive disease (e.g., patients with HDV-HBV or HIV-HBV co-infection as well as for nonadherent patients, lifelong combination HBIG-oral agent therapy should be considered. For patients receiving livers from anti-HBc-positive donors, lifelong oral-agent therapy is recommended (without HBIG).

Patients with HBV-HIV co-infection can have progressive HBV-associated liver disease and, occasionally, a severe exacerbation of hepatitis B resulting from immunologic reconstitution following ART. Lamivudine should never be used as monotherapy in patients with HBV-HIV infection because HIV resistance emerges rapidly to both viruses. Adefovir was used successfully in the past to treat chronic hepatitis B in HBV-HIV co-infected patients but is no longer considered a first-line agent for HBV. Entecavir has low-level activity against HIV and can result in selection of HIV resistance; therefore, it is not preferable in HBV-HIV co-infection. Tenofovir and the combination of tenofovir and emtricitabine in one pill are approved therapies for HIV and represent excellent choices for treating HBV infection in HBV-HIV co-infected patients. Generally, even for HBV-HIV co-infected patients who do not yet meet treatment criteria for HIV infection, treating for both HBV and HIV is recommended. In HIV-HBV co-infection, TAF is preferable to TDF because of its better safety profile.

Patients with chronic hepatitis B who undergo cytotoxic chemotherapy for treatment of malignancies as well as patients treated with immunosuppressive, anticytokine, or anti–tumor necrosis factor (TNF) therapies (the risk varies, from highest [e.g., B cell–depleting agents, anthracycline derivatives, moderate-/high-dose corticosteroids for ≥4 weeks] to moderate [e.g., TNF-α inhibitors, cytokine or integrin inhibitors, tyrosine kinase inhibitors, low-dose corticosteroids for ≥4 weeks] to lowest [e.g., immunosuppressive agents like methotrexate and azathioprine, intraarticular corticosteroids, any dose of corticosteroids for ≤1 week]) experience enhanced HBV replication and viral expression on hepatocyte membranes during chemotherapy coupled with suppression of cellular immunity. When chemotherapy is withdrawn, such patients are at risk for reactivation of hepatitis B, often severe and occasionally fatal. Such rebound reactivation represents restoration of cytolytic T-cell function against a target organ enriched in HBV expression. Preemptive treatment with the first of the oral HBV antivirals, lamivudine, prior to the initiation of chemotherapy was shown to reduce the risk of such reactivation substantially; treating *after* reactivation has occurred is less effective. The newer, more potent oral antiviral agents, entecavir and tenofovir, which are even more effective in preventing hepatitis B reactivation and with a lower risk of antiviral drug resistance, are preferred. The optimal duration of antiviral therapy after completion of chemotherapy is not known, but a suggested approach is 6 months (12 months for B cell–depleting agents) for inactive hepatitis B carriers and longer-duration therapy in patients with baseline HBV DNA levels >2 × 10^3 IU/mL, until standard clinical endpoints are met (Table 341-4). Such chemotherapy-associated reactivation of hepatitis B is common (4–68%, median 25%, in a meta-analysis) in persons with ongoing HBV infection (HBsAg-reactive); however, such reactivation can occur, albeit less commonly, in persons who have cleared HBsAg but express anti-HBc (moderate risk, <10%) and rarely (<5%) even in persons with serologic evidence of recovery from HBV infection (anti-HBs-reactive, anti-HBc-reactive). Therefore, most authorities (e.g., Centers for Disease Control and Prevention; AASLD; American Gastroenterological Association; EASL) recommend HBsAg and anti-HBc (± anti-HBs) screening of all patients undergoing such chemotherapy and preemptive antiviral prophylaxis for HBsAg-reactive persons and anti-HBc-reactive persons treated with the most potent immunomodulatory agents (especially B cell–depleting agents like rituximab) and close on-therapy monitoring of other anti-HBc-reactive/anti-HBs-reactive persons with treatment if and when reactivation occurs.

CHRONIC HEPATITIS D (DELTA HEPATITIS)

Chronic hepatitis D virus (HDV) may follow acute co-infection with HBV but at a rate no higher than the rate of chronicity of acute hepatitis B. That is, although HDV co-infection can increase the severity of acute hepatitis B, HDV does not increase the likelihood of progression to chronic hepatitis B. When, however, HDV superinfection occurs in a person who is already chronically infected with HBV, long-term HDV infection is the rule, and a worsening of the liver disease is the expected consequence. Except for severity, chronic hepatitis B plus D has similar clinical and laboratory features to those seen in chronic hepatitis B alone. Relatively severe and progressive chronic hepatitis, with or without cirrhosis, is the rule, and mild chronic hepatitis is the exception. Occasionally, however, mild hepatitis or even, rarely, inactive carriage occurs in patients with chronic hepatitis B plus D, and the disease may

become indolent after several years of infection. A distinguishing serologic feature of chronic hepatitis D is the presence in the circulation of antibodies to liver-kidney microsomes (anti-LKM); however, the anti-LKM seen in hepatitis D, anti-LKM3, are directed against uridine diphosphate glucuronosyltransferase and are distinct from anti-LKM1 seen in patients with autoimmune hepatitis and in a subset of patients with chronic hepatitis C (see below). **The clinical and laboratory features of chronic HDV infection are summarized in Chap. 339.**

TREATMENT

Chronic Hepatitis D

Management is not well defined, and the host cellular RNA polymerase upon which HDV replication depends cannot be targeted by conventional antiviral agents. Glucocorticoids are ineffective and are not used. Preliminary experimental trials of IFN-α suggested that conventional doses and durations of therapy lower levels of HDV RNA and aminotransferase activity only transiently during treatment but have no impact on the natural history of the disease. In contrast, high-dose IFN-α (9 million units three times a week) for 12 months was reported to be associated with a sustained loss of HDV replication and clinical improvement in up to 50% of patients. Moreover, in anecdotal reports, the beneficial impact of treatment has been observed to persist for 15 years and to be associated with a reduction in grade of hepatic necrosis and inflammation, reversion of advanced fibrosis (improved stage), and clearance of HDV RNA in some patients. A suggested approach to therapy has been high-dose, long-term IFN for at least a year and, in responders, extension of therapy until HDV RNA and HBsAg clearance; however, extension of therapy to a second year provided no advantage, and sustained responses after completion of therapy have been rare. While standard IFN-α is the only approved drug for hepatitis D, PEG IFN has been shown to be more effective but still of limited therapeutic value; after 48 weeks of therapy, durable undetectable HDV RNA for 24 posttreatment weeks has been reported in a quarter to just over a half of patients. Disappointingly, loss of virologic responses (reappearance of HDV RNA) was observed during long-term (median 4.5 years) monitoring in a majority of 24-week-posttreatment responders, with durable HDV RNA suppression to undetectable in only 12%. Even extending PEG IFN therapy for 5 years and driving treatment doses up to 270 μg weekly (of PEG IFN-α2a), as reported in a small trial among 13 patients, while achieving serologic, virologic, histologic, biochemical, and clinical improvement, yielded sustained virologic responses (SVRs) in only 3 patients (58–246 weeks of posttreatment observation). None of the nucleoside analogue antiviral agents for hepatitis B is effective in hepatitis D, and adding oral nucleoside agents to PEG IFN is no more effective than PEG IFN monotherapy. While recommended, 12 months of PEG IFN therapy is far from satisfactory.

Preliminary trials have been performed with an oral prenylation inhibitor, lonafarnib, and with an inhibitor of HBV/HDV viral entry into hepatocytes, myrcludex B. Prenylation, the posttranslational covalent addition of the prenyl lipid farnesyl to large HDV antigen, is required for this HDV protein to interact and form secreted viral particles with HBsAg. In 14 patients treated twice daily for 28 days with 100 or 200 mg of lonafarnib, HDV RNA fell by 0.73 $\log_{10}$ IU/mL and 1.54 $\log_{10}$ IU/mL, respectively, before rebounding after completion of therapy. HBV entry into hepatocytes requires the binding of the myristolated N-terminal pre-S1 peptide of large HBsAg to sodium taurocholate co-transporting peptide, the functional receptor for HBV into hepatocytes. The application of myrcludex B, a synthetic homologous myristolated lipopeptide that competes for binding with HBsAg, was reported in a study of 24 patients (with a baseline mean of 4.1–4.2 $\log_{10}$ copies/mL of HDV RNA) randomized to 24 weeks of treatment with myrcludex B (2 mg daily subcutaneously) as monotherapy or combined with PEG IFN compared to PEG IFN alone. A reduction in HDV RNA occurred in all three groups, by 1.67 $\log_{10}$ copies/mL (in two of eight patients RNA became undetectable), 2.59 $\log_{10}$ copies/mL (in five of eight patients RNA became undetectable), and 2.17 $\log_{10}$ copies/mL (in two of eight patients RNA became undetectable), respectively. No change occurred, however, in the level of HBsAg, which would have been expected. In these two exploratory brief-duration trials, sustained responses were not achieved, and toxicities were encountered (e.g., intermittent vomiting and weight loss [lonafarnib] and transient amylase and lipase elevations [myrcludex B]); however, from these proof-of-principle trials, more definitive and larger-scale studies of efficacy are awaited. Additional experimental approaches to the treatment of hepatitis D include nucleic acid polymer therapy to inhibit HBsAg release, administered alone or with PEG IFN and/or nucleoside analogues; so far, these studies have been done in one Eastern European site, have yielded some promising reductions in HDV RNA and HBsAg, but have been plagued by adverse effects, including marked ALT elevations. PEG IFN lambda has also been studied in small numbers of patients with hepatitis D; both IFN-associated side effects and elevations of aminotransferase and bilirubin levels accompanied modest on-treatment reductions in HDV RNA. Follow-up studies in larger numbers of patients have been frustratingly slow to materialize.

In patients with end-stage liver disease secondary to chronic hepatitis D, liver transplantation has been effective. If hepatitis D recurs in the new liver without the expression of hepatitis B (an unusual serologic profile in immunocompetent persons but common in transplant patients), liver injury is limited. In fact, the outcome of transplantation for chronic hepatitis D is superior to that for chronic hepatitis B; in such patients, combination HBIG and nucleoside analogue therapy for hepatitis B is indicated **(Chap. 345)**.

CHRONIC HEPATITIS C

Regardless of the epidemiologic mode of acquisition of hepatitis C virus (HCV) infection, chronic hepatitis follows acute hepatitis C in 50–70% of cases; chronic infection is common even in those with a return to normal in aminotransferase levels after acute hepatitis C, adding up to an 85% likelihood of chronic HCV infection after acute hepatitis C. Few clues had emerged to explain host differences associated with chronic infection until recently, when variation in a single nucleotide polymorphism (SNP) on chromosome 19, *IL28B* (which codes for IFN-λ3, now renamed *IFNL3*), was identified that distinguished between responders and nonresponders to IFN-based antiviral therapy (see below). The same variants correlated with spontaneous resolution after acute infection: 53% in genotype C/C, 30% in genotype C/T, but only 23% in genotype T/T. The association with HCV clearance after acute infection is even stronger when *IL28B* (*IFNL3*) haplotype is combined with haplotype G/G of a SNP near human leukocyte antigen (HLA) class II *DBQ1*03:01*.

In patients with chronic hepatitis C followed for 20 years, progression to cirrhosis occurs in ~20–25%. Such is the case even for patients with relatively clinically mild chronic hepatitis, including those without symptoms, with only modest elevations of aminotransferase activity, and with mild chronic hepatitis on liver biopsy. Even in cohorts of well-compensated patients with chronic hepatitis C referred for clinical research trials (no complications of chronic liver disease and with normal hepatic synthetic function), the prevalence of cirrhosis may be as high as 50%. Most cases of hepatitis C are identified initially in asymptomatic patients who have no history of acute hepatitis C (e.g., those discovered while attempting to donate blood, while undergoing lab testing as part of an application for life insurance, or as a result of routine laboratory tests). The source of HCV infection in many of these cases is not defined, although a long-forgotten percutaneous exposure (e.g., injection drug use) in the remote past can be elicited in a substantial proportion and probably accounts for most infections; most of these infections were acquired in the 1960s and 1970s among persons in the 1945–1965 birth cohort **(Chap. 339)**, coming to clinical attention decades later.

Approximately one-third of patients with chronic hepatitis C have normal or near-normal aminotransferase activity; although one-third to one-half of these patients have chronic hepatitis on liver biopsy, the grade of liver injury and stage of fibrosis tend to be mild in the vast majority. In some cases, more severe liver injury has been reported—even, rarely, cirrhosis, most likely the result of previous histologic activity. Among patients with persistent normal aminotransferase activity sustained over ≥5–10 years, histologic progression has been shown to be rare; however, approximately one-fourth of patients with normal aminotransferase activity experience subsequent aminotransferase elevations, and histologic injury can be progressive once abnormal biochemical activity resumes. Therefore, continued clinical monitoring and antiviral therapy are indicated, even for patients with normal aminotransferase activity.

Despite this substantial rate of progression of chronic hepatitis C and even though liver failure can result from end-stage chronic hepatitis C, the long-term prognosis over 1–2 decades for chronic hepatitis C in most patients is relatively benign. Mortality over 10–20 years among patients with transfusion-associated chronic hepatitis C has been shown not to differ from mortality in a matched population of transfused patients in whom hepatitis C did not develop. Although death in the hepatitis group is more likely to result from liver failure and although hepatic decompensation may occur in ~15% of such patients over the course of a decade, the majority (almost 60%) of patients remain asymptomatic and well compensated, with no clinical sequelae of chronic liver disease. Overall, chronic hepatitis C tends to be very slowly and insidiously progressive, if at all, in most patients, whereas in approximately one-fourth of cases, chronic hepatitis C will progress eventually to end-stage cirrhosis. In fact, because HCV infection is so prevalent, and because a proportion of patients progress inexorably to end-stage liver disease, hepatitis C was the most frequent indication for liver transplantation **(Chap. 345)** in the era prior to the availability of direct-acting antiviral (DAA) therapy (see below). In the United States, hepatitis C accounts for up to 40% of all chronic liver disease; as of 2007, mortality caused by hepatitis C surpassed that associated with HIV/AIDS, and as of 2012, reported deaths caused by hepatitis C surpassed those associated with all other notifiable infectious diseases (HIV, tuberculosis, hepatitis B, and 57 other infectious diseases). Moreover, because the prevalence of HCV infection is so much higher in the "baby boomer" cohort born between 1945 and 1965, three-quarters of the mortality associated with hepatitis C occurs in this age cohort. Referral bias may account for the more severe outcomes described in cohorts of patients reported from tertiary care centers (20-year progression of ≥20%) versus the more benign outcomes in cohorts of patients monitored from initial blood-product-associated acute hepatitis or identified in community settings (20-year progression of only 4–7%). Still unexplained, however, are the wide ranges in reported progression to cirrhosis, from 2% over 17 years (eventually 19% over 36 years) in a population of Irish women with hepatitis C infection acquired from contaminated anti-D immune globulin to 30% over ≤11 years in recipients of contaminated intravenous immune globulin.

Progression of liver disease in patients with chronic hepatitis C has been reported to be more likely in patients with older age, longer duration of infection, advanced histologic stage and grade, more complex HCV quasispecies diversity, increased hepatic iron, concomitant other liver disorders (alcoholic liver disease, chronic hepatitis B, hemochromatosis, α_1 antitrypsin deficiency, and steatohepatitis), HIV infection, and obesity. Among these variables, however, duration of infection appears to be one of the most important, and some of the others probably reflect disease duration to some extent (e.g., quasispecies diversity, hepatic iron accumulation). No other epidemiologic or clinical features of chronic hepatitis C (e.g., severity of acute hepatitis, level of aminotransferase activity, level of HCV RNA, presence or absence of jaundice during acute hepatitis) are predictive of eventual outcome. Despite the relatively benign nature of chronic hepatitis C over time in many patients, cirrhosis following chronic hepatitis C has been associated with the late development, after several decades, of HCC **(Chap. 82)**; the annual rate of HCC in cirrhotic patients with hepatitis C is 1–4%, occurring primarily in patients who have had HCV infection for 30 years or more.

Perhaps the best prognostic indicator in chronic hepatitis C is liver histology; the rate of hepatic fibrosis may be slow, moderate, or rapid. Patients with mild necrosis and inflammation as well as those with limited fibrosis have an excellent prognosis and limited progression to cirrhosis. In contrast, among patients with moderate to severe necroinflammatory activity or fibrosis, including septal or bridging fibrosis, progression to cirrhosis is highly likely over the course of 10–20 years. The pace of fibrosis progression may be accelerated by such factors as concomitant HIV infection, other causes of liver disease, excessive alcohol use, and hepatic steatosis. Among patients with compensated cirrhosis associated with hepatitis C, the 10-year survival rate is close to 80%; mortality occurs at a rate of 2–6% per year; decompensation at a rate of 4–5% per year; and, as noted above, HCC at a rate of 1–4% per year. Estimates of the natural history of chronic hepatitis C have been made, based on data available on the prevalence of HCV infection in the U.S. population and on the rate of disease progression. Weighted primarily by the concentration of chronic hepatitis C in the baby boomer generation, the peak prevalence was estimated to have occurred in 2015. The calculated frequency of cirrhosis in U.S. patients with hepatitis C was 5% in 1990 and 25% in 2010 and was projected to be 37% in 2020. Estimated peak mortality has been predicted to occur in 2032. **A discussion of the pathogenesis of liver injury in patients with chronic hepatitis C appears in Chap. 339.**

Clinical features of chronic hepatitis C are similar to those described above for chronic hepatitis B. Generally, fatigue is the most common symptom; jaundice is rare. Immune complex–mediated extrahepatic complications of chronic hepatitis C are less common than in chronic hepatitis B (despite the fact that assays for immune complexes are often positive in patients with chronic hepatitis C), with the exception of essential mixed cryoglobulinemia **(Chap. 339)**, which is linked to cutaneous vasculitis and membranoproliferative glomerulonephritis as well as lymphoproliferative disorders such as B-cell lymphoma and unexplained monoclonal gammopathy. In addition, chronic hepatitis C has been associated with extrahepatic complications unrelated to immune-complex injury. These include Sjögren's syndrome, lichen planus, porphyria cutanea tarda, renal injury, type 2 diabetes mellitus, and the metabolic syndrome (including insulin resistance and steatohepatitis). In addition, a link has been observed between HCV infection and cardiovascular/cerebrovascular disease, rheumatologic/immunologic disorders, mental health and cognitive disorders, and nonliver malignancies.

Laboratory features of chronic hepatitis C are similar to those in patients with chronic hepatitis B, but aminotransferase levels tend to fluctuate more (the characteristic episodic pattern of aminotransferase activity) and to be lower, especially in patients with long-standing disease. An interesting and occasionally confusing finding in patients with chronic hepatitis C is the presence of autoantibodies. Rarely, patients with autoimmune hepatitis (see below) and hyperglobulinemia have false-positive immunoassays for anti-HCV. On the other hand, some patients with serologically confirmable chronic hepatitis C have circulating anti-LKM. These antibodies are anti-LKM1, as seen in patients with autoimmune hepatitis type 2 (see below), and are directed against a 33-amino-acid sequence of cytochrome P450 IID6. The occurrence of anti-LKM1 in some patients with chronic hepatitis C may result from the partial sequence homology between the epitope recognized by anti-LKM1 and two segments of the HCV polyprotein. In addition, the presence of this autoantibody in some patients with chronic hepatitis C suggests that autoimmunity may be playing a role in the pathogenesis of chronic hepatitis C.

Histopathologic features of chronic hepatitis C, especially those that distinguish hepatitis C from hepatitis B, are described in Chap. 339.

TREATMENT

Chronic Hepatitis C

Therapy for chronic hepatitis C has evolved substantially in the 30 years since IFN-α was introduced for this indication in 1991. The therapeutic armamentarium grew to include PEG IFN with ribavirin and, then, in 2011, the introduction of the first protease

inhibitors, telaprevir and boceprevir, used in combination with PEG IFN and ribavirin in patients with HCV genotype 1. The field of antiviral therapy for hepatitis C was transformed beginning in 2013, with the approval of the first nucleoside analogue polymerase inhibitor, sofosbuvir. Although several of these combination regimens have been supplanted by better, later-generation drugs, as of 2020, five all-oral, highly effective (>95%), low-resistance, pangenotypic, well-tolerated, short-duration (primarily 8–12 weeks) combination regimens of DAA drugs are recommended. The remarkable historical evolution of antiviral therapy for hepatitis C is instructive.

THE INTERFERON ERA (1991–2011)

IFN-based therapy has been supplanted by DAA agents introduced in the second decade of the twenty-first century; however, many important lessons about antiviral therapy for chronic hepatitis C were learned from the experience with IFN-based treatment, and many of the limitations of—and disparities in responsiveness to—IFN-based therapy have been overcome by current-generation DAA treatments. Mechanistically, HCV proteins inhibit several steps of the JAK-STAT signal transduction pathway, and by activation of JAK-STAT signaling, exogenous IFN culminates in and restores intracellular expression of IFN-stimulated genes and their protein products that have antiviral properties.

When first approved, subcutaneous IFN-α three times a week for 6 months achieved an SVR **(Fig. 341-2)** (defined then as a reduction of HCV RNA to PCR-undetectable levels ≥24 weeks after completion of therapy) in <10%. Doubling the duration of therapy increased the SVR rate to ~20%, and addition to the regimen of daily ribavirin (ineffective when used alone), an oral guanosine nucleoside, increased the SVR rate to 40% by reducing the likelihood of virologic relapse after completion of treatment (Fig. 341-2). Although its mechanism of action remains poorly understood, ribavirin retains a limited role in supporting DAA agents in several subgroups of otherwise refractory patients (see below).

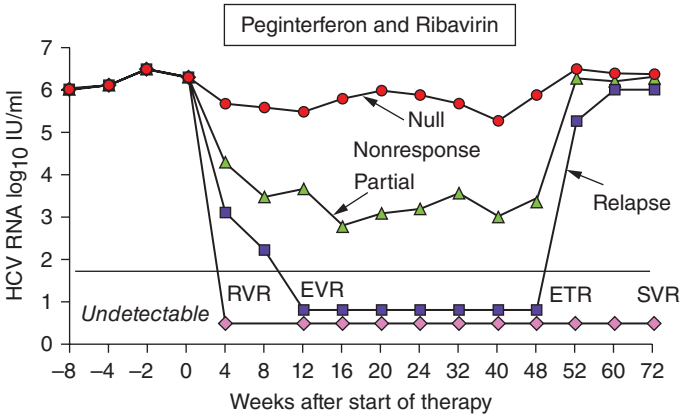

FIGURE 341-2 Classification of virologic responses based on outcomes during and after a 48-week course of pegylated interferon (PEG IFN) plus ribavirin antiviral therapy in patients with hepatitis C, genotype 1 or 4 (for genotype 2 or 3, the course would be 24 weeks). Nonresponders can be classified as null responders (hepatitis C virus [HCV] RNA reduction of <2 $\log_{10}$ IU/mL) or partial responders (HCV RNA reduction ≥2 $\log_{10}$ IU/mL but not suppressed to undetectable) by week 24 of therapy. In responders, HCV RNA can become undetectable, as shown with sensitive amplification assays, within 4 weeks (rapid virologic response [RVR]); can be reduced by ≥2 $\log_{10}$ IU/mL within 12 weeks (early virologic response [EVR]; if HCV RNA is undetectable at 12 weeks, the designation is "complete" EVR); or can be undetectable at the end of therapy, 48 weeks (end-treatment response [ETR]). In responders, if HCV RNA remains undetectable for 24 weeks after ETR, week 72, the patient has a sustained virologic response (SVR), but if HCV RNA becomes detectable again, the patient is considered to have relapsed. The posttreatment week-24 SVR (SVR_{24}) has been supplanted by an SVR at week 12 (SVR_{12}), which has been shown to be equivalent to an SVR_{24}. In patients treated with direct-acting antiviral therapy, RVR and EVR milestones are largely irrelevant, being met by almost all patients. *(Reproduced with permission from Marc G. Ghany, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health and the American Association for the Study of Liver Diseases. Hepatology 49:1335, 2009.)*

Treatment with the combination of PEG IFN and ribavirin increased SVR rates to 55% overall—to >40% in genotypes 1 and 4, requiring 48 weeks of therapy, and to >80% in genotypes 2 and 3, requiring only 24 weeks of therapy—and histologic improvement in approximately three-fourths of patients. After initiation of IFN treatment, ALT levels fell precipitously, and up to 90% of virologic responses were achieved within the first 12 weeks of therapy. Failure to achieve an early virologic response (EVR), a ≥2-$\log_{10}$ reduction in HCV RNA by week 12, predicted failure to experience a subsequent SVR. Similarly, patients in whom HCV RNA became undetectable within 4 weeks (i.e., who achieve a rapid virologic response [RVR]) had a very high likelihood of achieving an SVR (Fig. 341-2). Surprisingly, however, high-dose induction with IFN-based therapy did not yield higher SVR rates.

Most relapses occurred within the first 12 weeks after treatment, and absence of HCV RNA 12 weeks after completion of therapy has become the current standard for SVR (SVR_{12}); relapses are very rare 6 months to a year after SVR and almost unheard of after 2 years. Of documented durability decades after successful therapy, an SVR to antiviral therapy for chronic hepatitis C is tantamount to a cure and is followed by marked improvements in liver-disease outcomes (see below).

Patient variables that correlated with IFN-based SVRs included favorable genotype (genotypes 2 and 3 as opposed to genotypes 1 and 4; genotype 1b as opposed to genotype 1a); low baseline HCV RNA level (<800,000 IU/mL), low HCV quasispecies diversity, and histologically mild hepatitis and minimal fibrosis, especially absence of cirrhosis; immunocompetence; low liver iron levels; age <40; female gender; and absence of obesity, insulin resistance, type 2 diabetes mellitus, and hepatic steatosis. High levels of HCV RNA, more histologically advanced liver disease, and high HCV quasispecies diversity all went hand in hand with advanced duration of infection and reduced IFN responsiveness. Also associated with poor responses to IFN-based therapy were African-American ethnicity (contributed to, but not explained entirely by, a higher proportion with genotype 1, slower early treatment viral kinetics, impaired HCV-specific immunity, and host genetic differences in *IL28B* [*IFNL3*] alleles, described below), Latino ethnicity, and poor treatment adherence (<80% of IFN and ribavirin doses and <80% of prescribed duration of therapy). Ironically, patients whose disease was least likely to progress were the ones *most* likely to respond to IFN and vice versa.

As described above in the discussion of spontaneous recovery from acute hepatitis C, IFN gene variants discovered in genome-wide association studies were shown to have a substantial impact on IFN responsiveness of patients with genotype 1 to antiviral therapy. In studies of patients treated with PEG IFN and ribavirin, variants of the *IL28B* (now renamed *IFNL3*) SNP that code for IFN-λ3 (a type III IFN, the receptors for which are more discretely distributed than IFN-α receptors and more concentrated in hepatocytes) correlated significantly with responsiveness. Homozygotes for the C allele at this locus (C/C) achieved SVRs of ~80%, heterozygotes (C/T) SVRs of ~35%, and homozygotes for the T allele (T/T) SVRs of ~25%.

Side effects of IFN therapy are described in the section on treatment of chronic hepatitis B (see above). Besides ribavirin-associated nasal and chest congestion, pruritus, and precipitation of gout, the most pronounced ribavirin side effect is hemolysis, often requiring dose reduction or addition of erythropoietin therapy (not shown, however, to increase the likelihood of an SVR); therefore, close monitoring of blood counts is crucial, and ribavirin should be avoided in patients with anemia, hemoglobinopathies, coronary artery disease or cerebrovascular disease, or renal insufficiency (the drug is excreted renally) and in pregnancy (the drug is teratogenic, mandating contraception during, and for several months after, therapy in women of child-bearing age [because of their antiproliferative properties, IFNs also are contraindicated during pregnancy]). Overall, combination IFN-ribavirin therapy was more difficult to tolerate than IFN monotherapy and more likely to lead to dose reductions and discontinuation of therapy.

Beginning in 2011, for the treatment of hepatitis C, standard IFNs were supplanted by PEG IFNs, which have substantially longer half-lives, permitting administration once (rather than three times) a week. Once-a-week PEG IFN monotherapy was twice as effective as IFN monotherapy, approached the efficacy of combination standard IFN plus ribavirin, and was as well tolerated as standard IFNs. For most of the decade prior to 2011, when protease inhibitors were introduced for HCV genotype 1 (see below), the standard of care was a combination of PEG IFN plus ribavirin for all HCV genotypes.

Two PEG IFNs were available: PEG IFN-α2b, a 12-kD, linear PEG molecule bound to IFN-α2b, and PEG IFN-α2a, a larger, 40-kD, branched PEG molecule bound to IFN-α2a; because of its larger size and smaller volume of extravascular distribution, PEG IFN-α2a could be given at a uniform dose independent of weight, whereas the dose of the smaller PEG IFN-α2b, which has a much wider volume distribution, had to be weight-based. Between the two PEG IFNs, PEG IFN-α2a appeared to be slightly better tolerated and slightly more effective than PEG IFN-α2b in registration trials. The frequency of an SVR to PEG IFN–ribavirin therapy could be increased by tailoring therapy according to baseline variables and on-treatment virologic responsiveness. For example, in patients with baseline variables weighing against a response (e.g., high HCV RNA, obesity), raising the dose of PEG IFN and/or of ribavirin or extending therapy to 72 weeks for patients with genotype 1 and a slow virologic response, SVR rates could be improved. In contradistinction, in the ≤20% of patients with genotype 1 (and 4) who had a 4-week RVR and low baseline HCV RNA, treatment could be abbreviated to 24 weeks and SVR rates of ~90% achieved.

For most of the decade prior to 2011, when protease inhibitors were introduced for HCV genotype 1 (see below), the standard of care was a combination of PEG IFN plus ribavirin (unless ribavirin was contraindicated) for all HCV genotypes. Even after the introduction of protease inhibitors for genotypes 1 and 4, however, PEG IFN–ribavirin remained the standard of care for patients with genotypes 2 and 3 until late 2013. Responsiveness to IFN-ribavirin–based therapy was diminished in immunocompromised patients and in patients with HIV-HCV co-infection and contraindicated in patients with decompensated liver disease or end-stage renal disease. The cumbersome nature of IFN-ribavirin–based therapy (injections, complicated laboratory monitoring, side effects and poor tolerability, modest efficacy, variables and patient subsets associated with poor responsiveness, tailored therapy, futility rules, etc.) was supplanted eventually (in 2016) by DAAs for all genotypes (see below). Most of the variables associated with poor responsiveness to IFN-based therapy became irrelevant, and difficult-to-treat patient subpopulations began to experience responses to DAAs that were indistinguishable from responses in standard patients (see below).

Persons with chronic HCV infection suffer increased liver-related mortality, all-cause mortality, and multiple extrahepatic disorders (see above). On the other hand, successful antiviral therapy of chronic hepatitis C resulting in an SVR was shown to improve survival (and to reduce the need for liver transplantation); to lower the risk of liver failure, liver-related death, and all-cause mortality; to slow the progression of chronic hepatitis C; to reverse fibrosis and even cirrhosis; and to improve such HCV-associated extrahepatic disorders as type 2 diabetes and renal disease. Whereas the 10- and 20-year survival in the absence of an SVR is reduced in cirrhotic patients with chronic hepatitis C, survival at these intervals after an SVR has been found to be indistinguishable from that of the general population. In cirrhotic patients (and in those with advanced fibrosis), although successful treatment reduces mortality and liver failure (three- to fourfold 10-year reduction) and reduces the need for liver transplantation and the likelihood of HCC (14-fold 10-year reduction), the risk of liver-related death and HCC persists, albeit at a much reduced level, necessitating continued clinical monitoring and cancer surveillance after SVR in cirrhotics. On the other hand, in the absence of an SVR, IFN-based therapy does not reduce the risk of HCC. Fortunately, PEG IFN–ribavirin nonresponders can now be retreated with DAAs and experience SVR rates comparable to those in treatment-naïve persons (see below).

FIRST-GENERATION PROTEASE INHIBITORS (2011–2013)

The HCV RNA genome encodes a single polyprotein, which is cleaved during and after translation by host and viral-encoded proteases. One protease involved in the cleavage of the viral polyprotein is an NS3/4A viral protein that has serine protease activity. Telaprevir and boceprevir are serine protease inhibitors that target NS3/4A. In 2011, telaprevir and boceprevir used in combination with PEG IFN and ribavirin were approved by the U.S. Food and Drug Administration (FDA) as the first oral DAA agents for the treatment of hepatitis C genotype 1 (not other genotypes) in adults with stable liver disease, both in patients who had not been treated before and in patients who had failed previous treatment. Although now replaced by more effective, all-oral regimens, these first-in-class agents represented a breakthrough in the treatment of chronic hepatitis C and established milestones against which subsequent therapies could be measured.

Because resistance developed rapidly during monotherapy with telaprevir and boceprevir, these drugs had to be used in combination with PEG IFN and ribavirin. Ribavirin in particular appeared to reduce relapse rates significantly in protease-inhibitor-based regimens, such that those who could not take or were intolerant to ribavirin were unlikely to benefit from the addition of these agents. Telaprevir and boceprevir regimens consisted of periods of triple therapy (protease inhibitor plus PEG IFN plus ribavirin) and periods of dual therapy (PEG IFN plus ribavirin). Telaprevir regimens began with 12 weeks of triple therapy followed by dual therapy of a duration based on HCV RNA status at weeks 4 and 12 ("response-guided therapy") and prior treatment status. Boceprevir-based regimens consisted of a 4-week lead-in period of dual (PEG IFN–ribavirin) therapy followed by triple therapy and, in some instances, a further extension of dual therapy, with duration of response-guided therapy based on HCV RNA status at weeks 4, 8, and 24 and prior treatment status.

For patients with HCV genotype 1, protease inhibitors improved the frequency of RVRs and SVRs significantly as compared to PEG IFN plus ribavirin alone. In treatment-naïve patients, telaprevir-based SVRs were achieved in up to 79% of patients who received 12 weeks of triple therapy followed by 12–36 weeks of dual therapy, and among those with EVRs (undetectable HCV RNA at weeks 4 and 12) and response-guided therapy stopped at week 24 (12 weeks of triple therapy, then 12 weeks of dual therapy), SVRs occurred in 83–92%. In studies with boceprevir in treatment-naïve patients, SVRs occurred in 59–66% of patients, and among those with undetectable HCV RNA at 8 weeks, the SVR rate increased to 86–88%. Adding to the complexity of treatment with these protease inhibitors were absolute stopping rules for futility, that is, absence of HCV RNA reductions at critical treatment milestones, which were shown to be invariably predictive of nonresponse (telaprevir: HCV RNA >1000 IU/mL at weeks 4 or 12, or detectable at week 24; boceprevir: HCV RNA ≥100 IU/mL at week 12, or detectable at week 24).

In patients previously treated unsuccessfully with PEG IFN plus ribavirin, telaprevir-based treatment achieved SVRs in 83–88% of prior relapsers, 54–59% of partial responders (HCV RNA reduced by ≥2 $\log_{10}$ IU/mL but not to undetectable levels), and 29–33% of null responders (HCV RNA reduced by <2 $\log_{10}$ IU/mL). With boceprevir, a similar degradation in SVR rate occurred as a function of prior responsiveness—in 75% of prior relapsers, in 40–52% of previous partial responders, and in ~30–40% of null responders. In a substantial proportion of protease inhibitor nonresponders, resistance-associated substitutions (RASs, previously referred to as resistance-associated variants [RAVs]) could be identified, but these variants were not archived, and wild-type HCV reemerged in almost all cases within 1.5–2 years. SVRs to these protease inhibitors were highest in prior relapsers and treatment-naïve patients (white > black ethnicity), lower in prior partial responders, lower still in

prior null responders, and lowest in cirrhotic prior null responders, for whom no benefit accrued over PEG IFN–ribavirin treatment. Responses to protease inhibitor triple-drug regimens were higher in patients with *IL28B* (*IFNL3*) C than non-C genotypes, HCV genotype 1b than genotype 1a, less advanced than more advanced fibrosis stage, whites than blacks, lower body mass index (BMI) than elevated BMI, and, for boceprevir, achievement of a >1 $\log_{10}$ HCV RNA reduction during 4 weeks of PEG IFN–ribavirin lead-in therapy. Age and HCV RNA level were less influential and insulin resistance was noninfluential on response to these antiviral agents.

Both protease inhibitors had substantial toxicities. Telaprevir was associated with a severe, generalized (trunk and extremities), often confluent, maculopapular, pruritic rash in ~6% of treated patients (that required careful dermatologic monitoring in all patients and systemic corticosteroid therapy in the most severely affected). Other common side effects included pruritus, rectal burning, nausea, diarrhea, fatigue, dysgeusia (altered or unpleasant taste), and anemia, which required close monitoring, could be relatively refractory, and occasionally required transfusion and even hospitalization (especially in cirrhotic prior nonresponders). Anemia occurred in half of boceprevir-treated patients, neutropenia in up to 30%, and thrombocytopenia in 3–4%. Other side effects of boceprevir included fatigue, nausea, headache, dysgeusia, dry mouth, vomiting, and diarrhea.

Both drugs came with an inconveniently high pill burden and had to be administered every 8 h with food (telaprevir with a 20-g fat meal). Use of protease inhibitors was further complicated by numerous drug-drug interactions. As telaprevir and boceprevir are both eliminated by and inhibit CYP3A4, these agents could not be administered with other medications that induce CYP3A4 or are dependent on CYP3A4 for elimination. Care had to be taken to examine for any potential interactions between these protease inhibitors and other medications the patient was taking, and a convenient website became available to check for such drug-drug interactions (*www.hep-druginteractions.org*).

Despite the improvement in SVRs with protease-inhibitor-based regimens for genotype 1 compared to PEG IFN–ribavirin (e.g., in treatment-naïve patients 66–79% vs 38–44%), triple-drug protease inhibitor therapy was hampered by amplified intolerability, the complexity of response-guided regimens and futility stopping rules, the inconvenience of thrice-daily dosing with meals and a high pill burden, the need for PEG IFN injections and ribavirin with all their intolerability, and multiple drug-drug interactions. Moreover, side effects appeared to be more severe and burdensome once these drugs entered practice, especially in cirrhotic nonresponders, in whom studies reported from Europe showed serious adverse events in up to 45% and deaths in up to 3%. All these issues, as well as rapidly accelerating progress on next-generation and all-oral DAA therapy (see below), conspired to temper enthusiasm for these new antivirals; after a brief stint as recommended therapy (2011–2013), these drugs became obsolete and are no longer recommended or available.

DIRECT-ACTING ANTIVIRAL COMBINATIONS OF SECOND-GENERATION PROTEASE INHIBITORS, FIRST-GENERATION POLYMERASE INHIBITORS, AND FIRST-GENERATION NS5A INHIBITORS (2014–2015)

Since late 2013, the number of new antiviral agents for hepatitis C has expanded substantially, and currently, PEG IFN–based treatments have been supplanted by five remaining therapeutic regimens, which are all oral, IFN-free, highly efficacious (>95% SVR), and well tolerated, with high barriers to resistance, simple dosing, low pill burdens, treatment durations as brief as 8–12 weeks, and pangenotypic efficacy **(Table 341-6)**. These drugs are distributed among three classes of DAAs: NS3/4 protease inhibitors (which cleave the single HCV polyprotein into constituent structural and nonstructural proteins [drug name ending in "-previr"]), NS5B nucleoside and nonnucleoside polymerase inhibitors (which interfere with the RNA-dependent RNA polymerase [a replicase] involved in synthesis of viral RNA [drug name ending in "-buvir"]), and NS5A inhibitors (which interfere with a membrane-associated phosphoprotein essential to the HVC RNA replication complex [drug name ending in "-asvir"]).

The first of the new DAA agents (approved in November 2013) was simeprevir, a second-generation protease inhibitor for genotype 1, followed shortly thereafter (December 2013) by sofosbuvir, a pangenotypic nucleoside polymerase inhibitor. For genotype 1, both of these agents had to be combined with PEG IFN and ribavirin; for genotypes 2 and 3, sofosbuvir was administered with ribavirin, without PEG IFN; however, these treatment regimens have been supplanted by combinations of all-oral, IFN-free DAAs, and ribavirin is rarely needed and retained only for very limited indications.

Simeprevir: When simeprevir was used with PEG IFN, its efficacy (genotype 1b > 1a) was similar to that of first-generation protease inhibitors but required only once-a-day dosing without the complexity of response-guided therapy. Similar to first-generation protease inhibitors, simeprevir was hampered by many drug-drug interactions and side effects (including photosensitivity, rash, and mild hyperbilirubinemia); moreover, patients, with HCV NS3 polymorphism Q80K had markedly reduced drug efficacy, necessitating pretreatment genetic testing and disqualifying approximately a third of potential treatment candidates. Little about simeprevir supported its adoption in combination with PEG IFN and ribavirin. On the other hand, the combination of simeprevir (150 mg) along with sofosbuvir (400 mg) for 12 weeks was found to be effective in treatment-naïve (97% SVR_{12}) or treatment-experienced (95% SVR_{12}) patients without cirrhosis and in treatment-naïve (88% SVR_{12}) or treatment-refractory (79% SVR_{12}) patients with cirrhosis. Like first-generation protease inhibitors, however, simeprevir was limited to genotype 1, required pretreatment genotyping that disqualified a third of recipients, usually required concomitant PEG IFN and ribavirin, had multiple drug-drug interactions and side effects, and was not competitive with the improved combinations that followed; therefore, simeprevir is no longer recommended.

Sofosbuvir: Sofosbuvir, the first nonprotease inhibitor DAA to be approved, has an excellent profile—high potency, high barrier to resistance, pangenotypic activity, very well tolerated with limited adverse effects (most commonly mild fatigue, insomnia, headache, and nausea), once-daily oral administration, and relative freedom from major drug-drug interactions. Sofosbuvir has efficacy in all genotypes (1–6); in treatment-naïve subjects and prior nonresponders to PEG IFN–based and protease-inhibitor-based therapy; with PEG IFN–ribavirin or in IFN-free regimens; in combination with ribavirin or with NS5A inhibitors (see below); and for treatment periods as brief as 8–12 weeks. Currently, sofosbuvir is used in combination with one of two NS5A inhibitors and is a component of three of the five currently recommended DAA regimens (Table 341-6).

Sofosbuvir-ledipasvir: The DAA combination that has had a dominant role in the treatment of hepatitis C is sofosbuvir (400 mg) plus the NS5A inhibitor ledipasvir (90 mg) in a once-a-day, fixed-dose, single pill, approved in October 2014 for genotype 1 and in November 2015 for genotypes 4, 5, and 6. Phase 3 trials were conducted in treatment-naïve noncirrhotic patients, in treatment-naïve cirrhotic and noncirrhotic patients, and in treatment-experienced cirrhotic and noncirrhotic patients treated for 8, 12, or 24 weeks, both with and without ribavirin. In treatment-naïve noncirrhotics, an SVR_{12} was achieved in 97–99% of subjects, and no benefit was observed by extending therapy from 12 to 24 weeks or by adding ribavirin. Moreover, for treatment-naïve, noncirrhotic patients with baseline HCV RNA $<6 \times 10^6$ IU/mL, a treatment duration of 8 weeks was as effective as one of 12 weeks (94–95% SVR_{12}), which may be a consideration for a proportion of patients. In cirrhotic patients, SVR_{12} was achieved in 97–100% of treatment-naïve subjects (no advantage of extending therapy from 12 to 24 weeks or of adding ribavirin); however, for cirrhotic prior nonresponders to IFN-based therapy, 12 weeks of therapy was inferior (86% SVR_{12})

TABLE 341-6 Indications and Recommendations for Antiviral Therapy of Chronic Hepatitis C[a]

Standard Indications for Therapy

All patients with chronic HCV infection (detectable HCV RNA, with or without elevated ALT) except for those with short life expectancies owing to comorbid conditions.

Any stage of fibrosis; pretreatment biopsy is no longer embraced and has been supplanted by noninvasive measures of fibrosis, e.g., imaging to determine liver elasticity.

Responsiveness in groups previously refractory to interferon-based therapy (HIV-HCV co-infection, renal insufficiency, African-American and Latino ethnicity, *IL28B* non-C haplotype, obesity, insulin resistance, hepatic decompensation, etc.) is not diminished to contemporary direct-acting oral combination regimens.

Retreatment Recommended

Relapsers, partial responders, or nonresponders after a previous course of interferon-based therapy or prior direct-acting antiviral therapy (see genotype-specific recommendations below).

Antiviral Therapy Not Recommended

Pregnancy: No clinical studies of direct-acting antivirals during pregnancy are available. Ribavirin is contraindicated during pregnancy; therefore, any regimen including ribavirin should not be used. Sofosbuvir; sofosbuvir + ledipasvir; and paritaprevir-ritonavir + ombitasvir + dasabuvir are classified as pregnancy category B, but the other direct-acting antivirals do not have a pregnancy classification. Therefore, these therapies are not indicated routinely in pregnancy and should be used, with caution, only if the benefit of treatment outweighs the potential for fetal risk.

Therapeutic Regimens (based on AASLD-IDSA recommendations, *www.hcvguidelines.org*)[b]

The European Association for the Study of the Liver (EASL) recommendations diverge slightly from AASLD-IDSA recommendations.[c]

TREATMENT-NAÏVE OR RELAPSED AFTER PRIOR PEG IFN–RIBAVIRIN THERAPY

Genotype 1a and 1b

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 8 weeks

ledipasvir + sofosbuvir 12 weeks (consider 8 weeks for noncirrhotic HIV-negative patients with HCV RNA <6 × 10⁶ IU/mL)

grazoprevir + elbasvir 12 weeks (no cirrhosis or cirrhosis sans ELB NS5A RASs)

Genotype 2

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 8 weeks

Genotype 3

sofosbuvir + velpatasvir 12 weeks (in cirrhotics, recommended only if without baseline NS5A RAS Y93H for velpatasvir)

glecaprevir + pibrentasvir 8 weeks

sofosbuvir + velpatasvir 12 weeks + weight-based ribavirin (in cirrhotics with baseline NS5A RAS Y93H for velpatasvir)

sofosbuvir + velpatasvir + voxilaprevir 12 weeks (in cirrhotics with baseline NS5A RAS Y93H for velpatasvir)

Genotype 4

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 8 weeks (12 weeks for HIV co-infection)

ledipasvir + sofosbuvir 12 weeks *(consider 8 weeks for noncirrhotic HIV-negative patients with HCV RNA <6 × 10⁶ IU/mL)*

grazoprevir + elbasvir 12 weeks

Genotypes 5, 6

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 8 weeks

ledipasvir + sofosbuvir 12 weeks (except for genotype 6e)

FAILED PRIOR PEG IFN/RIBAVIRIN THERAPY, NO CIRRHOSIS[d]

Genotype 1a and 1b

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 8 weeks

ledipasvir + sofosbuvir 12 weeks

grazoprevir + elbasvir 12 weeks (without ELB NS5A RASs)

Genotype 2

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 8 weeks

Genotype 3

sofosbuvir + velpatasvir 12 weeks (for patients without baseline NS5A RAS Y93H for velpatasvir)

glecaprevir + pibrentasvir 16 weeks

sofosbuvir + velpatasvir + voxilaprevir 12 weeks for patients with baseline NS5A RAS Y93H for velpatasvir

Genotype 4

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 8 weeks

grazoprevir + elbasvir 12 weeks (for prior relapse)

ledipasvir + sofosbuvir 12 weeks

Genotypes 5, 6

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 8 weeks

ledipasvir + sofosbuvir 12 weeks

FAILED PRIOR PEG IFN–RIBAVIRIN THERAPY, COMPENSATED CIRRHOSIS[d]

Genotype 1a

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 12 weeks

grazoprevir + elbasvir 12 weeks (without ELB NS5A RASs)

ledipasvir + sofosbuvir + RBV 12 weeks

Genotype 1b

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 12 weeks

grazoprevir + elbasvir 12 weeks

ledipasvir + sofosbuvir + RBV 12 weeks

Genotype 2

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 12 weeks

Genotype 3

sofosbuvir + velpatasvir + voxilaprevir 12 weeks

glecaprevir + pibrentasvir 16 weeks

grazoprevir + elbasvir 12 weeks

sofosbuvir + velpatasvir + RBV 12 weeks

Genotype 4

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 12 weeks

grazoprevir + elbasvir 12 weeks (for prior relapse)

ledipasvir + sofosbuvir 12 weeks

Genotypes 5, 6

sofosbuvir + velpatasvir 12 weeks

glecaprevir + pibrentasvir 12 weeks

ledipasvir + sofosbuvir 12 weeks

FEATURES ASSOCIATED WITH REDUCED RESPONSIVENESS TO DIRECT-ACTING ANTIVIRAL COMBINATION THERAPY

Genotype and subtype (genotype 1a less responsive than genotype 1b for several drugs)

Treatment experience

Advanced fibrosis (bridging fibrosis, cirrhosis)

Reduced adherence

(*Continued*)

TABLE 341-6 Indications and Recommendations for Antiviral Therapy of Chronic Hepatitis C[a] (Continued)

[a]Rapidly evolving new recommendations continue to be issued; for up-to-date treatment recommendations, please see *www.hcvguidelines.org*. [b]For treatment-naïve patients, **simplified** treatment regimen recommendations are in **bold** font (based on broad applicability, pangenotypic coverage, and simplicity). For treatment-experienced patients, **recommended** regimens are in **bold** font, and alternative regimens are in standard font. [c]The following EASL recommendations differ from those of AASLD-IDSA:

Genotype 1

For genotype 1a, noncirrhotic, prior IFN/RBV nonresponders, sofosbuvir + ledipasvir is not recommended.

For genotype 1b, treatment-naïve or -experienced patients, EASL retains paritaprevir/ritonavir + ombitasvir + dasabuvir **for** 12 weeks (for 8 weeks in patients with stage F0–F2 fibrosis).

For genotype 1b, noncirrhotic, treatment-naïve or -experienced patients with stage F0–F2 fibrosis, the recommended duration of grazoprevir + elbasvir is 8 weeks.

Genotype 3

For cirrhotic, treatment-naïve or -experienced patients (IFN-based regimen failures), sofosbuvir + velpatasvir is not recommended. For noncirrhotic patients with genotype 3, sofosbuvir + ledipasvir + voxilaprevir is not recommended.

Genotype 4

For genotype 4, prior IFN/RBV nonresponders, sofosbuvir + ledipasvir is not recommended. In treatment-naïve noncirrhotics, shorter duration (8 weeks) is not recommended for patients with HCV RNA $\leq 6 \times 10^6$ IU/mL.

[d]For nonresponders to prior direct-acting antiviral therapy (protease, polymerase, or NS5A inhibitors) and for decompensated cirrhosis, please consult *www.hcvguidelines.org*.

Abbreviations: AASLD, American Association for the Study of Liver Diseases; ALT, alanine aminotransferase; ELB NS5A RASs, elbasvir NS5A resistance-associated substitutions; HCV, hepatitis C virus; IFN, interferon; IDSA, Infectious Diseases Society of America; PEG IFN, pegylated interferon; IU, international units (1 IU/mL is equivalent to ~2.5 copies/mL); RASs, resistance-associated substitutions; RBV, ribavirin.

to 24 weeks of therapy (100% SVR_{12}). This combination, which is equally effective in patients with HIV-HCV co-infection and in African-American patients, has been shown to be highly effective in patients with decompensated cirrhosis and in patients with hepatitis C after liver transplantation and after kidney transplantation. Initially, sofosbuvir-ledipasvir was not recommended in patients with advanced renal failure; however, subsequently, the safety and efficacy of sofosbuvir-ledipasvir in patients with advanced renal failure were established, and the DAA was approved for this indication (November 2019). All sofosbuvir-containing regimens can be associated with severe bradycardia in patients taking the antiarrhythmic agent amiodarone, especially along with beta blockers; sofosbuvir-containing combinations are contraindicated with amiodarone. Drug-drug interactions are few, but P-glycoprotein inducers, such as St. John's wort and rifampin, and proton pump gastric acid inhibitors, such as omeprazole, may reduce sofosbuvir-ledipasvir concentrations. Generally, responsiveness to sofosbuvir-ledipasvir is not reduced in patients with baseline RASs to these agents, with the exception of treatment-experienced patients who have baseline NS5A RASs (see Table 341-6).

Paritaprevir-ritonavir, ombitasvir, and dasabuvir: The combination of ritonavir (100 mg)–boosted paritaprevir (150 mg), a protease inhibitor; ombitasvir (25 mg), an NS5A inhibitor; and dasabuvir (250 mg), a nonnucleoside polymerase inhibitor, with or without weight-based ribavirin (total of five drugs), was approved in December 2014 for genotypes 1 and 4. Paritaprevir-ritonavir and ombitasvir, formulated in a single tablet, are taken once daily, and both dasabuvir (a separate pill) and weight-based ribavirin (when included in the regimen) are taken twice daily. In clinical trials, this combination achieved SVR_{12} rates of 87–100% in treatment-naïve and treatment-experienced patients with genotype 1; without ribavirin, this combination in genotype 1a was ~7% less responsive than in genotype 1b. Therefore, in treatment-naïve patients with genotype 1a, this combination was administered *with* ribavirin for 12 weeks in the absence of cirrhosis (95–97% SVR_{12}) or for 24 weeks in the presence of compensated cirrhosis (94% SVR_{12}), whereas in patients with genotype 1b, the combination did not require ribavirin, and the duration of therapy was 12 weeks for both noncirrhotics and cirrhotics (99–100% SVR_{12}). In prior nonresponders without cirrhosis, the combination was administered for 12 weeks, *with* ribavirin in genotype 1a (96% SVR_{12}) and *without* ribavirin in genotype 1b (100% SVR_{12}). In prior nonresponders with cirrhosis, the combination was administered for 24 weeks *with* ribavirin in genotype 1a (SVR_{12} 100% in prior relapsers and partial responders, 95% in prior null responders [in whom treatment without ribavirin was associated with an 80% SVR_{12}]), but only for 12 weeks and *without* ribavirin in genotype 1b (100% SVR_{12}). For genotype 4, the regimen was given for 12 weeks with ribavirin but without dasabuvir in treatment-naïve and treatment-experienced patients (100% SVR_{12}), including those with compensated cirrhosis. In July 2016, the FDA approved a long-acting formulation of dasabuvir, allowing once-a-day instead of twice-a-day treatment; for genotype 1a, twice-daily ribavirin dosing remained.

This combination was well tolerated with generally mild side effects, for example, fatigue, asthenia, insomnia, headache, and pruritus. Hyperbilirubinemia (primarily unconjugated) and elevations in alanine aminotransferase activity could occur but resolved during or shortly after treatment. Because of occasional hyperbilirubinemia and potential hepatotoxicity (FDA warning letter issued October 2015 regarding hepatic failure/decompensation reported in treated cirrhotic patients), this combination (and all subsequently introduced protease-inhibitor-containing combinations) was contraindicated in patients with decompensated cirrhosis, and treated cirrhotic patients had be monitored closely for decompensation; however, the safety and efficacy of this combination was demonstrated for patients with advanced renal insufficiency. Similar to other regimens containing protease inhibitors, drug-drug interactions are common with other drugs that induce CYP3A4 or are dependent on CYP3A4 for elimination. Checking for potential drug-drug interactions was important prior to initiating therapy with this drug combination (*www.hep-druginteractions.org*). Responsiveness to this multidrug regimen was not reduced in patients with baseline RASs to these agents.

Compared to sofosbuvir-ledipasvir, this regimen had the disadvantage of requiring twice-a-day ribavirin therapy for genotype 1a and of being contraindicated in decompensated cirrhosis; however, it had the advantage of offering a 12-week, ribavirin-free regimen for prior null responders with cirrhosis and providing an option for patients with renal failure. Based on regimen simplicity and superiority, subsequent-generation, ribavirin-free combination DAAs have supplanted paritaprevir-ritonavir, ombitasvir, and dasabuvir; this regimen is no longer recommended at all by the AASLD; however, it is retained in EASL recommendations as an alternative regimen for genotype 1b only.

Sofosbuvir and daclatasvir: Daclatasvir, an NS5A inhibitor, along with the polymerase inhibitor sofosbuvir, was approved by the FDA in July 2015 for genotype 3 and in February 2016 for genotype 1. At the time of its approval for genotype 3, daclatasvir filled a need inadequately met by other available combination DAAs; however, eventually, recommendation of this combination regimen was extended to genotypes 1–4 in the United States and to all genotypes (1–6) in Europe. Daclatasvir, a 60-mg tablet, and sofosbuvir, a separate 400-mg tablet, were taken once a day for 12–24 weeks.

In clinical trials among treatment-naïve or treatment-experienced patients, SVR_{12} rates for 12 weeks of daclatasvir plus sofosbuvir were 98% for genotype 1 (comparable results in genotypes 1a and 1b),

92% for genotype 2, and 89% for genotype 3. For noncirrhotic patients, the addition of ribavirin or the extension of therapy to 24 weeks did not improve efficacy. In patients with compensated cirrhosis, limited prospective data and data from observational cohorts suggested that extending therapy to 24 weeks, with or without ribavirin, improved efficacy. In cirrhotics, SVR_{12} was achieved in 93% with Child-Pugh class A and B but in only 56% with class C decompensated cirrhosis. For patients with genotype 3 and cirrhosis, the combination was effective in treatment-naïve patients (94% SVR_{12}) but less so in prior nonresponders (69% SVR_{12}). Outcomes in patients with HIV-HCV co-infection were comparable.

Like other sofosbuvir–NS5A inhibitor combinations, daclatasvir plus sofosbuvir was well tolerated (mild fatigue, headache, nausea, or diarrhea in 5–14%) but could cause severe bradycardia when administered with amiodarone (contraindicated), especially along with beta blockers. Because daclatasvir is a substrate for CYP3A, CYP3A inducers can reduce daclatasvir levels, and CYP3A inhibitors reduce daclatasvir levels. Similarly, daclatasvir, an inhibitor of P-glycoprotein, OATP1B1 and OATP1B3, and breast cancer resistance protein (BCRP), can increase the levels of drugs that are substrates of these transporters. Responsiveness to daclatasvir-containing drug combination therapy was reduced in cirrhotic patients with genotype 1a and in both cirrhotic and noncirrhotic patients with genotype 3 who had baseline daclatasvir-associated NS5A RASs.

As new combination DAAs were introduced, however, daclatasvir-sofosbuvir was less competitive and no longer filled a niche; it has been supplanted by better, later-generation combination DAAs and is no longer recommended.

DIRECT-ACTING ANTIVIRAL COMBINATIONS OF THIRD-GENERATION PROTEASE INHIBITORS AND SECOND-GENERATION NS5A INHIBITORS (2016)

Elbasvir-grazoprevir: Elbasvir (50 mg), an NS5A inhibitor, combined in a single, fixed-dose pill with grazoprevir (100 mg), an NS3/4 protease inhibitor, was approved in January 2016 as a once-a-day (with or without food) treatment for genotypes 1 and 4. In clinical trials, a 12-week course was effective in treatment-naïve and treatment-experienced patients without cirrhosis or with compensated cirrhosis. In treatment-naïve patients, this combination yielded an SVR_{12} in 92% of patients with genotype 1a, 99% with genotype 1b, and 100% with genotype 4 (very small numbers, however); 10 patients with genotype 6 were included, but only 80% achieved SVR_{12}. Cirrhotic and noncirrhotic patients had comparable rates of SVR_{12}, 97% and 94%, respectively. For this drug combination, however, ~11% of patients with genotype 1a harbor NS5A polymorphisms, that is, RASs, at baseline. If present, these NS5A RASs reduce efficacy of elbasvir-grazoprevir (unlike baseline RASs to most of the other combination DAA regimens described above and below) from 99 to 58% in treatment-naïve patients. Therefore, all patients with genotype 1a require baseline RAS testing; when these RASs were present, treatment extension to 16 weeks and the addition of weight-based ribavirin were documented to bring SVR_{12} rates up to expected levels of close to 100%. In treatment-experienced patients, both extending treatment to 16 weeks and adding ribavirin were studied; however, generally, in the absence of baseline NS5A RASs, SVR_{12} rates were not increased over those without ribavirin for 12 weeks (94–97%). For genotype 1a, among prior nonresponders to PEG IFN–ribavirin, 12 weeks of elbasvir-grazoprevir sufficed without ribavirin except for patients with baseline NS5A RASs, who required 16 weeks of therapy and ribavirin. Among nonresponders to prior protease inhibitor therapy, even in the absence of baseline NS5A RASs, ribavirin had to be added to a 12-week regimen; in the presence of baseline NS5A RASs, treatment was extended to 16 weeks and ribavirin added. For genotype 1b, NS5A RASs are not an issue, and the only subgroup requiring modification of a 12-week course of therapy were prior nonresponders to protease inhibitor regimens, for whom ribavirin was added. For genotype 4, the recommended regimen for all prior nonresponders (whether to PEG IFN–ribavirin or protease inhibitor regimens) was 16 weeks of elbasvir-grazoprevir plus ribavirin. Now that simpler, improved combination regimens are available, for patients with NS5A RASs, extending the duration of elbasvir-grazoprevir and adding ribavirin have been abandoned (Table 341-6); however, *elbasvir-grazoprevir is one of the currently recommended DAA combinations* (Table 341-6).

This combination is just as effective in patients with HIV-HCV co-infection and in patients with advanced renal failure (including those requiring hemodialysis), but like all protease-inhibitor-including DAA combinations, it is contraindicated in decompensated cirrhosis. In this vein, like other protease inhibitor regimens, elbasvir-grazoprevir can be associated with aminotransferase elevations and potential hepatotoxicity; because these drugs are excreted by the liver, plasma drug concentrations may become elevated substantially in the presence of impaired hepatic function. Therefore, all treated patients should have ALT screening periodically during therapy, and the drug should be stopped for elevations exceeding tenfold or for elevations of conjugated bilirubin, alkaline phosphatase, or prothrombin time.

Elbasvir-grazoprevir is well tolerated, with only low levels of mild adverse effects (fatigue, headache, or nausea in 5–11%) seen just as frequently in placebo recipients. Both elbasvir and grazoprevir are substrates for CYP3A and are subject to multiple potential drug-drug interactions. Therefore, this combination should not be used with potent CYP3A inducers; conversely, CYP3A and OATP1B1 inhibitors can lead to untoward elevations of plasma elbasvir-grazoprevir concentrations. Checking for potential drug-drug interactions is advisable prior to initiating therapy (*www.hep-druginteractions.org*).

Compared to other available regimens for genotypes 1 and 4, elbasvir-grazoprevir has the disadvantage/inconvenience of requiring baseline NS5A RAS testing but the advantages of a comparable regimen for cirrhotics and noncirrhotics, for treatment-naïve and treatment-experienced patients, and for patients with normal renal function and with renal failure.

Sofosbuvir-velpatasvir: The combination in a single, fixed-dose pill of velpatasvir (100 mg), a highly potent, pangenotypic NS5A inhibitor, and the polymerase inhibitor sofosbuvir (400 mg) was approved in June 2016 for genotypes 1–6 in treatment-naïve and treatment-experienced noncirrhotics and cirrhotics. In August 2017, approval was extended to include patients with HCV-HIV co-infection. Ribavirin is not required, including in patients with genotypes 2 and 3, except in patients with decompensated cirrhosis.

In a series of clinical trials, this combination for 12 weeks in the absence of ribavirin was shown to yield a 99% SVR_{12} (range 97–100%) in genotypes 1, 2, 4, 5, and 6 and 95% in genotype 3. Baseline NS5A RASs had no impact on responsiveness.

Prior to the availability of this drug combination, patients with genotype 3, especially those with cirrhosis and prior null response to other therapies, proved to be the most refractory subset of patients. In treatment-naïve patients with genotype 3, 12 weeks of sofosbuvir-velpatasvir (95% SVR_{12}) was superior to 24 weeks of sofosbuvir plus ribavirin (80% SVR_{12}). In patients with genotype 3, the combination of sofosbuvir-velpatasvir for 12 weeks was comparable in noncirrhotics (97% SVR_{12}) and cirrhotics (91% SVR_{12}) and in treatment-naïve (97% SVR_{12}) and treatment-experienced (90% SVR_{12}) patients and was superior in all these categories to 24 weeks of sofosbuvir plus ribavirin (87%, 66%, 86%, and 63%, respectively). In cirrhotic null responders, most available IFN-free regimens for genotype 3 (including daclatasvir plus sofosbuvir, which had been approved specifically for this genotype) achieved SVR_{12} rates in the range of ~60–75%, while the combination of PEG IFN, ribavirin, and sofosbuvir could boost SVR_{12} to the mid-80% range. For treatment-experienced patients with genotype 3, sofosbuvir-velpatasvir in noncirrhotics and cirrhotics had similarly high efficacy (91% and 89% SVR_{12}, respectively); this was the highest recorded SVR_{12} for genotype 3 cirrhotic null responders treated with IFN-free DAA regimens. Finally, in patients with

genotypes 1–4 and 6 and with decompensated, class B cirrhosis (55% treatment-experienced), sofosbuvir-velpatasvir plus ribavirin for 12 weeks yielded an SVR_{12} in 94%; this result was better than sofosbuvir-velpatasvir without ribavirin for 12 weeks (83% SVR_{12}) or 24 weeks (86% SVR_{12}).

Like other all-oral DAAs, sofosbuvir-velpatasvir was very well tolerated; in noncirrhotic and compensated cirrhotic patients, mild headache and fatigue were seen in >10% (this occurred in a comparable proportion of placebo recipients), and in patients with decompensated cirrhosis, mild fatigue, headache, nausea, insomnia, diarrhea, and anemia (ribavirin was part of the regimen) were seen in >10%. Like other sofosbuvir-containing regimens, sofosbuvir-velpatasvir should not be administered along with amiodarone (potential serious bradycardia); in addition, P-glycoprotein inducers and moderate-to-potent CYP3A inducers can reduce plasma levels of sofosbuvir and/or velpatasvir. Checking for drug-drug interactions prior to therapy is advisable (*www.hep-druginteractions.org*). Baseline RASs do not influence responsiveness to this combination. Sofosbuvir-velpatasvir is one of the currently recommended DAA combinations for hepatitis C (Table 341-6). *Because it is so simple and broadly effective across patient subgroups, sofosbuvir-velpatasvir is one of the two combination DAA regimens recommended by the AASLD and EASL as a preferred, simplified treatment algorithm* (Table 341-6).

DIRECT-ACTING ANTIVIRAL COMBINATIONS OF THIRD-GENERATION NS5A INHIBITORS AND FOURTH-GENERATION PROTEASE INHIBITORS—CURRENT STANDARD OF CARE (SINCE 2017)

Sofosbuvir-velpatasvir-voxilaprevir: Approved in July 2017, the pangenotypic, high-barrier-to-resistance protease inhibitor voxilaprevir (100 mg) added to the polymerase inhibitor–NS5A inhibitor combination of sofosbuvir-velpatasvir yields a very well-tolerated *triple-drug* combination with ~97% SVR_{12} across all HCV genotypes and patient subgroups. These include the small percentage of patients with genotype 1 and genotype 3 refractory to previously approved DAA combinations as well as noncirrhotic/cirrhotic, treatment-naïve/treatment-experienced groups, including those who had or who had not received prior NS5A treatment. Efficacy was independent of the number of prior DAA drug classes received, and no effects of baseline NS5A RASs were noted.

The potential for abbreviated (8-week) treatment with this triple combination was explored in a clinical trial involving treatment-naïve patients; however, the shortened duration was inferior to a full 12-week course. The side effect profile for sofosbuvir-velpatasvir-voxilaprevir was similar to that in the placebo arm of clinical trial patients and included mild and uncommon headache, fatigue, nausea, and diarrhea.

Because other DAA regimens are so effective in most patients with chronic hepatitis C, recommendations for sofosbuvir-velpatasvir-voxilaprevir are limited to a small subset of otherwise refractory patients: for treatment-naïve cirrhotic patients with genotype 3 and baseline NS5A velpatasvir RAS Y93H, for treatment-naïve (according to AASLD, not EASL) or IFN-ribavirin–experienced noncirrhotic or cirrhosis patients with genotype 3 (Table 341-6), and for patients with or without compensated cirrhosis and prior, failed NS5A inhibitor–containing therapy (consult *www.hcvguidelines.org*).

This triple-drug combination, like all sofosbuvir-containing combinations, is contraindicated in patients taking amiodarone and, like all protease inhibitor-containing combinations, in patients with decompensated cirrhosis. Concomitant omeprazole, 20 mg, can be taken with this sofosbuvir-containing regimen. Prior to initiating therapy, checking for drug-drug interactions is recommended.

Glecaprevir-pibrentasvir: A regimen of 8 weeks of this single-pill, fixed-dose combination of the protease inhibitor glecaprevir (300 mg) and NS5A inhibitor pibrentasvir (120 mg), two pangenotypic, high-potency DAAs with high barriers to resistance (approved in August 2017), achieves SVR_{12} in close to 100% of treatment-naïve patients with all genotypes, with or without cirrhosis: SVR_{12} of ~99% for genotypes 1, 2, and 4–6 and of 95–98% for genotype 3. Extended treatment for 12 weeks did not increase efficacy. In trials among treatment-experienced patients, treatment with 12 weeks of this DAA combination was just as effective as 16 weeks for all genotypes except genotype 3; however, with increasing numbers of prior treatment courses, SVR_{12} rates fell—100% for patients treated with a protease inhibitor only, 88% for patients treated with an NS5A inhibitor only, and 79% for patients treated previously with both a protease inhibitor and an NS5A inhibitor. Similarly, baseline RASs reduced SVR_{12} rates—from 100% without RASs (or with RASs limited to those reflecting protease inhibitor resistance) to 89% for baseline NS5A RASs.

For retreatment of patients with prior glecaprevir-pibrentasvir failure, 16 weeks of glecaprevir-pibrentasvir plus sofosbuvir are recommended (alternatively, sofosbuvir-velpatasvir-voxilaprevir for 12 weeks [+ ribavirin in cirrhotics]). Glecaprevir-pibrentasvir for 16 weeks is recommended as well after failure to respond to the triple-drug combination of sofosbuvir-velpatasvir-voxilaprevir (see below). For retreatment of patients with sofosbuvir-velpatasvir-voxilaprevir failure, 16 weeks of glecaprevir-pibrentasvir plus ribavirin is recommended, as is a repeat course of sofosbuvir-velpatasvir-voxilaprevir plus ribavirin for 24 weeks.

As is the case for any DAA combination containing a protease inhibitor, glecaprevir-pibrentasvir is contraindicated in decompensated cirrhosis; it has been shown to achieve an SVR_{12} in 98% of patients with stage 4 or 5 renal disease (in treatment-naïve or experienced, cirrhotic or noncirrhotic patients) and is a preferred treatment for patients with severe renal impairment. This DAA combination should be taken with food, and drug-drug interactions should be considered prior to initiating treatment. *Because it is so simple and broadly effective across patient subgroups (8 weeks for all noncirrhotic treatment-naïve patients except patients with HIV co-infection [12 weeks]; 12 weeks for all treatment-experienced cirrhotics and treatment-naïve cirrhotics with genotype 3 [except treatment-experienced cirrhotic or noncirrhotic genotype 3 (16 weeks)]), glecaprevir-pibrentasvir is one of the two combination DAA regimens recommended by the AASLD and EASL as a preferred, simplified treatment algorithm* (Table 341-6).

Emerging data on the impact of DAAs on the natural history of chronic hepatitis C indicated that, as was documented for IFN-based therapy, successful DAA therapy is associated with a gradual reduction in fibrosis progression and a regression of advanced fibrosis (cirrhosis), improvement in survival among patients with decompensated cirrhosis, a reduction in HCC, and a decline in the number of patients with hepatitis C being referred for liver transplantation. Early observations purported to show an *increase* in HCC after a DAA-associated SVR for chronic hepatitis C. On the contrary, HCC rates are reduced dramatically and consistently after successful DAA therapy. Ultimately, the initial observation was attributed to a cohort bias resulting from the application of simple-to-use DAA therapy to an older and sicker population with more advanced chronic hepatitis C (including decompensated cirrhosis); this cohort effect explains why the *baseline* risk for HCC was higher in DAA-treated patients than it had been when IFN-based therapy was withheld from such patients. Thus, the increased risk in HCC cases was not linked to DAA treatment but to more advanced liver disease at baseline in patients treated with DAAs. The reports of HCC after DAA therapy drive home the residual HCC risk after SVR in patients with cirrhosis (advanced hepatic fibrosis) treated either in the IFN or DAA era; therefore, continued HCC surveillance after therapy is recommended for anyone with baseline advanced fibrosis prior to therapy.

Based on the known prevalence, natural history, and rate of progression of chronic hepatitis C and on the efficacy of DAA therapies and their impact on the complications of hepatitis C, modeling estimates have suggested that the availability and application of these therapies have the potential to reduce the hepatitis C–associated disease burden, including liver-related death, HCC, decompensated cirrhosis, and liver transplantation, by 50–70% between 2015 and 2050.

TREATMENT RECOMMENDATIONS

Because the pace of new drug development and approval has been so rapid, the AASLD and the Infectious Diseases Society of America (IDSA) have been providing a consensus of updated treatment recommendations for patients with hepatitis C; these recommendations, which continue to be revised regularly based on new data, are available online at *www.hcvguidelines.org* and should be consulted before initiating therapy (Table 341-6). The EASL issues similar (but not identical) treatment recommendations annually for hepatitis C (*www.easl.eu*), most recently in November 2020. Divergences between AASLD-IDSA and EASL recommendations are noted in Table 341-6.

Prior to therapy, HCV genotype should be determined, because the genotype contributes to decisions about which treatment regimens are indicated (Table 341-6). Monitoring of serum HCV RNA levels before, during, and after treatment is crucial in assessing response to therapy; moreover, the baseline level may contribute to determining the duration of therapy (e.g., in noncirrhotic patients with genotype 1 and HCV RNA $<6 \times 10^6$ IU/mL, 8 [instead of the usual 12] weeks of sofosbuvir-ledipasvir may be a consideration). The goal of treatment is to eradicate HCV RNA during therapy and to document that the virus remains undetectable for at least 12 weeks after completion of therapy (SVR_{12}). Several reports have appeared describing hepatitis B reactivation, often severe, during and after DAA therapy in patients co-infected with HCV and HBV who were not being treated for their HBV infections. Therefore, screening for HBV infection is recommended prior to initiating DAA therapy for hepatitis C (which should have been done to determine HBV immunity status as a prelude to recommended hepatitis B vaccination in patients with chronic hepatitis C), and therapy for HBV infection (for those meeting HBV treatment criteria, see above) should be initiated prior to or simultaneously with HCV therapy.

Because of their high efficacy and pangenotypic range, two DAA regimens, glecaprevir-pibrentasvir (8 weeks) and sofosbuvir-velpatasvir (12 weeks), are recommended as simplified treatment algorithms that can be prescribed for all treatment-naïve patients with or without cirrhosis (Table 341-6).

INDICATIONS FOR ANTIVIRAL THERAPY

Patients with chronic hepatitis C who have detectable HCV RNA in serum, whether or not aminotransferase levels are increased, and chronic hepatitis of any grade and stage are candidates for antiviral therapy with DAA agents. The only exception would be patients with short life expectancies, for whom treating hepatitis C would have no influence on longevity. Certainly, for patients with advanced liver disease, early treatment merits a high priority. Although patients with persistently normal aminotransferase activity tend to progress histologically very slowly or not at all, they respond to antiviral therapy just as well as do patients with elevated aminotransferase levels; therefore, such patients are candidates for antiviral therapy. As noted above, antiviral therapy has been shown to improve survival and complication-free survival and to slow progression of and to reverse fibrosis.

HCV genotype determines the regimen to be selected (Table 341-6). Similarly, the absence or presence of cirrhosis or advanced fibrosis determines the treatment options from which to select, including the antiviral agents to be used, the duration of therapy, and the now rare need for ribavirin (Table 341-6). In the past, a pretreatment liver biopsy was relied upon to assess histologic grade and stage as well as to identify such histologic factors as steatosis, which can influence responsiveness to therapy. As therapy has improved for patients with a broad range of histologic severity and as noninvasive measures of the stage of fibrosis (e.g., assessment of liver elasticity by imaging, FIB-4 score [see above]) have gained in accuracy and popularity, noninvasive approaches have supplanted histology in almost most cases. As noted above, if cirrhosis or advanced fibrosis is present prior to therapy, the risk of HCC, although reduced substantially by successful therapy, is not eliminated, and twice-yearly posttreatment imaging for HCC surveillance (and endoscopic surveillance for esophageal varices at intervals of 1–3 years) is indicated even after an SVR. In patients with low-level fibrosis at baseline, achievement of an SVR allows the cessation of such surveillance.

Patients who have relapsed after, or failed to respond to, a course of IFN-based or DAA agent–based therapy are candidates for retreatment with a DAA therapy regimen (Table 341-6). For patients who have failed to respond to a DAA combination, options include increasing the duration of therapy with the failed regimen, adding ribavirin, or changing the drug class (e.g., after failed protease and polymerase inhibitors, switching to an NS5A-containing combination). In the presence of cirrhosis or a need for urgent retreatment, patients who have failed protease inhibitor plus polymerase inhibitor combination therapy or who have failed an NS5A combination are candidates for RAS testing and tailored therapy based on such resistance testing. If reliable RAS testing is not available, adding ribavirin or extending the duration of therapy are options. For prior nonresponders to IFN-based therapy, NS5A inhibitor–containing regimens are highly effective; however, reduced responsiveness can be encountered, especially in cirrhotic patients. For this relatively refractory group, ideally, the most potent or effective NS5A regimen should be selected to give such patients the best chance of responding and to avoid treatment-emergent NS5A RASs. Noted above (see discussion of sofosbuvir-velpatasvir-voxilaprevir and of glecaprevir-pibrentasvir) are potential retreatment approaches after failure of a prior NS5A-containing regimen. Additional details for treatment of such patient subgroups can be found at *www.hcvguidelines.org*. It is worth reiterating that protease inhibitors are contraindicated for patients with decompensated cirrhosis, and sofosbuvir-containing regimens are not recommended for patients taking amiodarone (especially with beta blockers) for treatment of cardiac arrhythmias. While sofosbuvir-containing DAA combinations were not recommended initially for patients with advanced renal failure, subsequent studies demonstrated safety and efficacy in this subgroup, and sofosbuvir-containing DAA combinations are now approved for advanced renal failure.

Persons with acute hepatitis C are also candidates for antiviral therapy **(Chap. 339)** with the same pangenotypic combination DAA agents (and the same duration of treatment) approved for chronic hepatitis C; delaying the initiation of therapy to allow for spontaneous recovery is no longer recommended. According to EASL recommendations, patients with acute hepatitis C should be treated ideally with a currently recommended 8-week DAA regimen. In patients with biochemically and histologically mild chronic hepatitis C, the rate of progression is slow; however, such patients respond just as well to antiviral therapy as those with elevated aminotransferase levels and more histologically severe hepatitis. Because of the high cost of DAA treatments, in the past, a higher priority was assigned to patients with advanced fibrosis/cirrhosis; however, this controversial approach was relied upon by some medical insurers and pharmacy benefit management organizations to withhold therapy from patients with low-level fibrosis. Unfortunately, delaying therapy until fibrosis becomes advanced misses the opportunity to prevent all the dire consequences of chronic hepatitis C (liver failure, death/transplantation, HCC), which can be reduced, but not eliminated completely, once advanced fibrosis is established. Therefore, therapy for patients with mild disease is justified as well as cost-effective.

Patients with compensated cirrhosis can respond to therapy, and their likelihood of a sustained response with DAAs is comparable to that in noncirrhotics. Patients with decompensated cirrhosis, who were not candidates for IFN-based antiviral therapy, respond well to DAA therapy regimens consisting of combinations of polymerase inhibitors and NS5A inhibitors (e.g., sofosbuvir-ledipasvir, sofosbuvir-velpatasvir); however, protease-inhibitor-containing combinations have been associated with potential hepatotoxicity and hepatic decompensation and, as noted above, are contraindicated in this patient subset. For decompensated cirrhosis, ribavirin should be

added to a 12-week course of sofosbuvir-NS5A therapy; however, in cases of ribavirin ineligibility, the duration of therapy should be extended to 24 weeks. In cases of prior failure to respond to sofosbuvir-NS5A therapy, the sofosbuvir-NS5A regimen should be repeated but supplemented with ribavirin and extended to 24 weeks (*www.hcvguidelines.org*). Patients with decompensated cirrhosis should be referred to a liver transplantation center. DAAs are highly effective not only for patients with end-stage liver disease awaiting liver transplantation but also for patients with recurrent hepatitis C after liver transplantation. Ideally, patients should be treated prior to liver transplantation; however, a concern is that eradication of HCV infection will disqualify such patients from accepting donor livers from persons with HCV infection, thus contracting the potential donor pool and limiting accessibility to donor organs and timely transplantation. In addition, responsiveness to DAA therapy appears to be reduced in patients with decompensated cirrhosis and with high Model for End-Stage Liver Disease (MELD) scores; in this subgroup, responsiveness after liver transplantation would be substantially better. Therefore, advocacy has been expressed for postponing DAA therapy in patients with high-MELD-score (≥18–20), HCV-associated, end-stage liver disease until after liver transplantation; for patients with MELD scores <18–20, pretransplantation DAA therapy is advised. Still, the decision whether to treat pretransplantation or posttransplantation should be individualized thoughtfully for each patient, based on such factors as MELD score, time anticipated prior to availability of a donor organ, relative clinical stability, and comorbidities **(Chap. 345)**. Because DAA therapy is so effective, many transplantation centers, to expand the donor pool, are accepting organs from HCV-infected donors, transplanting them into HCV-uninfected recipients, and treating recipients with sofosbuvir-velpatasvir for 12 weeks or glecaprevir-pibrentasvir for 8 weeks after transplantation—with excellent results.

The cutaneous and renal vasculitis of HCV-associated essential mixed cryoglobulinemia **(Chap. 339)** may respond to antiviral therapy, but sustained responses were rare after discontinuation of therapy in the IFN era, and prolonged, potentially indefinite, therapy was recommended. Now that more effective DAAs are available, a 12-week course of sofosbuvir-based combination therapy has been shown to yield an SVR_{12} rate exceeding 80% in cryoglobulinemic vasculitis. Anecdotal reports suggest that IFN-based antiviral therapy may be effective in porphyria cutanea tarda or lichen planus associated with hepatitis C; whether the more appealing DAAs are effective in these groups remains to be documented.

In patients with HCV/HIV co-infection, hepatitis C is more progressive and severe than in HCV-monoinfected patients. Although patients with HCV/HIV co-infection responded less well to IFN-based antiviral therapy for hepatitis C, they respond as well as patients with HCV infection alone to DAA combination regimens. For patients with HCV/HIV co-infection, an abbreviated, 8-week course of sofosbuvir-ledipasvir for low-level HCV RNA is not recommended, and a full 12 weeks should be given; similarly, for patients with genotype 4, a 12-week course of glecaprevir-pibrentasvir is recommended instead of an 8-week course for treatment-naïve or -experienced patients with or without cirrhosis (Table 341-6). In HCV/HIV-infected patients, ribavirin can potentiate the toxicity of didanosine (e.g., lactic acidosis) and the lipoatrophy of stavudine, and zidovudine can exacerbate ribavirin-associated hemolytic anemia; therefore, these drug combinations should be avoided. In HCV/HIV co-infected persons, the list of potential drug-drug interactions is extensive and should be consulted carefully before beginning DAA treatment (*www.hcvguidelines.org*).

Patients with a history of injection drug use and alcoholism can be treated successfully for chronic hepatitis C, preferably in conjunction with drug and alcohol treatment programs. Moreover, because injection drug users, as a source of transmission to others, account disproportionately for perpetuating the spread of HCV infection in the population, the impact of treating active injection drug users is amplified by reducing such transmission.

The approved oral DAA combinations are effective in patients with mild-modest renal failure and require no dose adjustments. For patients with severe renal impairment (creatinine clearances <30 mL/min), including those undergoing hemodialysis, recommended combinations are 12 weeks of elbasvir-grazoprevir for genotypes 1 and 4 or 12 weeks of glecaprevir-pibrentasvir for all genotypes. Both in severe renal impairment and after renal transplantation, levels of SVR_{12} in patients treated with these oral DAA combinations have approached 100%. Initially, in patients with severe renal impairment, sofosbuvir-containing combinations were not recommended. Subsequently, however, based on efficacy and safety in a series of clinical trials, sofosbuvir-containing regimens were approved by the FDA in November 2019 for patients with severe renal impairment.

No clinical studies of the use of DAAs during pregnancy are available. Ribavirin is contraindicated during pregnancy; therefore, any regimen including ribavirin should not be used. Sofosbuvir; sofosbuvir-ledipasvir; and paritaprevir-ritonavir, ombitasvir, and dasabuvir are classified as pregnancy category B; the other DAAs do not have a pregnancy classification. Therefore, these therapies are not indicated routinely in pregnancy and should be used, with caution, only if the benefit of treatment is compelling and justified compared to the potential for fetal risk. Currently, screening all pregnant women for HCV infection is recommended. Breast feeding is not contraindicated in women with HCV infection (unless the mother has a break in the integrity of the nipples or is co-infected with HIV).

Choosing Among Available Treatment Options Choosing among the number of all-oral DAA combinations approved since 2013 was daunting to treating clinicians. Currently, however, the number of recommended DAA combinations has narrowed to a very manageable few. The most popular of the regimens have been fixed-dose, single-pill, pangenotypic combinations. Although sofosbuvir-ledipasvir and elbasvir-grazoprevir are among the recommended DAA combinations (Table 341-6), for simplicity, two "one-size-fits-all" pangenotypic regimens—sofosbuvir-velpatasvir and glecaprevir-pibrentasvir—can be used, for 8–12 weeks, mostly without ribavirin, in almost all treatment-naïve, noncirrhotic and cirrhotic patients, including those with advanced renal failure and HCV-HIV co-infection. Applicability of the triple-drug combination sofosbuvir-velpatasvir-voxilaprevir is quite limited in treatment-naïve patients, reserved primarily for cirrhotic patients with genotype 3. As noted above, protease-inhibitor-containing DAA regimens (elbasvir-grazoprevir, glecaprevir-pibrentasvir, and sofosbuvir-velpatasvir-voxilaprevir) are contraindicated in decompensated cirrhosis.

AUTOIMMUNE HEPATITIS

DEFINITION

Autoimmune hepatitis is a chronic disorder characterized by continuing hepatocellular necrosis and inflammation, usually with fibrosis, which can progress to cirrhosis and liver failure. When fulfilling criteria of severity, this type of chronic hepatitis, when untreated, may have a 6-month mortality of as high as 40%. Based on contemporary estimates of the natural history of autoimmune hepatitis, the 10-year survival is 80–98% for treated and 67% for untreated patients. The prominence of extrahepatic features of autoimmunity and seroimmunologic abnormalities in this disorder supports an autoimmune process in its pathogenesis; this concept is reflected in the prior labels *lupoid* and *plasma cell hepatitis*. Autoantibodies and other typical features of autoimmunity, however, do not occur in all cases; among the broader categories of "idiopathic" or cryptogenic chronic hepatitis, many, perhaps the majority, are probably autoimmune in origin. Cases in which hepatotropic viruses, metabolic/genetic derangements (including nonalcoholic fatty liver disease), and hepatotoxic drugs have been excluded represent a spectrum of heterogeneous liver disorders of unknown cause, a proportion of which are most likely autoimmune hepatitis.

IMMUNOPATHOGENESIS

The weight of evidence suggests that the progressive liver injury in patients with autoimmune hepatitis is the result of a cell-mediated immunologic attack directed against liver cells in the setting of a loss of, or failed, immunologic tolerance for self-liver antigens. In all likelihood, predisposition to autoimmunity is inherited, whereas the liver specificity of this injury is triggered by environmental (e.g., chemical, drug [e.g., minocycline], or viral) factors. For example, patients have been described in whom apparently self-limited cases of acute hepatitis A, B, or C led to autoimmune hepatitis, presumably because of genetic susceptibility or predisposition. Evidence to support an autoimmune pathogenesis in this type of hepatitis includes the following: (1) in the liver, the histopathologic lesions are composed predominantly of cytotoxic T cells and plasma cells; (2) circulating autoantibodies (nuclear, smooth muscle, thyroid, etc.; see below), rheumatoid factor, and hyperglobulinemia are common; (3) other autoimmune disorders—such as autoimmune thyroiditis, rheumatoid arthritis, autoimmune hemolytic anemia, ulcerative colitis, membranoproliferative glomerulonephritis, juvenile diabetes mellitus, vitiligo, celiac disease, and Sjögren's syndrome—occur with increased frequency in patients who have autoimmune hepatitis and in their relatives; (4) histocompatibility haplotypes associated with autoimmune diseases, such as HLA-B1, B8, DR3, and DR4 as well as extended haplotype *DRB1*0301* and *DRB1*0401* alleles, are common in patients with autoimmune hepatitis; and (5) this type of chronic hepatitis is responsive to glucocorticoid/immunosuppressive therapy, effective in a variety of autoimmune disorders.

Cellular immune mechanisms appear to be important in the pathogenesis of autoimmune hepatitis. In vitro studies have suggested that in patients with this disorder, CD4+ T lymphocytes are capable of becoming sensitized to hepatocyte membrane proteins and of destroying liver cells. Molecular mimicry by cross-reacting antigens that contain epitopes similar to liver antigens is postulated to activate these T cells, which infiltrate, and result in injury to, the liver. Abnormalities of immunoregulatory control over cytotoxic lymphocytes (impaired regulatory CD4+CD25+ T-cell influences) may play a role as well. Studies of genetic predisposition to autoimmune hepatitis demonstrate that certain haplotypes are associated with the disorder, as enumerated above, as are polymorphisms in cytotoxic T lymphocyte antigens (*CTLA-4*) and tumor necrosis factor α (*TNFA*2*). The precise triggering factors, genetic influences, and cytotoxic and immunoregulatory mechanisms involved in this type of liver injury remain incompletely defined.

Intriguing clues into the pathogenesis of autoimmune hepatitis come from the observation that circulating autoantibodies are prevalent in patients with this disorder. Among the autoantibodies described in these patients are antibodies to nuclei (so-called antinuclear antibodies [ANAs], primarily in a homogeneous pattern) and smooth muscle (so-called anti-smooth-muscle antibodies, directed at actin, vimentin, and skeletin), antibodies to F-actin, anti-LKM (see below), antibodies to "soluble liver antigen" (directed against a uracil-guanine-adenine transfer RNA suppressor protein), antibodies to α-actinin, and antibodies to the liver-specific asialoglycoprotein receptor (or "hepatic lectin") and other hepatocyte membrane proteins. Although some of these provide helpful diagnostic markers, their involvement in the pathogenesis of autoimmune hepatitis has not been established.

Humoral immune mechanisms have been shown to play a role in the extrahepatic manifestations of autoimmune and idiopathic hepatitis. Arthralgias, arthritis, cutaneous vasculitis, and glomerulonephritis occurring in patients with autoimmune hepatitis appear to be mediated by the deposition of circulating immune complexes in affected tissue vessels, followed by complement activation, inflammation, and tissue injury. While specific viral antigen-antibody complexes can be identified in acute and chronic viral hepatitis, the nature of the immune complexes in autoimmune hepatitis has not been defined.

CLINICAL FEATURES

Many of the *clinical features* of autoimmune hepatitis are similar to those described for chronic viral hepatitis. The onset of disease may be insidious or abrupt; the disease may present initially like, and be confused with, acute viral hepatitis; a history of recurrent bouts of what had been labeled *acute hepatitis* is not uncommon. In approximately a quarter of patients, the diagnosis is made in the absence of symptoms, based on abnormal liver laboratory tests. A subset of patients with autoimmune hepatitis has distinct features. Such patients are predominantly young to middle-aged women with marked hyperglobulinemia and high titer circulating ANAs. This is the group with positive lupus erythematosus (LE) preparations (initially labeled *lupoid* hepatitis) in whom other autoimmune features are common. Fatigue, malaise, anorexia, amenorrhea, acne, arthralgias, and jaundice are common. Occasionally, arthritis, maculopapular eruptions (including cutaneous vasculitis), erythema nodosum, colitis, pleuritis, pericarditis, anemia, azotemia, and sicca syndrome (keratoconjunctivitis, xerostomia) occur. In some patients, complications of cirrhosis, such as ascites and edema (associated with portal hypertension and hypoalbuminemia), encephalopathy, hypersplenism, coagulopathy, or variceal bleeding may bring the patient to initial medical attention.

The course of autoimmune hepatitis may be variable. In patients with mild disease or limited histologic lesions (e.g., piecemeal necrosis [inflammation and erosion of the limiting place of periportal hepatocytes] without bridging), progression to cirrhosis is limited, but, even in this subset, clinical monitoring is important to identify progression; up to half left untreated can progress to cirrhosis over the course of 15 years. In North America, cirrhosis at presentation is more common in African Americans than in whites. In those with severe symptomatic autoimmune hepatitis (aminotransferase levels >10 times normal, marked hyperglobulinemia, "aggressive" histologic lesions—bridging necrosis or multilobular collapse, cirrhosis), the 6-month mortality without therapy may be as high as 40%. Such severe disease accounts for only 20% of cases; the natural history of milder disease is variable, often accentuated by spontaneous remissions and exacerbations. In a 10-year (2006–2016) national Dutch study, mortality in patients with autoimmune hepatitis was higher than that of the general population only in patients with cirrhosis; for patients without cirrhosis, survival was comparable to that of the general population. Especially poor prognostic signs include the presence histologically of multilobular collapse at the time of initial presentation and failure of serum bilirubin to improve after 2 weeks of therapy. Death may result from hepatic failure, hepatic coma, other complications of cirrhosis (e.g., variceal hemorrhage), and intercurrent infection. In patients with established cirrhosis, HCC may be a late complication **(Chap. 82)** but occurs less frequently than in cirrhosis associated with viral hepatitis.

Laboratory features of autoimmune hepatitis are similar to those seen in chronic viral hepatitis. Liver biochemical tests are invariably abnormal but may not correlate with the clinical severity or histopathologic features in individual cases. Many patients with autoimmune hepatitis have normal serum bilirubin, alkaline phosphatase, and globulin levels with only minimal aminotransferase elevations. Serum AST and ALT levels are increased and fluctuate in the range of 100–1000 units. In severe cases, the serum bilirubin level is moderately elevated (51–171 μmol/L [3–10 mg/dL]). Hypoalbuminemia occurs in patients with very active or advanced disease. Serum alkaline phosphatase levels may be moderately elevated or near normal. In a small proportion of patients, marked elevations of alkaline phosphatase activity occur; in such patients, clinical and laboratory features overlap with those of primary biliary cholangitis **(Chap. 344)**. The prothrombin time is often prolonged, particularly late in the disease or during active phases.

Polyclonal hypergammaglobulinemia (>2.5 g/dL) is common in autoimmune hepatitis, as is the presence of rheumatoid factor. As noted above, circulating autoantibodies are also prevalent, most characteristically ANAs in a homogeneous staining pattern. Smooth-muscle antibodies are less specific, seen just as frequently in chronic viral hepatitis. Because of the high levels of globulins achieved in the circulation of some patients with autoimmune hepatitis, occasionally the globulins may bind nonspecifically in solid-phase binding immunoassays for viral antibodies. This has been recognized most commonly in tests for antibodies to HCV, as noted above. In fact, studies of autoantibodies in autoimmune hepatitis have led to the recognition of new categories

of autoimmune hepatitis. *Type I autoimmune hepatitis* is the classic syndrome prevalent in North America and northern Europe occurring in young women, associated with marked hyperglobulinemia, lupoid features, circulating ANAs, and HLA-DR3 or HLA-DR4 (especially *B8-DRB1*03*). Also associated with type I autoimmune hepatitis are autoantibodies against actin and atypical perinuclear antineutrophilic cytoplasmic antibodies (pANCA). Included in the spectrum of type I autoimmune hepatitis is a subset of patients who lack ANA and anti-LKM1 but who have circulating antibodies to soluble liver antigen. Most of these patients are women and have clinical features similar to, or perhaps more severe than, those of other patients with type I autoimmune hepatitis.

Type II autoimmune hepatitis, often seen in children, more common in Mediterranean populations, and linked to HLA-DRB1 and HLA-DQB1 haplotypes, is associated not with ANA but with anti-LKM. Actually, anti-LKM represent a heterogeneous group of antibodies. In type II autoimmune hepatitis, the antibody is anti-LKM1, directed against cytochrome P450 2D6. This is the same anti-LKM seen in some patients with chronic hepatitis C. Anti-LKM2 is seen in drug-induced hepatitis, and anti-LKM3 (directed against uridine diphosphate glucuronyltransferases) is seen in patients with chronic hepatitis D. Another autoantibody observed in type II autoimmune hepatitis is directed against liver cytosol formiminotransferase cyclodeaminase (anti-liver cytosol 1).

Liver biopsy abnormalities are similar to those described for chronic viral hepatitis. Expanding portal tracts and extending beyond the plate of periportal hepatocytes into the parenchyma (designated *interface hepatitis* or *piecemeal necrosis*) is a mononuclear cell infiltrate that, in autoimmune hepatitis, may include the presence of plasma cells. Necroinflammatory activity characterizes the lobular parenchyma, and evidence of hepatocellular regeneration is reflected by "rosette" formation, the occurrence of thickened liver cell plates, and regenerative "pseudolobules." Septal fibrosis, bridging fibrosis, and cirrhosis are frequent. In patients with early autoimmune hepatitis presenting as an acute-hepatitis-like illness, lobular and centrilobular (as opposed to the more common periportal) necrosis has been reported. Bile duct injury and granulomas are uncommon; however, a subgroup of patients with autoimmune hepatitis has histologic, biochemical, and serologic features overlapping those of primary biliary cholangitis **(Chap. 344)**.

DIAGNOSTIC CRITERIA

An international group has suggested a set of criteria for establishing a diagnosis of autoimmune hepatitis. Exclusion of liver disease caused by genetic disorders, viral hepatitis, drug hepatotoxicity, and alcohol is linked with such inclusive diagnostic criteria as hyperglobulinemia, autoantibodies, and characteristic histologic features. This international group has also suggested a comprehensive diagnostic scoring system that, rarely required for typical cases, may be helpful when typical features are not present. Factors that weigh in favor of the diagnosis include female gender; predominant aminotransferase elevation; presence and level of globulin elevation; presence of nuclear, smooth-muscle, LKM1, and other autoantibodies; concurrent other autoimmune diseases; characteristic histologic features (interface hepatitis, plasma cells, rosettes); HLA-DR3 or DR4 markers; and response to treatment (see below). A more simplified, more specific scoring system relies on four variables: autoantibodies, serum IgG level, typical or compatible histologic features, and absence of viral hepatitis markers. Weighing against the diagnosis are predominant alkaline phosphatase elevation, mitochondrial antibodies, markers of viral hepatitis, history of hepatotoxic drugs or excessive alcohol, histologic evidence of bile duct injury, or such atypical histologic features as fatty infiltration, iron overload, and viral inclusions.

DIFFERENTIAL DIAGNOSIS

Early during the course of chronic hepatitis, autoimmune hepatitis may resemble typical *acute viral hepatitis* **(Chap. 339)**. Without histologic assessment, severe chronic hepatitis cannot be readily distinguished based on clinical or biochemical criteria from mild chronic hepatitis. In adolescence, *Wilson's disease* **(Chaps. 344 and 415)** may present with features of chronic hepatitis long before neurologic manifestations become apparent and before the formation of Kayser-Fleischer rings (copper deposition in Descemet's membrane in the periphery of the cornea). In this age group, serum ceruloplasmin and serum and urinary copper determinations plus measurement of liver copper levels establish the correct diagnosis. *Postnecrotic* or *cryptogenic cirrhosis* and *primary biliary cholangitis* **(Chap. 344)** share clinical features with autoimmune hepatitis, and both alcoholic hepatitis **(Chap. 342)** and nonalcoholic steatohepatitis **(Chap. 343)** may present with many features common to autoimmune hepatitis; historic, biochemical, serologic, and histologic assessments are usually sufficient to allow these entities to be distinguished from autoimmune hepatitis. Of course, the distinction between autoimmune and chronic viral hepatitis is not always straightforward, especially when viral antibodies occur in patients with autoimmune disease or when autoantibodies occur in patients with viral disease. Furthermore, the presence of extrahepatic features such as arthritis, cutaneous vasculitis, or pleuritis—not to mention the presence of circulating autoantibodies—may cause confusion with *rheumatologic disorders* such as rheumatoid arthritis and systemic LE. The existence of clinical and biochemical features of progressive necroinflammatory liver disease distinguishes chronic hepatitis from these other disorders, which are not associated with severe liver disease. Rarely, hepatic venous outflow obstruction (Budd-Chiari syndrome) may present with features suggestive of autoimmune hepatitis, but painful hepatomegaly, ascites, and vascular imaging provide distinguishing diagnostic clues. Other diagnostic considerations would include celiac disease and ischemic liver disease, which would be readily distinguishable by clinical and laboratory features from autoimmune hepatitis.

In patients treated with immune checkpoint inhibitors for malignancy, the liver may be one of the autoimmune targets of therapy; the syndrome resembles autoimmune hepatitis in clinical features and response to glucocorticoid-based treatment. Finally, occasionally, features of autoimmune hepatitis overlap with features of autoimmune biliary disorders such as primary biliary cholangitis, primary sclerosing cholangitis **(Chaps. 344 and 346)**, or, even more rarely, mitochondrial antibody-negative autoimmune cholangitis. Such overlap syndromes are difficult to categorize, and often response to therapy may be the distinguishing factor that establishes the diagnosis.

TREATMENT

Autoimmune Hepatitis

The mainstay of management in autoimmune hepatitis is glucocorticoid therapy. Several controlled clinical trials have documented that such therapy leads to symptomatic, clinical, biochemical, and histologic improvement as well as increased survival. A therapeutic response can be expected in up to 80% of patients. Unfortunately, therapy has not been shown in clinical trials to prevent ultimate progression to cirrhosis; however, instances of reversal of fibrosis and cirrhosis have been reported in patients responding to treatment, and rapid treatment responses within 1 year do translate into a reduction in progression to cirrhosis. Although some advocate the use of prednisolone (the hepatic metabolite of prednisone), prednisone is just as effective and is favored by most authorities. Therapy may be initiated at 20 mg/d, but a popular regimen in the United States relies on an initiation dose of 60 mg/d. This high dose is tapered successively over the course of a month down to a maintenance level of 20 mg/d. An alternative, but equally effective, more appealing approach is to begin with half the prednisone dose (30 mg/d) along with azathioprine (50 mg/d). With azathioprine maintained at 50 mg/d, the prednisone dose is tapered over the course of a month down to a maintenance level of 10 mg/d. The advantage of the combination approach is a reduction, over the span of an 18-month course of therapy, in serious, life-threatening complications of steroid therapy (e.g., cushingoid features, hypertension, diabetes, osteoporosis) from 66% down to <20%. Genetic analysis for thiopurine *S*-methyltransferase allelic variants does not

correlate with azathioprine-associated cytopenias or efficacy and is not assessed routinely in patients with autoimmune hepatitis. In combination regimens, 6-mercaptopurine may be substituted for its prodrug azathioprine, but this is rarely required. Azathioprine alone, however, is not effective in achieving remission, nor is alternate-day glucocorticoid therapy. Limited experience with budesonide in noncirrhotic patients suggests that this steroid side effect–sparing drug may be effective; however, the few randomized controlled trials of budesonide have not consistently shown efficacy. Although therapy has been shown to be effective for severe autoimmune hepatitis (AST ≥10× the upper limit of normal or ≥5× the upper limit of normal in conjunction with serum globulin greater than or equal to twice normal; bridging necrosis or multilobular necrosis on liver biopsy; presence of symptoms), therapy is not indicated for mild forms of chronic hepatitis, and the efficacy of therapy in mild or asymptomatic autoimmune hepatitis has not been established.

Improvement of fatigue, anorexia, malaise, and jaundice tends to occur within days to several weeks; biochemical improvement occurs over the course of several weeks to months, with a fall in serum bilirubin and globulin levels and an increase in serum albumin. Serum aminotransferase levels usually drop promptly, but improvements in AST and ALT alone do not appear to be reliable markers of recovery in individual patients; histologic improvement, characterized by a decrease in mononuclear infiltration and in hepatocellular necrosis, may be delayed for 6–24 months. Still, if interpreted cautiously, aminotransferase levels are valuable indicators of relative disease activity, and, although recommended, many authorities do *not* advocate for serial liver biopsies to assess therapeutic success or to guide decisions to alter or stop therapy. Rapidity of response is more common in older patients (≥69 years) and those with HLA *DBR1*04*; although rapid responders may progress less slowly to cirrhosis and liver transplantation, they are no less likely than slower responders to relapse after therapy. Therapy should continue for at least 12–18 months. After tapering and cessation of therapy, the likelihood of relapse is at least 50%, even if posttreatment histology has improved to show mild chronic hepatitis, and most patients require therapy at maintenance doses indefinitely. Continuing azathioprine alone (2 mg/kg body weight daily) after cessation of prednisone therapy has been shown to reduce the frequency of relapse. Long-term maintenance with low-dose prednisone (≤10 mg daily) has also been shown to keep autoimmune hepatitis in check without the theoretical risk of azathioprine marrow suppression and, in young women of child-bearing age, teratogenicity; however, maintenance azathioprine is more effective in preserving remission.

In medically refractory cases, an attempt should be made to intensify treatment with high-dose glucocorticoid monotherapy (60 mg daily) or combination glucocorticoid (30 mg daily) plus high-dose azathioprine (150 mg daily) therapy. After a month, doses of prednisone can be reduced by 10 mg a month, and doses of azathioprine can be reduced by 50 mg a month toward ultimate, conventional maintenance doses. Patients refractory to this regimen may be treated with cyclosporine, tacrolimus, or mycophenolate mofetil. Similarly, in exploratory studies, infusions of monoclonal antibodies directed at tumor necrosis factor (infliximab) and against the B-lymphocyte antigen CD20 (rituximab) have been reported to be of clinical benefit (improved aminotransferase levels, immunoglobulin G levels, histologic inflammatory activity) as rescue therapy for refractory autoimmune hepatitis. To date, however, only limited, often anecdotal, data in small numbers of patients support these alternative approaches. If medical therapy fails, or when chronic hepatitis progresses to cirrhosis and is associated with life-threatening complications of liver decompensation, liver transplantation is the only recourse **(Chap. 345)**; in patients with severe autoimmune hepatitis, failure of the bilirubin to improve after 2 weeks of therapy should prompt early consideration of the patient for liver transplantation. Recurrence of autoimmune hepatitis in the new liver occurs rarely in most experiences but in as many as 35–40% of cases in others; nonetheless, 5-year patient and graft survival exceed 80%.

Like all patients with chronic liver disease, patients with autoimmune hepatitis should be vaccinated against hepatitis A and B, ideally before immunosuppressive therapy is begun, if practical. Patients with autoimmune hepatitis and cirrhosis should be screened for HCC with ultrasound at 6-month intervals and for gastroesophageal varices with upper gastrointestinal endoscopy at intervals of 1–3 years, based on severity of liver disease.

342 Alcohol-Associated Liver Disease

Bernd Schnabl

Alcohol-associated liver diseases (ALD) comprise a spectrum of diseases associated with chronic alcohol consumption ranging from alcohol-associated fatty liver disease and steatohepatitis to more advanced liver disease including fibrosis and cirrhosis. Acute alcoholic hepatitis is an acute-on-chronic form of ALD that is associated with liver failure and high mortality.

EPIDEMIOLOGY

Approximately 5.8% of adults in the United States have an alcohol use disorder, defined as >2 drinks per day in women and >3 drinks per day in men, or partake in binge drinking, defined as 4 drinks for women and 5 drinks for men in ~2 h (1 drink equals ~14 g of ethanol, which is 1 beer, 4 oz of wine, or 1 oz of 80% spirits). Prevalence of ALD correlates with the amount of alcohol consumption in different regions. Prevalence of alcohol-associated fatty liver disease is 4.7% of the general population in the United States, and 1.5% has stage 2 or greater fibrosis. Liver cirrhosis is the eleventh leading cause of mortality worldwide, causing 1.16 million deaths annually; 48% of cases of cirrhosis can be attributed to alcohol. Among patients with alcohol use disorder, 18% had fibrosis, 26% had cirrhosis, and 7% had acute alcoholic hepatitis without underlying cirrhosis. In the European population, the annual incidence rate for acute alcoholic hepatitis is between 24 and 27 per million persons in women and between 46 and 65 per million persons in men.

PATHOGENESIS

Alcohol in the form of ethanol is rapidly absorbed in the upper gastrointestinal tract and predominantly metabolized in the liver. Ethanol reaches the liver through the portal vein, and the majority of ethanol is oxidized via alcohol dehydrogenase 1 (ADH1) into acetaldehyde in hepatocytes. Chronic alcohol consumption induces the expression of a second ethanol-metabolizing enzyme, cytochrome P450 family 2 subfamily E member 1 (CYP2E1), which also converts ethanol into acetaldehyde. In addition to the direct cellular toxic effects of acetaldehyde, metabolism of ethanol into acetaldehyde causes the generation of reactive oxygen species (ROS), resulting in further injury of hepatocytes via lipid peroxidation and DNA damage. Acetaldehyde is then oxidized into acetate via acetaldehyde dehydrogenase (ALDH). Inherited deficiency of ALDH2 is common in Asian countries and leads to acetaldehyde accumulation after alcohol consumption. These individuals develop nausea and cutaneous flushing. Several mechanisms contribute to the development of hepatic steatosis related to alcohol consumption. Acetate is converted into acetyl-coenzyme A (CoA), which contributes to fatty acid and triglyceride synthesis. Alcohol, in part through epigenetic changes, increases the expression of genes involved in lipogenesis, while genes involved in fatty acid transport and oxidation are suppressed. Alcohol also increases the ratio of reduced nicotinamide adenine dinucleotide (NAD)/oxidized NAD ($NADH/NAD^+$) in hepatocytes, which further reduces mitochondrial β-oxidation. Alcohol can increase fatty acid mobilization in adipose tissue and the intestine, which will lead to hepatic accumulation of fatty acids and increased hepatic steatosis. Overall, the net effect of these processes contributes to fat accumulation in the liver.

RISK FACTORS FOR PROGRESSION OF ALD

Daily alcohol consumption or heavy drinking results in hepatic steatosis, but only 10–20% of such individuals will develop progressive liver disease and cirrhosis. Therefore, other cofactors such as behavioral, environmental, and genetic factors play important roles in progression of ALD **(Table 342-1)**. There is a dose-dependent increase, with regard to the amount of alcohol consumed, in the likelihood of developing liver cirrhosis. Women develop ALD at a lower daily alcohol intake. Cigarette smoking is an independent risk factor for alcohol-associated cirrhosis. The drinking pattern, in particular binge drinking and excessive alcohol drinking outside meals, increases the risk of developing progressive ALD. Obesity and other chronic liver diseases such as viral hepatitis, hemochromatosis, and nonalcoholic steatohepatitis (NASH), are frequent cofactors contributing to progression of ALD. Twin studies demonstrated a genetic predisposition to alcohol-associated liver cirrhosis that is independent from the genetic predisposition to alcohol use disorder. Gene polymorphisms conferring increased risk of alcohol-associated liver cirrhosis have been found in three genes, patatin-like phospholipase domain-containing 3 (*PNPLA3*),

TABLE 342-1 Factors for Progression of Alcohol-Associated Liver Disease

- Alcohol dose (>1 drink per day for women, >2 drinks per day for men)
- Drinking pattern (drinking without meal, binge drinking)
- Genetic factors, especially *PNPLA3* polymorphism
- Female gender
- Smoking
- Increased body mass index and chronic liver diseases
- Intestinal microbiota

TABLE 342-2 Symptoms and Signs Associated with Alcohol-Associated Cirrhosis and Alcoholic Hepatitis

- Tiredness
- Malnutrition and sarcopenia
- Abdomen: abdominal discomfort, hepatomegaly, splenomegaly, caput medusae, ascites with weight gain, abdominal pain, and shortness of breath
- Skin: spider angioma, palmar erythema, jaundice, ecchymoses
- Eyes: icteric sclerae
- Hands: Dupuytren contracture
- Face: rhinophyma
- Reproductive system: gynecomastia, gonadal atrophy, loss of libido, amenorrhea
- Neurologic:
  - Peripheral neuropathy
  - Alcohol withdrawal: tachycardia, agitation, tremor, seizures, delirium
  - Hepatic encephalopathy: asterixis (flapping tremor), forgetfulness, inversion of sleep/wake pattern, altered consciousness, confusion, lethargy, coma
  - Wernicke-Korsakoff syndrome

membrane bound O-acyltransferase domain-containing 7 (*MBOAT7*), and transmembrane 6 superfamily member 2 (*TM6SF2*), although the molecular mechanism is not well understood. A subset of patients with alcohol use disorder develop changes in the gut microbiome and increased intestinal permeability resulting in activation of hepatic inflammation, hepatocyte death, and activation of fibrotic pathways. Ongoing fibrosis due to continued alcohol consumption can result in the development of cirrhosis with portal hypertension **(Chap. 344)**.

CLINICAL FEATURES

The development of alcohol-associated steatosis, steatohepatitis, and cirrhosis is most often clinically silent. Symptoms arise once the patient with alcohol-associated liver cirrhosis decompensates or develops alcoholic hepatitis **(Table 342-2)**. Patients with alcoholic hepatitis have been drinking heavily for typically >5 years and until at least 8 weeks before onset of symptoms. They present with rapid onset of jaundice (serum bilirubin >3 mg/dL), often accompanied by fever, malaise, tender hepatomegaly, and clinical signs of hepatic decompensation, such as ascites, bacterial infection, variceal bleeding, and hepatic encephalopathy. Infections occur in 12–26% of patients with severe alcoholic hepatitis at the time of admission. Alcoholic hepatitis is often accompanied by systemic inflammatory response syndrome (SIRS) and acute kidney injury (AKI) secondary to hepatorenal syndrome.

LABORATORY FINDINGS

Patients with simple hepatic steatosis can present with normal liver function tests. Steatohepatitis is characterized by elevated levels of aspartate aminotransferase (AST) and γ-glutamyl transferase (GGT). Characteristic laboratory parameters for ALD include a ratio of AST to alanine aminotransferase (ALT) of >1, and serum AST is rarely >300 IU/L. Serum bilirubin and international normalized ratio (INR) are typically normal. Elevated bilirubin and INR and low serum albumin and platelet count are common laboratory finings in patients with cirrhosis. Patients with alcoholic hepatitis have AST and ALT elevations that do not exceed 400 IU/L, with AST/ALT ratio of >1.5 and serum bilirubin >3 mg/dL.

DIAGNOSIS

The Alcohol Use Disorders Inventory Test (AUDIT) is a validated tool for identifying patients with alcohol use disorder **(Chap. 453)**. Diagnosis of ALD requires exclusion of other liver diseases in heavy drinkers. Alcohol-associated steatosis can be diagnosed by simple ultrasound, magnetic resonance imaging (MRI), or computed tomography (CT). Noninvasive quantification of hepatic fat can be achieved with the ultrasound technique of controlled attenuation parameter (CAP) or with magnetic resonance proton density fat fraction (MR-PDFF). Liver biopsy is rarely indicated for diagnosing alcohol-associated hepatic steatosis or steatohepatitis. Liver biopsy typically shows hepatocytes with large lipid droplets (macrovesicular steatosis) around pericentral veins (zone 3). Morphologic features of alcohol-associated steatohepatitis include hepatocyte injury and ballooning with Mallory-Denk bodies, necrosis, and lobular inflammation with mononuclear and neutrophilic granulocytes.

Progression of alcohol-associated steatohepatitis to fibrosis can be diagnosed using liver stiffness measurement by techniques such as transient elastography (e.g., FibroScan). Liver stiffness <6 kPa indicates normal liver, whereas cutoffs for each stage of alcohol-associated liver fibrosis have been validated (>8 kPa indicates ≥F3 advanced fibrosis; >12.5 kPa indicates F4 cirrhosis). Histology shows initially perivenular fibrosis with subsequent extension of collagen fibers into hepatic lobules, described as septal fibrosis. Patients with cirrhosis show liver nodularity on imaging with ultrasound, MRI, or CT scan. Radiologic signs of portal hypertension include ascites, splenomegaly, and portal-systemic collateral vessels. Prognosis and risk of mortality are assessed using Child-Pugh-Turcotte (CPT) or Model for End-Stage Liver Disease (MELD; or sodium-MELD) scores **(Chap. 344)**.

In patients presenting with features suggestive of alcoholic hepatitis, imaging is obtained to exclude biliary obstruction and hepatocellular carcinoma (HCC). In addition, other causes of liver disease such as viral hepatitis, Wilson's disease, and severe autoimmune liver disease should be ruled out. Histology shows macrovesicular steatosis, hepatocyte ballooning with Mallory-Denk bodies, megamitochondria, neutrophil infiltration, bilirubinostasis, and chicken wire fibrosis. The majority of patients with alcoholic hepatitis have underlying cirrhosis (80%) **(Chap. 344)**, and 10–20% of patients with a clinical diagnosis of alcoholic hepatitis will have other liver diseases on biopsy. Therefore, in the presence of potential confounding factors, including possible ischemic hepatitis (in the setting of, e.g., hypotension, massive gastrointestinal bleeding, recent cocaine use, septic shock), drug-induced liver injury (DILI), autoimmune liver disease, uncertain alcohol use assessment, or atypical laboratory tests (AST <50 IU/L or >400 IU/L, AST/ALT ratio <1.5), a transjugular liver biopsy is recommended to confirm the diagnosis of alcoholic hepatitis. Infections need to be assessed routinely with chest x-ray and blood, urine, and ascites cultures in patients presenting with alcoholic hepatitis.

TREATMENT

Alcohol-Associated Liver Disease (Fig. 342-1)

To date, the most effective therapy to reduce the progression of and reverse ALD is prolonged alcohol abstinence. In particular, alcohol-associated hepatic steatosis and steatohepatitis are reversible with cessation of alcohol consumption. Thus, treatment of the underlying alcohol use disorder is an integral part for therapy of ALD. There are currently no approved drugs for treatment of alcohol-associated steatosis and steatohepatitis with or without fibrosis.

Patients with alcohol-associated cirrhosis and ongoing alcohol consumption are at risk for decompensation and development of hepatic encephalopathy, ascites, variceal bleeding, hepatorenal syndrome, and HCC **(Chap. 344)**. Patients with cirrhosis should undergo an upper gastrointestinal endoscopy to screen for varices. HCC screening is recommended using ultrasonography every 6 months in patients with cirrhosis. Management of complications of cirrhosis such as variceal bleeding, ascites, hepatic encephalopathy, and HCC does not differ from patients with cirrhosis due to a different etiology **(Chap. 344)**. Liver transplantation for patients with alcohol-associated decompensated cirrhosis or HCC is a definitive therapy and is currently the leading indication for liver transplantation in the United States. Liver transplantation evaluation should be taken into consideration for patients with end-stage liver disease **(Chap. 345)**.

In patients diagnosed with alcoholic hepatitis, short-term mortality can be predicted using the Maddrey discriminant function (MDF; calculated as 4.6 × [the prolongation of the prothrombin time above control {seconds}] + serum bilirubin [mg/dL]), MELD score **(Chap. 344)**, or age-bilirubin-INR-creatinine (ABIC) score.

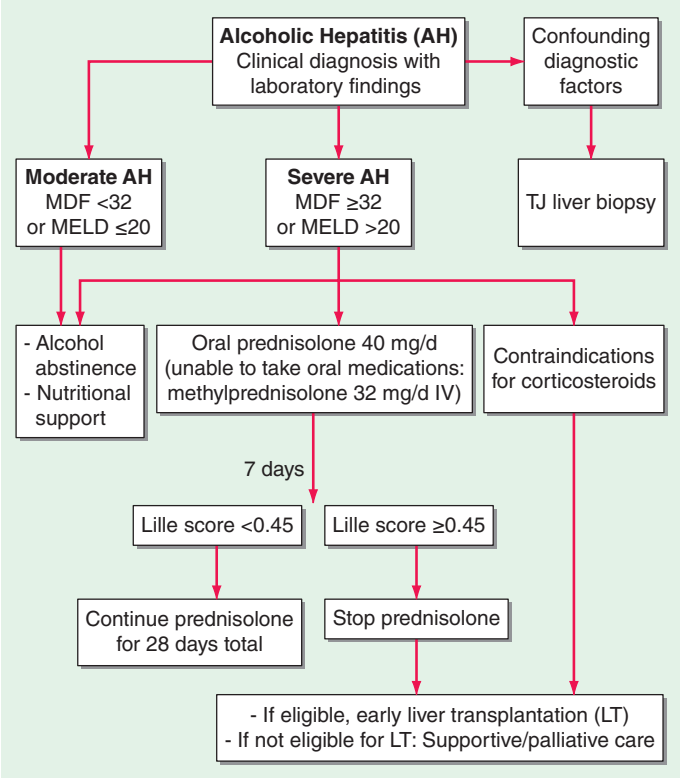

FIGURE 342-1 Treatment algorithm for alcoholic hepatitis. In patients with a clinical diagnosis of alcoholic hepatitis, confounding factors (see text) need to be ruled out, if necessary, by transjugular (TJ) liver biopsy. Patients with severe alcoholic hepatitis (AH), defined as Maddrey discriminant function (MDF) ≥32 or Model for End-Stage Liver Disease (MELD) score >20, without contraindications for glucocorticoids (see text) are candidates for such treatment. Nonresponders or patients with contraindications for treatment should be considered for early liver transplantation (LT) or supportive or palliative care, as clinically appropriate.

Patients with MDF <32 or MELD ≤20 are defined as having moderate alcoholic hepatitis. Currently, patients with moderate alcoholic hepatitis are treated under a multidisciplinary team including an alcohol use disorder specialist, dietitian for nutritional supplementation for patients with markedly reduced intake, and hepatologist for managing liver disease complications. Enteral nutrition with a goal of >21 kcal/kg and supplementation of micronutrients (in particular zinc) and vitamin supplementation (in particular vitamin B_1) are recommended for patients with alcoholic hepatitis. Intravenous albumin is preferred for volume expansion. MDF ≥32 or MELD >20 identifies patients with severe alcoholic hepatitis and high short-term mortality who will have a survival benefit with glucocorticoid treatment. Contraindications for glucocorticoid treatment include uncontrolled infections or sepsis, AKI and hepatorenal syndrome, uncontrolled upper gastrointestinal bleeding, concomitant diseases (including viral hepatitis, HCC, pancreatitis, DILI, active tuberculosis, and HIV), multiorgan failure, and shock. Glucocorticoids can be used once infection, sepsis, and gastrointestinal bleeding are adequately controlled. Glucocorticoid use reduces the risk of death in patients with severe alcoholic hepatitis within 28 days of treatment but not in the following 6 months. Oral prednisolone, 40 mg/d for a total duration of 4 weeks, is preferred. For patients unable to take oral medications, methylprednisolone, 32 mg/d IV, is used. The combination of glucocorticoids with *N*-acetylcysteine infusion might add short-term survival benefit at 1 month. Failure of improvement of Lille score (≥0.45) after 7 days of glucocorticoid treatment will determine patients with severe alcoholic hepatitis who will unlikely benefit from continued treatment with glucocorticoids. Glucocorticoids should be stopped in nonresponders, and early liver transplantation should be considered. Although short-term prognosis is dependent on liver disease severity at the time of presentation, long-term prognosis (>1 year) largely depends on alcohol abstinence and underlying cirrhosis. Patients with severe alcoholic hepatitis that is nonresponsive to medical therapy have high 30-day mortality and are therefore unable to fulfill a minimum of 6 months of alcohol abstinence, which is required in many centers for liver transplantation evaluation. Early liver transplantation can be successfully performed in highly selected patients with an excellent psychosocial profile **(Chap. 345)**. If a nonresponder is ineligible for early liver transplantation, supportive or palliative care should be considered for patients with multiple-organ failure.

343 Nonalcoholic Fatty Liver Diseases and Nonalcoholic Steatohepatitis

Manal F. Abdelmalek, Anna Mae Diehl

INCIDENCE, PREVALENCE, AND NATURAL HISTORY

Nonalcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease in the United States, as well as worldwide. The global prevalence of NAFLD is estimated to be as high as one billion. In the United States, NAFLD is estimated to effect between 80 and 100 million individuals. NAFLD is strongly associated with insulin resistance, overweight/obesity, and metabolic syndrome. However, it can also occur in lean individuals and is particularly common in those with a paucity of adipose depots (i.e., lipodystrophy). Ethnic/racial factors also appear to influence liver fat accumulation; the documented prevalence of NAFLD is lowest in African Americans (~25%), highest in Americans of Hispanic ancestry (~50%), and intermediate in American whites (~33%).

NAFLD encompasses a spectrum of liver pathology with different clinical prognoses **(Fig. 343-1)**. The simple accumulation of triglyceride within hepatocytes (hepatic steatosis) is on the most clinically benign extreme of the spectrum. On the opposite, most clinically ominous extreme, are cirrhosis **(Chap. 344)** and primary liver cancer **(Chap. 82)**. The risk of developing cirrhosis is extremely low in individuals with isolated steatosis (nonalcoholic fatty liver [NAFL]) but increases as steatosis becomes complicated by liver-cell injury and death and the accumulation of inflammatory cells (i.e., nonalcoholic steatohepatitis [NASH]). At least a quarter of adults with NAFLD are presumed to have NASH. NASH itself is also a heterogeneous condition; it can improve to steatosis or normal histology, remain relatively stable for years, or cause progressive accumulation of fibrous scar that eventuates in cirrhosis (stage 4 fibrosis). Advanced hepatic fibrosis is the primary predictor of eventual liver-related morbidity and mortality

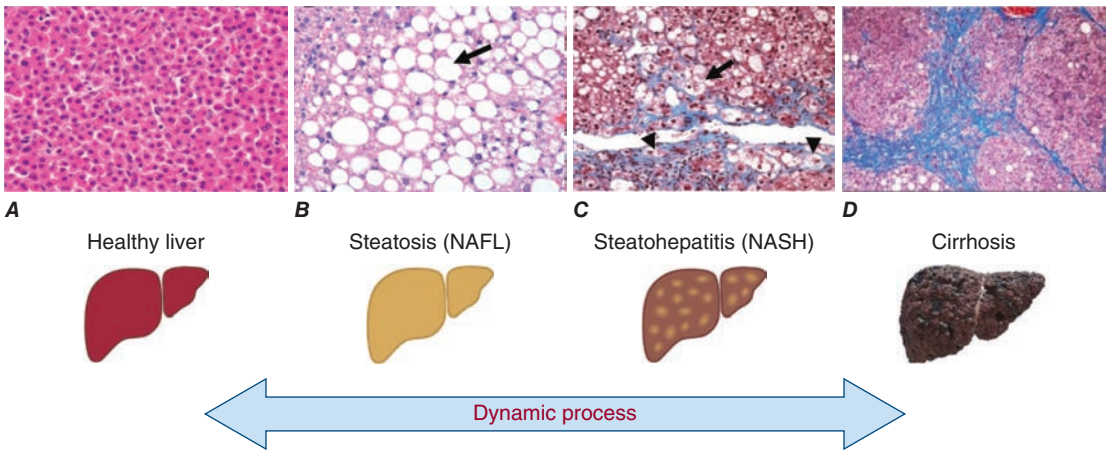

FIGURE 343-1 Histopathologic spectrum of nonalcoholic fatty liver disease (NAFLD). NAFLD encompasses a dynamic spectrum of liver pathology. ***A.*** Healthy liver. ***B.*** Simple steatosis (nonalcoholic fatty liver [NAFL]); *arrow* shows fatty hepatocyte. ***C.*** Nonalcoholic steatohepatitis (NASH); ballooned hepatocyte (*arrow*) near central vein with adjacent blue-stained pericellular fibrosis (*arrowheads*). ***D.*** Cirrhosis with blue-stained bridging fibrosis surrounding micronodules of liver parenchyma.

in NAFLD. Once NAFLD-related cirrhosis develops, the annual incidence of primary liver cancer can be as high as 1–2% per year.

Abdominal imaging is not able to determine which individuals with NAFLD have associated liver-cell death and inflammation (i.e., NASH), and specific blood tests to diagnose NASH are not yet available. However, population-based studies that have used elevated serum alanine aminotransferase (ALT) as a marker of liver injury indicate that ~6–8% of American adults have serum ALT elevations that cannot be explained by excessive alcohol consumption, other known causes of fatty liver disease (Table 343-1), viral hepatitis, or drug-induced or congenital liver diseases. Because the prevalence of such "cryptogenic" ALT elevations increases with body mass index, it is presumed that they are due to NASH. Hence, at any given point in time, NASH is present in ~25% of individuals who have NAFLD (i.e., ~6–8% of the general U.S. adult population has NASH). Smaller cross-sectional studies in which liver biopsies have been performed on NASH patients at tertiary referral centers consistently demonstrate advanced fibrosis or cirrhosis in ~25% of those cohorts. By extrapolation, therefore,

TABLE 343-1 Alternative Causes of Hepatic Steatosis

- Alcoholic liver disease
- Hepatitis C (particularly genotype 3)
- Inborn errors of metabolism
  - Abetalipoproteinemia
  - Cholesterol ester storage disease
  - Galactosemia
  - Glycogen storage disease
  - Hereditary fructose intolerance

  - 5-Fluorouraci
  - l-Asparaginase
  - Azacitidine
  - Azaserine
  - Bleomycin
  - Methotrexate
  - Puromycin
  - Tetracycline
  - Doxycycline
- Metals
  - Antimony
  - Barium salts
  - Chromates
  - Phosphorus
  - Rare earths of low atomic number
  - Thallium compounds
  - Uranium compounds
- Other drugs and toxins
  - Amiodarone
  - 4,4′-Diethylaminoethoxyhexesterol
  - Ethionine
  - Ethyl bromide
  - Estrogens
  - Glucocorticoids
- Highly active antiretroviral therapy
  - Hydralazine
  - Hypoglycin
  - Orotate
  - Perhexiline maleate
  - Safrole
  - Tamoxifen
  - Valproic acid
  - Acetylsalicylic acid intoxication
  - Apo-B inhibitors: Mipomersen and lomitapide

cirrhosis develops in ~6% of individuals with NAFLD (i.e., in ~1.5–2% of the general U.S. population). The risk for advanced liver fibrosis is highest in individuals with NASH who are aged >45–50 years and overweight/obese or afflicted with type 2 diabetes. Having a first-degree relative with cryptogenic hepatitis or cirrhosis also increases the risk for developing cirrhosis.

Heritable factors clearly impact susceptibility to hepatic steatosis, NASH, liver fibrosis, and liver cancer. Genetic variants on or near *TM6SF2* or *MBOAT7* (genes involved in lipid homeostasis) and palatin-like phospholipase domain-containing 3 gene (*PNPLA3*, a gene that encodes an enzyme involved in intracellular trafficking of lipids) may increase the heritability of NAFLD. A recent meta-analysis showed that *PNPLA3* exerts a strong influence not only on hepatic fat accumulation but also on the severity of NASH and liver fibrosis. Indeed, recent twin studies suggest that inheritance accounts for about half the risk for developing cirrhosis. Epigenetic factors (i.e., heritable traits that do not result from direct changes in DNA) may also influence NAFLD pathogenesis and/or progression based on evidence that intrauterine exposures influence susceptibility to obesity and the metabolic syndrome in adolescence. Studies of families with adult-onset obesity have identified genome-wide epigenetic alterations that dysregulate metabolic pathways controlling adiposity, insulin sensitivity, and tissue generation or regeneration. Whether such epigenetic mechanisms influence susceptibility to NASH and cirrhosis is being investigated.

NAFLD is currently the leading indication for liver transplantation in the United States. Similar to cirrhosis caused by other liver diseases, cirrhosis caused by NAFLD increases the risk for primary liver cancer. Both hepatocellular carcinoma and intrahepatic cholangiocarcinoma (ICC) have also been reported to occur in NAFLD patients without cirrhosis, suggesting that NAFLD per se may be a premalignant condition. NAFLD, NASH, and NAFLD-related cirrhosis are not limited to adults. All have been well documented in children. As in adults, obesity and insulin resistance are the main risk factors for pediatric NAFLD. Thus, the rising incidence and prevalence of childhood obesity suggests that NAFLD will be a major contributor to society's burden of liver disease in the future.

PATHOGENESIS

The mechanisms underlying the pathogenesis and progression of NAFLD are not entirely clear. The best-understood mechanisms pertain to hepatic steatosis. This is proven to result when hepatocyte mechanisms for triglyceride synthesis (e.g., lipid uptake and de novo lipogenesis) overwhelm mechanisms for triglyceride disposal (e.g., degradative metabolism and lipoprotein export), leading to accumulation of fat (i.e., triglyceride) within hepatocytes. Obesity stimulates hepatocyte triglyceride accumulation by altering the intestinal microbiota to enhance both energy harvest from dietary sources and intestinal permeability. Reduced intestinal barrier function increases hepatic exposure to gut-derived products, which stimulate liver cells to generate inflammatory mediators that inhibit insulin actions. Obese adipose depots also produce excessive soluble factors (adipokines) that inhibit tissue insulin sensitivity. Insulin resistance promotes hyperglycemia, which drives the pancreas to produce more insulin to maintain glucose homeostasis. However, hyperinsulinemia also promotes lipid uptake, fat synthesis, and fat storage. The net result is hepatic triglyceride accumulation (i.e., steatosis).

Triglyceride per se is not hepatotoxic. However, its precursors (e.g., fatty acids and diacylglycerols) and metabolic by-products (e.g., reactive oxygen species) may damage hepatocytes, leading to hepatocyte lipotoxicity. Lipotoxicity also triggers the generation of other factors (e.g., inflammatory cytokines, hormonal mediators) that deregulate systems that normally maintain hepatocyte viability. The net result is increased hepatocyte death. Dying hepatocytes, in turn, release various factors that trigger wound healing responses that aim to replace (regenerate) lost hepatocytes. Such repair involves transient expansion of other cell types, such as myofibroblasts and progenitor cells, that make and degrade matrix, remodel the vasculature, and generate replacement hepatocytes, as well as the recruitment of immune cells that release factors that modulate liver injury and repair. NASH is the morphologic manifestation of lipotoxicity and resultant wound healing responses. Because the severity and duration of lipotoxic liver injury dictate the intensity and duration of repair, the histologic features and outcomes of NASH are variable. Cirrhosis and liver cancer are potential outcomes of chronic NASH. Cirrhosis results from futile repair, i.e., progressive accumulation of wound healing cells, fibrous matrix, and abnormal vasculature (scarring), rather than efficient reconstruction/regeneration of healthy hepatic parenchyma. Primary liver cancers develop when malignantly transformed liver cells escape mechanisms that normally control regenerative growth. The mechanisms responsible for futile repair (cirrhosis) and liver carcinogenesis are not well understood. Because normal liver regeneration is a very complex process, there are multiple opportunities for deregulation and, thus, pathogenic heterogeneity. To date, this heterogeneity has confounded development of both diagnostic tests and treatments for defective/deregulated liver repair (i.e., cirrhosis and cancer). Hence, current strategies focus on circumventing misrepair by preventing and/or reducing lipotoxic liver injury.

DIAGNOSIS

Diagnosing NAFLD requires demonstration of increased liver fat in the absence of hazardous levels of alcohol consumption. Thresholds for potentially dangerous alcohol ingestion have been set at more than one drink per day in women and two drinks per day in men based on epidemiologic evidence that the prevalence of serum aminotransferase elevations increases when alcohol consumption habitually exceeds these levels. In those studies, one drink was defined as having 10 g of ethanol and, thus, is equivalent to one can of beer, 4 oz of wine, or 1.5 oz (one shot) of distilled spirits. Other causes of liver fat accumulation (particularly exposure to certain drugs; **Table 343-2**) and liver injury (e.g., viral hepatitis, autoimmune liver disease, iron or copper overload, α_1 antitrypsin deficiency) must also be excluded. Thus, establishing the diagnosis of NAFLD does not require invasive testing: it can be accomplished by history and physical examination, liver imaging (ultrasound is an acceptable first-line test; computed tomography [CT] or magnetic resonance imaging [MRI] enhances sensitivity for liver fat detection but adds expense), and blood tests to exclude other liver diseases.

It is important to emphasize that, in individuals with NAFLD, the liver may not be enlarged and serum aminotransferases and liver function tests (e.g., bilirubin, albumin, prothrombin time) may be completely normal. Because there is yet no one specific blood test for NAFLD, confidence in the diagnosis of NAFLD is increased by identification of NAFLD risk factors. The latter include increased body mass index, insulin resistance/type 2 diabetes mellitus, and other parameters indicative of the metabolic syndrome (e.g., systemic hypertension, dyslipidemia, hyperuricemia/gout, cardiovascular disease; **Chap. 408**) in the patient or family members. Individuals who have, or have had, pituitary or hypothalamic neoplasms and women with polycystic ovary syndrome are also at increased risk for NAFLD. Hypothyroidism and obstructive sleep apnea may also increase NAFLD, presumably by promoting obesity and/or exacerbating the metabolic syndrome.

Establishing the severity of NAFLD-related liver injury and related scarring (i.e., *staging* NAFLD) is more difficult than simply *diagnosing* NAFLD. *Staging* is critically important, however, because it is necessary to define prognosis and thereby determine treatment recommendations. The goal of staging is to distinguish patients with NASH from those with simple steatosis and to identify which of the NASH patients have advanced fibrosis. The 10-year probability of developing liver-related morbidity or mortality in steatosis is negligible, and hence, this subgroup of NAFLD patients tends to be managed conservatively (see below). In contrast, more intensive follow-up and therapy are justified in NASH patients, and the subgroup with advanced fibrosis merits the most intensive scrutiny and intervention because their 10-year risk of liver-related morbidity and mortality is clearly increased.

Staging approaches can be separated into noninvasive testing (i.e., blood testing, physical examination, and imaging) and invasive approaches (i.e., liver biopsy). Blood test evidence of hepatic dysfunction (e.g., hyperbilirubinemia, hypoalbuminemia, prothrombin time prolongation) or portal hypertension (e.g., thrombocytopenia) and

stigmata of portal hypertension on physical examination (e.g., spider angiomata, palmar erythema, splenomegaly, ascites, clubbing, encephalopathy) suggest a diagnosis of advanced NAFLD. Liver biopsy has been the gold standard for establishing the severity of liver injury and fibrosis because it is both more sensitive and more specific than these other tests for establishing NAFLD severity. Further, although invasive, liver biopsy is seldom complicated by serious adverse sequelae such as significant bleeding, pain, or inadvertent puncture of other organs and thus is relatively safe. However, biopsy suffers from potential sampling error unless tissue cores of 2 cm or longer are acquired. Also, examination of tissue at a single point in time is not reliable for determining whether the pathologic processes are progressing or regressing. The risk of serial liver biopsies within short time intervals is generally deemed as unacceptable outside of research studies. These limitations of liver biopsy have stimulated efforts to develop noninvasive approaches to stage NAFLD.

As is true for many other types of chronic liver disease, in NAFLD, the levels of serum aminotransferases (aspartate aminotransferase [AST] and ALT) do not reliably reflect the severity of liver cell injury, extent of liver-cell death, or related liver inflammation and fibrosis. Thus, they are imperfect for determining which individuals with NAFLD have NASH. This has prompted efforts to identify superior markers of NASH and, particularly, liver fibrosis, because fibrosis stage predicts eventual liver outcomes and mortality in NASH. Algorithms that combine various laboratory tests (e.g., Enhanced Liver Fibrosis [ELF] score, BARD score, AST to Platelet Ratio Index [APRI] score, NAFLD fibrosis score, and Fibrosis-4 [FIB-4] score) are somewhat helpful in separating NASH patients with advanced versus mild liver fibrosis. The NAFLD fibrosis score (NFS) and FIB-4 score, two of the most commonly employed noninvasive tests to assess severity of hepatic fibrosis, can be calculated from a few readily available clinical variables (age, body mass index, glucose, platelet count, albumin, AST, ALT) using published formulas that are readily accessed via an online calculator. Both scores are helpful for gauging the severity of NASH and liver fibrosis. Combining these tests with new imaging approaches that permit noninvasive quantification of liver fat (e.g., MRI using proton density fat fraction [MRI-PDFF]) and liver stiffness, a surrogate marker of liver fibrosis (e.g., magnetic resonance elastography [MRE], and transient elastography [FibroScan]), improves their predictive power **(Chap. 337)**. Transient elastography in particular has become widely available and is relatively inexpensive. It is most useful for excluding advanced liver fibrosis as cirrhosis is extremely unlikely when the liver stiffness score is low. However, higher stiffness scores must be interpreted with caution since several factors (obesity, nonfasting state, hepatic inflammation, iron overload, and/or hepatic congestion) decrease the specificity of the test. Increasingly, these new serologic and imaging tools are being used serially or in combination to monitor fibrosis progression and regression in NAFLD patients. As a result, liver biopsy staging is becoming restricted to patients who cannot be stratified reliably using these noninvasive assessments. Indeterminant or discordant results of noninvasive testing should prompt referral to a liver specialist and consideration of liver biopsy.

CLINICAL FEATURES OF NAFLD

Most subjects with NAFLD are asymptomatic. The diagnosis is often made when abnormal liver aminotransferases or features of fatty liver are noted during an evaluation performed for other reasons. NAFLD may also be diagnosed during the workup of vague right upper quadrant abdominal pain, hepatomegaly, or an abnormal-appearing liver at time of abdominal surgery. Obesity is present in 50–90% of subjects. Most patients with NAFLD also have other features of the metabolic syndrome **(Chap. 408)**. Some have subtle stigmata of chronic liver disease, such as spider angiomata, palmer erythema, or splenomegaly. In a small minority of patients with advanced NAFLD, complications of end-stage liver disease (e.g., jaundice, features of portal hypertension such as ascites or variceal hemorrhage) may be the initial findings.

The association of NAFLD with obesity, diabetes, hypertriglyceridemia, hypertension, and cardiovascular disease is well known. Other associations include chronic fatigue, mood alterations, obstructive sleep apnea, thyroid dysfunction, polycystic ovary syndrome, and chronic pain syndrome. NAFLD is an independent risk factor for metabolic syndrome **(Chap. 408)**. Longitudinal studies suggest that patients with NASH are at two- to threefold increased risk for the development of metabolic syndrome. Similarly, studies have shown that patients with NASH have a higher risk for the development of hypertension and diabetes mellitus. The presence of NAFLD is also independently associated with endothelial dysfunction, increased carotid intimal thickness, and the number of plaques in carotid and coronary arteries. Such data indicate that NAFLD has many deleterious effects on health in general.

TREATMENT OF NAFLD

Treatment of NAFLD can be divided into three components: (1) specific therapy of NAFLD-related liver disease; (2) treatment of NAFLD-associated comorbidities; and (3) treatment of the complications of advanced NAFLD. The subsequent discussion focuses on specific therapies for NAFLD, with some mention of their impact on major NAFLD comorbidities (insulin resistance/diabetes, obesity, and dyslipidemia). Treatment of the complications of advanced NAFLD involves management of the complications of cirrhosis and portal hypertension, including primary liver cancers. Approaches to accomplish these objectives are similar to those used in other chronic liver diseases and are covered elsewhere in the textbook **(Chaps. 344 and 82)**.

At present, there are no U.S. Food and Drug Administration (FDA)–approved therapies for the treatment of NAFLD. Thus, the current approach to NAFLD management focuses on treatment to improve the risk factors for NASH (i.e., obesity, insulin resistance, metabolic syndrome, dyslipidemia). Based on our understanding of the natural history of NAFLD, only patients with NASH or hepatic fibrosis are considered currently for targeted pharmacologic therapies. This approach may change as our understanding of disease pathophysiology improves and potential targets of therapy evolve.

Diet and Exercise Lifestyle changes and dietary modifications that result in weight loss and/or improve insulin sensitivity are the primary treatments for NAFLD. Many studies indicate that loss of 3–5% of body weight improves steatosis and that greater weight loss (i.e., ≥7–10%) improves steatohepatitis and hepatic fibrosis. The benefits of modifying dietary macronutrient contents (e.g., low-carbohydrate vs low-fat diets, saturated vs unsaturated fat diets) generally parallel changes in calorie consumption, suggesting that diet modifications are mainly beneficial because they reduce energy intake and improve obesity. However, a Mediterranean-type diet has been reported to improve NASH and liver fibrosis independently of weight loss. Excluding foods and beverages high in added fructose and increasing coffee consumption are also recommended because high-fructose diets have been shown to exacerbate hepatic steatosis, steatohepatitis, and fibrosis, and consuming two or more cups of coffee per day is associated with reduced risk of liver fibrosis. Changes in diet composition particularly merit consideration in lean individuals with NAFLD, although available data are insufficient to determine if this improves their liver histology. Modifying lifestyle to increase physical activity (i.e., energy expenditure) complements dietary caloric restriction and, thus, expedites weight loss. Exercise also improves muscle insulin sensitivity, which improves the metabolic syndrome independent of weight loss. Both aerobic exercise and resistance training effectively reduce liver fat. At least 30 min of moderate-intensity aerobic exercise or resistance training five times per week is recommended. The choice of training should be tailored to patients' preferences and functional capacity to enable long-term maintenance. Any activity is better than remaining sedentary. Unfortunately, most NAFLD patients cannot sustain long-term compliance with diet and lifestyle modifications and, thus, fail to maintain a healthier weight. Although pharmacologic therapies to facilitate weight loss, such as orlistat, topiramate, phentermine, and GLP-1 receptor agonists, are available, their role in the treatment of NAFLD remains experimental.

Pharmacologic Therapies Several drug therapies have been tried in both research and clinical settings. There are currently no FDA-approved drugs for the treatment of NAFLD. Hence, at present,

NAFLD patients without NASH or fibrosis should receive only counseling for healthy diet and physical activity. Consideration of additional specific pharmacotherapy for liver disease is restricted to NAFLD patients with more serious liver damage (i.e., NASH or liver fibrosis). A number of large clinical trials designed to identify effective and safe treatments for these conditions are in progress. Because NAFLD is strongly associated with the metabolic syndrome and type 2 diabetes **(Chaps. 403 and 404)**, the efficacy of various insulin-sensitizing agents has been examined. *Metformin*, an agent that mainly improves hepatic insulin sensitivity, has been evaluated in several small, open-label studies in adults and a recent larger, prospectively randomized trial in children (dubbed the TONIC study). Although several of the adult NASH studies suggested improvements in aminotransferases and, less consistently, liver histology, metformin did not improve liver histology in the TONIC study of children with NASH. Thus, it is not currently recommended as a treatment for NASH. *Thiazolidinediones (pioglitazone and rosiglitazone),* drugs known to improve systemic insulin resistance, have been studied in adults with NASH. Both agents reduced aminotransferases and improved some of the histologic features of NASH in small, uncontrolled studies. A large, randomized, placebo-controlled clinical trial sponsored by the National Institutes of Health, the PIVENS Study (Pioglitazone vs Vitamin E vs Placebo for the Treatment of 247 Nondiabetic Adults with NASH), demonstrated that resolution of histologic NASH occurred more often in subjects treated with *pioglitazone* (30 mg/d) than with placebo for 18 months (47 vs 21%, $p = .001$). However, many subjects in the pioglitazone group gained weight, and liver fibrosis did not improve. Five-year follow-up of subjects who were treated with *rosiglitazone* for up to 2 years demonstrated that extending treatment and follow-up duration did not further improve NASH or liver fibrosis, and rosiglitazone has been associated with increased long-term risk for cardiovascular mortality. Pioglitazone may be safer than rosiglitazone, however, because in a recent large meta-analysis it was associated with reduced overall morality, myocardial infarction, and stroke. Caution is still warranted, however, because long-term use of thiazolidinediones has been associated with weight gain, increased risk for bladder cancer, and bone fractures in women.

Incretin mimetics, drugs that act on the pancreas to optimize insulin and glucagon release, have improved liver enzyme elevations. A small pilot trial of daily injections of *liraglutide* and phase 2 studies of *semaglutide* demonstrated remission of NASH without worsening liver fibrosis. Agents that improve hyperglycemia by blocking renal reabsorption of glucose, *sodium glucose cotransporter* (*SGLT2*) *inhibitors,* have been observed to improve serum liver enzymes in diabetic patients with and are also under formal evaluation as treatments for NASH. Both *incretin mimetics* and *SGLT2 inhibitors* can be used in NASH patients with type 2 diabetes or obesity (conditions for which the drugs have an FDA-registered indication for use); however, they are not currently approved specifically for the treatment of NASH.

Antioxidants have also been evaluated for the treatment of NAFLD because oxidant stress is thought to contribute to the pathogenesis of NASH. *Vitamin E*, an inexpensive yet potent antioxidant, has been examined in several small pediatric and adult studies with varying results. In all of those studies, vitamin E was well tolerated, and most studies showed modest improvements in aminotransferase levels, radiographic features of hepatic steatosis, and/or histologic features of NASH. Vitamin E (800 IU/d) was compared to placebo in the PIVENS and TONIC studies. In PIVENS, vitamin E was the only agent that achieved the predetermined primary endpoint (i.e., improvement in steatohepatitis without worsening of fibrosis). This endpoint was met in 43% of patients in the vitamin E group ($p = .001$ vs placebo), 34% in the pioglitazone group ($p = .04$ vs placebo), and 19% in the placebo group. Vitamin E also improved NASH histology in pediatric patients with NASH (TONIC trial). However, recent population-based studies suggest that chronic vitamin E therapy may increase the risk for cardiovascular mortality, hemorrhagic stroke, and prostate cancer. Thus, vitamin E should only be considered as a first-line pharmacotherapy for nondiabetic, noncirrhotic NASH patients who are at low risk for cardiovascular disease or prostate cancer. Further studies are needed before firm recommendations can be made regarding the risk-to-benefit ratio and long-term therapeutic efficacy of vitamin E in NASH. *Ursodeoxycholic acid* (a bile acid that improves certain cholestatic liver diseases) and *betaine* (a metabolite of choline that raises *S*-adenosylmethionine [SAM] levels and decreases cellular oxidative damage) offer no histologic benefit over placebo in patients with NASH. Experimental evidence to support the use of *omega-3 fatty acids* in NAFLD exists; however, a recent large, multicenter, placebo-controlled study failed to demonstrate a histologic benefit.

Many other pharmacotherapies that target dysregulated energy homeostasis, lipotoxicity, cell death, and liver inflammation, processes that are critically involved in the pathogenesis and/or progression of NASH and liver fibrosis, are currently in clinical trials (e.g., *probiotics, farnesoid X receptor agonists, fibroblast growth factor agonists, anti-apoptotic agents, anticytokine agents, dipeptidyl IV antagonists, PPAR modulators, thyroid hormone receptor β-selective agonists, stearyl-CoA desaturase-1 inhibitors, DGAT inhibitors, acyl-CoA carboxylase inhibitors, and direct modulators of liver fibrosis*). Sufficient data do not yet exist to justify their use as NASH treatments in clinical practice. Given that liver disease outcomes in NASH patients are highly heterogeneous, optimal treatment of NASH may need to be individualized by tailoring therapy based on clinical or histologic phenotypes of NASH and/or genetic susceptibility for disease progression.

Statins are an important class of agents to treat dyslipidemia and decrease cardiovascular risk. There is no evidence to suggest that statins cause liver failure in patients with any chronic liver disease, including NAFLD. The incidence of liver enzyme elevations in NAFLD patients taking statins is also no different than that of healthy controls or patients with other chronic liver diseases. Moreover, several studies have suggested that statins may improve aminotransferases and histology in patients with NASH. Yet there is continued reluctance to use statins in patients with NAFLD. The lack of evidence that statins harm the liver in NAFLD patients, combined with the increase risk for cardiovascular morbidity and mortality in NAFLD patients, justifies the use of statins to treat dyslipidemia in patients with NAFLD/NASH.

Bariatric Surgery Although interest in bariatric surgery as a treatment for NAFLD exists, a recently published Cochrane review concluded that lack of randomized clinical trials or adequate clinical studies prevents definitive assessment of benefits and harms of bariatric surgery as a treatment for NASH. Most studies of bariatric surgery have shown that bariatric surgery is generally safe in individuals with well-compensated chronic liver disease and improves hepatic steatosis and necroinflammation (i.e., features of NAFLD/NASH); however, effects on hepatic fibrosis have been variable. Concern lingers because some of the largest prospective studies suggest that hepatic fibrosis might progress after bariatric surgery. Thus, the Cochrane review deemed it premature to recommend bariatric surgery as a primary treatment for NASH. This opinion was challenged by a recently study that demonstrated that fibrosis stage had improved by 5 years after surgery in about half the patients in one large bariatric surgery cohort. However, most of those individuals had relatively mild fibrosis initially, and thus, it is unclear if similar outcomes would occur in individuals with more advanced liver disease. Indeed, there is general agreement that patients with NAFLD-related cirrhosis and, particularly, those with portal hypertension should be excluded as candidates for bariatric surgery. However, given growing evidence for the benefits of bariatric surgery on metabolic syndrome complications in individuals with refractory obesity, it is not contraindicated in otherwise eligible patients with NAFLD or NASH.

Liver Transplantation Patients with NAFLD in whom end-stage liver disease develops should be evaluated for liver transplantation **(Chap. 345)**. The outcomes of liver transplantation in well-selected patients with NAFLD are generally good, but comorbid medical conditions associated with NAFLD, such as diabetes mellitus, obesity, and cardiovascular disease, often limit transplant candidacy. NAFLD may recur after liver transplantation. The risk factors for recurrent or de novo NAFLD after liver transplantation are multifactorial and include hypertriglyceridemia, obesity, diabetes mellitus, and immunosuppressive therapies, particularly glucocorticoids.

GLOBAL HEALTH CONSIDERATIONS

Obesity is an accelerating global disease. The worldwide prevalence of obesity has more than doubled since 1980, and there are now >1 billion overweight adults, of whom at least 300 million are obese. In the wake of the obesity epidemic follow numerous comorbidities, including NAFLD. NAFLD is the most common liver disease identified in Western countries and the fastest rising form of chronic liver disease worldwide. The economic burden directly attributable to NAFLD is already enormous (estimated direct medical costs of ~$103 billion/year in the United States and €35 billion/year in the Europe-4 countries: Germany, France, Italy, and United Kingdom) and predicted to increase tenfold by the year 2025. Present understanding of NAFLD's natural history is based mainly on studies in whites who became overweight/obese and developed the metabolic syndrome in adulthood. The impact of the global childhood obesity epidemic on NAFLD pathogenesis/progression is unknown. Emerging evidence demonstrates that advanced NAFLD, including cirrhosis and primary liver cancer, can occur in children, prompting concerns that childhood-onset NAFLD might follow a more aggressive course than typical adult-acquired NAFLD. Some of the most populated parts of the world are in the midst of industrial revolutions, and certain environmental pollutants seem to exacerbate NAFLD. Some studies also suggest that the risk for NASH and NAFLD-related cirrhosis may be higher in certain ethnic groups such as Asians, Hispanics, and Native Americans, and lower in others such as African Americans, compared with whites. Although all of these variables confound efforts to predict the net impact of this obesity-related liver disease on global health, it seems likely that NAFLD will remain a major cause of chronic liver disease worldwide for the foreseeable future.

344 Cirrhosis and Its Complications

Alex S. Befeler, Bruce R. Bacon

Cirrhosis is a condition that is defined histopathologically and has a variety of clinical manifestations and complications, some of which can be life-threatening. In the past, it has been thought that cirrhosis was never reversible; however, it has become apparent that when the underlying insult that has caused the cirrhosis has been removed, there can be reversal of fibrosis. This is most apparent with the successful treatment of chronic hepatitis C; however, reversal of fibrosis is also seen in patients with hemochromatosis who have been successfully treated and in patients with alcohol associate liver disease who have discontinued alcohol use.

Regardless of the cause of cirrhosis, the pathologic features consist of the development of fibrosis to the point that there is architectural distortion with the formation of regenerative nodules. This results in a decrease in hepatocellular mass, and thus function, and an alteration of blood flow. The induction of fibrosis occurs with activation of hepatic stellate cells, resulting in the formation of increased amounts of collagen and other components of the extracellular matrix.

TABLE 344-1 Causes of Cirrhosis

Alcohol	Cardiac cirrhosis
Chronic viral hepatitis	Inherited metabolic liver disease
Hepatitis B	Hemochromatosis
Hepatitis C	Wilson's disease
Autoimmune hepatitis	α_1 Antitrypsin deficiency
Nonalcoholic steatohepatitis	Cystic fibrosis
Biliary cirrhosis	Cryptogenic cirrhosis
Primary biliary cholangitis	
Primary sclerosing cholangitis	
Autoimmune cholangiopathy	

Clinical features of cirrhosis are the result of pathologic changes and mirror the severity of the liver disease. Most hepatic pathologists provide an assessment of grading and staging when evaluating liver biopsy samples. These grading and staging schemes vary between disease states and have been developed for most conditions, including chronic viral hepatitis, nonalcoholic fatty liver disease, and primary biliary cholangitis. Advanced fibrosis usually includes bridging fibrosis with nodularity designated as stage 3 and cirrhosis designated as stage 4. Patients who have cirrhosis have varying degrees of liver function, and clinicians need to differentiate between those who have stable, compensated cirrhosis and those who have decompensated cirrhosis. Patients who have developed ascites, hepatic encephalopathy, or variceal bleeding are classified as decompensated. They should be considered for liver transplantation, particularly if the decompensations are poorly controlled. Many of the complications of cirrhosis will require specific therapy. *Portal hypertension* is a significant complicating feature of decompensated cirrhosis and is responsible for the development of ascites and bleeding from esophagogastric varices, two complications that signify decompensated cirrhosis. Loss of hepatocellular function results in jaundice, coagulation disorders, and hypoalbuminemia and contributes to the causes of portosystemic encephalopathy. The complications of cirrhosis are basically the same regardless of the etiology. Nonetheless, it is useful to classify patients by the cause of their liver disease (Table 344-1); patients can be divided into broad groups, including those with alcohol-associated cirrhosis, cirrhosis due to chronic viral hepatitis, biliary cirrhosis, nonalcoholic fatty liver disease, and other, less common causes, such as cardiac cirrhosis, cryptogenic cirrhosis, and other miscellaneous causes.

ALCOHOL-ASSOCIATED CIRRHOSIS

Excessive chronic alcohol use can cause several different types of chronic liver disease, including alcohol-associated fatty liver, alcoholic hepatitis, and alcohol-associated cirrhosis. Furthermore, use of excessive alcohol can contribute to liver damage in patients with other liver diseases, such as hepatitis C, hemochromatosis, and fatty liver disease related to obesity. Chronic alcohol use can produce fibrosis in the absence of accompanying inflammation and/or necrosis. Fibrosis can be centrilobular, pericellular, or periportal. When fibrosis reaches a certain degree, there is disruption of the normal liver architecture and replacement of liver cells by regenerative nodules. In alcohol-associated cirrhosis, the nodules are usually <3 mm in diameter; this form of cirrhosis is referred to as *micronodular*. With cessation of alcohol use, larger nodules may form, resulting in a mixed micronodular and macronodular cirrhosis.

Pathogenesis Alcohol is the most commonly used drug in the United States, and >70% of adults drink alcohol each year. Twenty percent have had a binge within the past month, and >7% of adults regularly consume more than four or five drinks five or more times a month. Unfortunately, >14 million adults in the United States meet

the diagnostic criteria for alcohol use disorder. In the United States, chronic liver disease is the tenth most common cause of death in adults, and alcohol-associated cirrhosis accounts for ~48% of deaths due to cirrhosis.

Ethanol is mainly absorbed by the small intestine and, to a lesser degree, through the stomach. Gastric alcohol dehydrogenase (ADH) initiates alcohol metabolism. Three enzyme systems account for metabolism of alcohol in the liver. These include cytosolic ADH, the microsomal ethanol oxidizing system (MEOS) utilizing the inducible cytochrome P450 CYP2E1, and peroxisomal catalase. Normally the majority of ethanol oxidation occurs via ADH to form acetaldehyde, which is a highly reactive molecule that may have multiple effects. The MEOS pathway in chronic alcohol use causes induction of CYP2E1, which leads to generation of reactive oxygen species and produces more acetaldehyde. Ultimately, acetaldehyde is metabolized to acetate by aldehyde dehydrogenase (ALDH). Intake of ethanol increases intracellular accumulation of triglycerides by increasing fatty acid uptake and by reducing fatty acid oxidation and lipoprotein secretion. Protein synthesis, glycosylation, and secretion are impaired. Oxidative damage to hepatocyte membranes occurs due to the formation of reactive oxygen species; acetaldehyde is a highly reactive molecule that combines with proteins and nucleic acids to form acetaldehyde adducts. These adducts may interfere with specific enzyme activities, including microtubular formation and hepatic protein trafficking. With acetaldehyde-mediated hepatocyte damage, certain reactive oxygen species can result in Kupffer cell activation. As a result, profibrogenic cytokines are produced that initiate and perpetuate stellate cell activation, with the resultant production of excess collagen and extracellular matrix. Connective tissue appears in both periportal and pericentral zones and eventually connects portal triads with central veins forming regenerative nodules. Hepatocyte loss occurs, and with increased collagen production and deposition, together with continuing hepatocyte destruction, the liver contracts and shrinks in size. This process generally takes from years to decades to occur and requires repeated insults.

Clinical Features The diagnosis of alcohol associate liver disease requires an accurate history regarding both amount and duration of alcohol consumption. Patients with alcohol associate liver disease can present with nonspecific symptoms such as vague right upper quadrant abdominal pain, fever, nausea and vomiting, diarrhea, anorexia, and malaise. Alternatively, they may present with more specific complications of chronic liver disease, including ascites, edema, upper gastrointestinal (GI) hemorrhage, jaundice, or encephalopathy. Many cases present incidentally at the time of autopsy or elective surgery. The abrupt onset of any of these complications may be the first event prompting the patient to seek medical attention. Other patients may be identified in the course of an evaluation of routine laboratory studies that are found to be abnormal. On physical examination, the liver and spleen may be enlarged, with the liver edge being firm and nodular. Other frequent findings include scleral icterus, palmar erythema **(Fig. 344-1)**, spider angiomas **(Fig. 344-2)**, parotid gland enlargement, digital clubbing, muscle wasting, edema, and ascites. Men may have decreased body hair and gynecomastia as well as testicular atrophy, which may be a consequence of hormonal abnormalities or a direct toxic effect of alcohol on the testes. In women with advanced alcohol-associated cirrhosis, menstrual irregularities usually occur including amenorrhea. These changes are often reversible following cessation of alcohol ingestion.

FIGURE 344-1 Palmar erythema. This figure shows palmar erythema in a patient with alcohol-associated cirrhosis. The erythema is peripheral over the palm with central pallor.

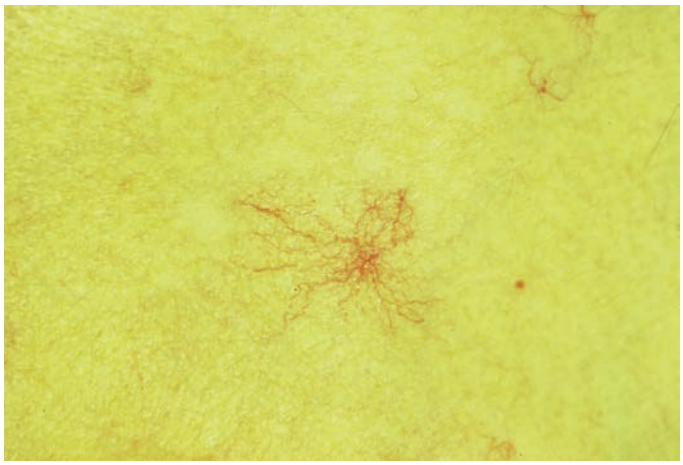

FIGURE 344-2 Spider angioma. This figure shows a spider angioma in a patient with hepatitis C cirrhosis. With release of central compression, the arteriole fills from the center and spreads out peripherally.

Laboratory tests may be completely normal in patients with early compensated alcohol-associated cirrhosis. Alternatively, in advanced liver disease, many abnormalities usually are present. Patients may be anemic from chronic GI blood loss, nutritional deficiencies, or hypersplenism or as a direct suppressive effect of alcohol on the bone marrow. A unique form of hemolytic anemia (with spur cells and acanthocytes) called *Zieve's syndrome* can occur in patients with severe alcoholic hepatitis. Platelet counts are often reduced early in the disease, reflective of portal hypertension with hypersplenism. Serum total bilirubin can be normal or elevated with advanced disease. Prothrombin times are often prolonged and usually do not respond to administration of parenteral vitamin K. Serum sodium levels are usually normal unless patients have ascites and then can be depressed, largely due to ingestion of excess free water. Serum alanine and aspartate aminotransferases (ALT, AST) are typically elevated, particularly in patients who continue to drink, with AST levels being higher than ALT levels, usually by a 2:1 ratio.

Diagnosis Patients who have any of the above-mentioned clinical features, physical examination findings, or laboratory studies should be considered to have alcohol associate liver disease. The diagnosis, however, requires accurate knowledge that the patient is continuing to use or has recently stopped alcohol. Furthermore, other forms of chronic liver disease (e.g., chronic viral hepatitis or metabolic or autoimmune liver diseases) must be considered or ruled out, or if present, an estimate of relative causality along with the alcohol use should be determined. Liver biopsy can be helpful to confirm a diagnosis but generally is not performed unless there is a suspicion of an alternative diagnosis.

In patients who have had complications of cirrhosis and who continue to drink, there is a <50% 5-year survival. In contrast, in patients who are able to remain abstinent, the prognosis is significantly improved, particularly when they have resolution of liver complications; however, some individuals who remain abstinent do not improve and liver transplantation is a viable option.

TREATMENT

Alcohol-Associated Cirrhosis and Alcoholic Hepatitis

Abstinence is the cornerstone of therapy for patients with alcohol associate liver disease. In addition, patients require good nutrition and long-term medical supervision to manage underlying complications that may develop. Complications such as the development of

ascites and edema, variceal hemorrhage, or portosystemic encephalopathy all require specific management and treatment. Liver transplantation can be an effective long-term treatment in those who have been deemed a low enough risk for alcohol relapse and do not respond to other treatments.

Glucocorticoids are occasionally used in patients with severe alcoholic hepatitis in the absence of infection. Short-term survival has been shown to be improved in certain studies and meta-analysis, although 6-month survival is more dependent on abstinence. Treatment is restricted to patients with a discriminant function (DF) value of >32. The DF is calculated as the serum total bilirubin plus the difference in the patient's prothrombin time compared to upper limit of control (in seconds) multiplied by 4.6. Failure to improve total bilirubin after 7 days predicts treatment failure, and glucocorticoids can be stopped; otherwise, they are continued for 28 days.

There is modest evidence that intravenous *N*-acetylcysteine plus glucocorticoids may have survival benefit in alcoholic hepatitis if the DF is >32. Other therapies including oral pentoxifylline, parenterally administered inhibitors of tumor necrosis factor (TNF) α such as infliximab or etanercept, anabolic steroids, propylthiouracil, antioxidants, colchicine, and penicillamine have not shown clear-cut benefits and are not recommended. A variety of nutritional therapies have been tried, both parenteral and enteral feedings; however, there is no clear evidence of improved survival. There is evidence that persons who consume >21.5 kcal/kg body weight per day have better survival, so achieving better caloric intake is recommended. Finally, in highly selected patients with good social support structure who fail other treatments for alcoholic hepatitis, early liver transplant can be an effective treatment.

The cornerstone to treatment is cessation of alcohol use. Recent experience with medications that reduce craving for alcohol, such as acamprosate calcium and baclofen, have been favorable. Patients may take other necessary medications even in the presence of cirrhosis. Acetaminophen use is often discouraged in patients with liver disease; however, if no more than 2 g of acetaminophen per day are consumed, there generally are no problems unless there is active alcohol use.

CIRRHOSIS DUE TO CHRONIC VIRAL HEPATITIS B OR C

Of patients exposed to the hepatitis C virus (HCV), ~80% develop chronic hepatitis C, and of those, ~20–30% will develop cirrhosis over 20–30 years. Many of these patients have had concomitant alcohol use, and the true incidence of cirrhosis due to hepatitis C alone is unknown. It is expected that an even higher percentage will go on to develop cirrhosis over longer periods of time. In the United States, ~5–6 million people have been exposed to HCV, and ~4–5 million are chronically viremic. Worldwide, ~170 million individuals have hepatitis C, with some areas of the world (e.g., Egypt) having up to 15% of the population infected. HCV is a noncytopathic virus, and liver damage is probably immune-mediated. Progression of liver disease due to chronic hepatitis C is characterized by portal-based fibrosis with bridging fibrosis and nodularity developing, ultimately culminating in the development of cirrhosis. In cirrhosis due to chronic hepatitis C, the liver is small and shrunken with characteristic features of a mixed micro- and macronodular cirrhosis seen on liver biopsy. In addition to the increased fibrosis that is seen in cirrhosis due to hepatitis C, an inflammatory infiltrate is found in portal areas with interface hepatitis and occasionally some lobular hepatocellular injury and inflammation. In patients with HCV genotype 3, steatosis is often present.

Similar findings are seen in patients with cirrhosis due to chronic hepatitis B. Of adult patients exposed to hepatitis B, ~5% develop chronic hepatitis B, and ~20% of those patients will go on to develop cirrhosis. Special stains for hepatitis B core (HBc) and hepatitis B surface (HBs) antigen will be positive, and ground-glass hepatocytes signifying HBs antigen (HBsAg) may be present. In the United States, there are ~2 million carriers of hepatitis B, whereas in other parts of the world where hepatitis B virus (HBV) is endemic (i.e., Asia, Southeast Asia, sub-Saharan Africa), up to 15% of the population may be infected, having acquired the infection vertically at the time of birth. Thus, >300–400 million individuals are thought to have hepatitis B worldwide. Approximately 25% of these individuals may ultimately develop cirrhosis.

Clinical Features and Diagnosis Patients with cirrhosis due to either chronic hepatitis C or B can present with the usual symptoms and signs of chronic liver disease. Fatigue, malaise, vague right upper quadrant pain, and laboratory abnormalities are frequent presenting features. Diagnosis requires a thorough laboratory evaluation, including quantitative HCV RNA testing and analysis for HCV genotype, or hepatitis B serologies to include HBsAg, anti-HBs, HBeAg (hepatitis B e antigen), anti-HBe, and quantitative HBV DNA levels.

TREATMENT

Cirrhosis due to Chronic Viral Hepatitis B or C

Management of complications of cirrhosis revolves around specific therapy for treatment of whatever complications occur (e.g., esophageal variceal hemorrhage, development of ascites and edema, or encephalopathy). In patients with chronic hepatitis B, numerous studies have shown beneficial effects of antiviral therapy, which is effective at viral suppression, as evidenced by reducing aminotransferase levels and HBV DNA levels and improving histology by reducing inflammation and fibrosis. Several clinical trials and case series have demonstrated that patients with decompensated liver disease can become compensated with the use of antiviral therapy directed against hepatitis B. Currently available therapy includes lamivudine, adefovir, telbivudine, entecavir, and tenofovir, with the latter two being preferred because of reduced risk of viral resistance. Interferon α can also be used for treating hepatitis B, but it should not be used in cirrhotics **(see Chap. 341)**.

Treatment of patients with cirrhosis due to hepatitis C used to be more difficult because the side effects of pegylated interferon and ribavirin therapy were difficult to manage. Over the past several years, interferon-based regimens have been replaced by direct-acting antiviral protocols that are highly successful (>95% cure rate), well tolerated, and usually of short duration (8–12 weeks), but costly. These medications have truly revolutionized the treatment of hepatitis C **(see Chap. 341)**.

CIRRHOSIS FROM AUTOIMMUNE HEPATITIS AND NONALCOHOLIC FATTY LIVER DISEASE

Other causes of posthepatitic cirrhosis include autoimmune hepatitis (AIH) and cirrhosis due to nonalcoholic steatohepatitis. Many patients with AIH present with cirrhosis that is already established. Typically, these patients will not benefit from immunosuppressive therapy with glucocorticoids or azathioprine because the AIH is "burned out." In this situation, liver biopsy does not show a significant inflammatory infiltrate. Diagnosis in this setting requires positive autoimmune markers such as antinuclear antibody (ANA) or anti-smooth-muscle antibody (ASMA). When patients with AIH present with cirrhosis and active inflammation accompanied by elevated liver enzymes, there can be considerable benefit from the use of immunosuppressive therapy.

Patients with nonalcoholic steatohepatitis are increasingly being found to have progressed to cirrhosis. With the epidemic of obesity that continues in Western countries, more and more patients are identified with nonalcoholic fatty liver disease **(Chap. 343)**. Of these, a significant subset has nonalcoholic steatohepatitis and can progress to increased fibrosis and cirrhosis. Over the past several years, it has been increasingly recognized that many patients who were thought to have cryptogenic cirrhosis in fact have nonalcoholic steatohepatitis. As their cirrhosis progresses, they become catabolic and then lose the telltale signs of steatosis seen on biopsy. Management of complications of cirrhosis due to either AIH or nonalcoholic steatohepatitis is similar to that for other forms of cirrhosis.

BILIARY CIRRHOSIS

Biliary cirrhosis has pathologic features that are different from either alcohol-associated cirrhosis or posthepatitic cirrhosis, yet the manifestations of end-stage liver disease are the same. Cholestatic liver disease may result from necroinflammatory lesions, congenital or metabolic processes, or external bile duct compression. Thus, two broad categories reflect the anatomic sites of abnormal bile retention: *intrahepatic* and *extrahepatic*. The distinction is important for obvious therapeutic reasons. Extrahepatic obstruction may benefit from surgical or endoscopic biliary tract decompression, whereas intrahepatic cholestatic processes will not improve with such interventions and require a different approach.

The major causes of chronic cholestatic syndromes are primary biliary cholangitis (PBC), autoimmune cholangitis (AIC), primary sclerosing cholangitis (PSC), and idiopathic adulthood ductopenia. These syndromes are usually clinically distinguished from each other by antibody testing, cholangiographic findings, and clinical presentation. However, they all share the histopathologic features of chronic cholestasis, such as cholate stasis; copper deposition; xanthomatous transformation of hepatocytes; and irregular, so-called biliary fibrosis. In addition, there may be chronic portal inflammation, interface activity, and chronic lobular inflammation. Ductopenia is a result of this progressive disease as patients develop cirrhosis.

PRIMARY BILIARY CHOLANGITIS

PBC is seen in about 100–200 individuals per million, with a strong female preponderance and a median age of ~50 years at the time of diagnosis. The cause of PBC is unknown; it is characterized by portal inflammation and necrosis of cholangiocytes in small- and medium-sized bile ducts. Cholestatic features prevail, and biliary cirrhosis is characterized by an elevated bilirubin level and progressive liver failure. Liver transplantation is the treatment of choice for patients with decompensated cirrhosis due to PBC. Ursodeoxycholic acid (UDCA) is the first-line treatment that has some degree of efficacy by slowing the rate of progression of the disease.

Antimitochondrial antibodies (AMAs) are present in ~95% of patients with PBC. These autoantibodies recognize lipoic acid on the inner mitochondrial membrane proteins that are enzymes of the pyruvate dehydrogenase complex (PDC), the branched-chain 2-oxoacid dehydrogenase complex, and the 2-oxogluterate dehydrogenase complex. These autoantibodies are not pathogenic, but rather are useful markers for making a diagnosis.

Pathology Histopathologic analyses of liver biopsies of patients with PBC have resulted in identifying four distinct stages of the disease as it progresses. The earliest lesion is termed *chronic nonsuppurative destructive cholangitis* and is a necrotizing inflammatory process of the portal tracts. Medium and small bile ducts are infiltrated with lymphocytes and undergo duct destruction. Mild fibrosis and sometimes bile stasis can occur. With progression, the inflammatory infiltrate becomes less prominent, but the number of bile ducts is reduced and there is proliferation of smaller bile ductules. Increased fibrosis ensues with the expansion of periportal fibrosis to bridging fibrosis. Finally, cirrhosis, which may be micronodular or macronodular, develops.

Clinical Features Currently, most patients with PBC are middle-aged women diagnosed well before the end-stage manifestations of the disease are present, and as such, most patients are asymptomatic. When symptoms are present, they most prominently include a significant degree of fatigue out of proportion to either the severity of the liver disease or the age of the patient. Pruritus is seen in ~50% of patients at the time of diagnosis, and it can be debilitating. It might be intermittent and usually is most bothersome in the evening. In some patients, pruritus can develop toward the end of pregnancy and can be mistaken for cholestasis of pregnancy. Pruritus that presents prior to the development of jaundice indicates severe disease and a poor prognosis.

Physical examination can show jaundice and other complications of chronic liver disease including hepatomegaly, splenomegaly, ascites, and edema. Other features that are unique to PBC include hyperpigmentation, xanthelasma, and xanthomata, which are related to altered cholesterol metabolism. Hyperpigmentation is evident on the trunk and the arms and is seen in areas of exfoliation and lichenification associated with progressive scratching related to the pruritus. Bone pain resulting from osteopenia or osteoporosis is occasionally seen at diagnosis.

Laboratory Findings Laboratory findings in PBC show cholestatic liver enzyme abnormalities with an elevation in γ-glutamyl transpeptidase and alkaline phosphatase (ALP) along with mild elevations in aminotransferases (ALT and AST). Immunoglobulins, particularly IgM, are typically increased. Hyperbilirubinemia usually is seen once cirrhosis has developed. Thrombocytopenia, leukopenia, and anemia may be seen in patients with portal hypertension and hypersplenism. Liver biopsy shows characteristic features as described above and should be evident to any experienced hepatopathologist. Up to 10% of patients with characteristic PBC will have features of AIH (moderate to severe interphase hepatitis on biopsy, elevated ALT >5× the upper limit of normal, and elevated IgG levels) as well and are defined as having "overlap" syndrome. These patients are usually treated as PBC patients and may progress to cirrhosis with the same frequency as typical PBC patients. Some patients require immunosuppressive medications as well.

Diagnosis PBC should be considered in patients with chronic cholestatic liver enzyme abnormalities. AMA testing may be negative in as many as 5–10% of patients with PBC. These patients usually are positive for other PBC-specific autoantibodies including sp100 or gp210, although these tests are not universally available. Liver biopsy is most important in this setting of AMA-negative PBC. In patients who are AMA negative with cholestatic liver enzymes, PSC should be ruled out by way of cholangiography.

TREATMENT

Primary Biliary Cholangitis

Treatment of the typical manifestations of cirrhosis is no different for PBC than for other forms of cirrhosis. UDCA has been shown to improve both biochemical and histologic features of the disease, thus slowing but not reversing or curing the disease. Improvement is greatest when therapy is initiated early; the likelihood of significant improvement with UDCA is low in patients with PBC who present with manifestations of cirrhosis. UDCA is given in doses of 13–15 mg/kg per d; the medication is usually well tolerated, although some patients have worsening pruritus with initiation of therapy. A small proportion of patients may have diarrhea or headache as a side effect of the drug. About 30–40% of patients with PBC do not have a satisfactory response to UDCA; about half of these patients will have significant improvement with obeticholic acid. Patients with PBC require long-term follow-up by a physician experienced with the disease. Certain patients may need to be considered for liver transplantation should their liver disease decompensate.

The main symptoms of PBC are fatigue and pruritus, and symptom management is important. Several therapies have been tried for treatment of fatigue, but none of them has been successful; frequent naps should be encouraged. Pruritus is treated with antihistamines, narcotic receptor antagonists (naltrexone), and rifampin. Cholestyramine, a bile salt–sequestering agent, has been helpful in some patients but is somewhat tedious and difficult to take. Plasmapheresis has been used rarely in patients with severe intractable pruritus. There is an increased incidence of osteopenia and osteoporosis in patients with cholestatic liver disease, and bone density testing should be performed. Oral calcium and vitamin D are also recommended. Treatment with a bisphosphonate should be instituted when bone disease is identified.

PRIMARY SCLEROSING CHOLANGITIS

As in PBC, the cause of PSC remains unknown. PSC is a chronic cholestatic syndrome that is characterized by diffuse inflammation and fibrosis involving the entire biliary tree, resulting in chronic cholestasis.

This pathologic process ultimately results in obliteration of both the intra- and extrahepatic biliary tree, leading to biliary cirrhosis, portal hypertension, and liver failure. The cause of PSC remains unknown despite extensive investigation into various mechanisms related to bacterial and viral infections, toxins, genetic predisposition, and immunologic mechanisms, all of which have been postulated to contribute to the pathogenesis and progression of this syndrome.

Liver biopsy changes in PSC are not pathognomonic, and establishing the diagnosis of PSC must involve imaging of the biliary tree. Pathologic changes occurring in PSC show bile duct proliferation as well as ductopenia and fibrous cholangitis (pericholangitis). Periductal fibrosis is occasionally seen on biopsy specimens and can be quite helpful in making the diagnosis. As the disease progresses, biliary cirrhosis is the end-stage manifestation of PSC.

Clinical Features The usual clinical features of PSC are those found in cholestatic liver disease, with fatigue, pruritus, steatorrhea, deficiencies of fat-soluble vitamins, and the associated consequences. As in PBC, the fatigue is profound and nonspecific. Pruritus can often be debilitating and is related to the cholestasis. The severity of pruritus does not correlate with the severity of the disease. Metabolic bone disease, as seen in PBC, can occur with PSC and should be treated (see above).

Laboratory Findings Patients with PSC typically are identified during an evaluation of abnormal liver enzymes. Most patients have at least a twofold increase in ALP and may have elevated aminotransferases as well. Albumin levels may be decreased, and prothrombin times are prolonged in a substantial proportion of patients at the time of diagnosis. Some degree of correction of a prolonged prothrombin time may occur with parenteral vitamin K. A small subset of patients has aminotransferase elevations >5× the upper limit of normal and may have features of AIH on biopsy indicating an overlap syndrome between PSC and AIH. Autoantibodies are frequently positive in patients with the overlap syndrome but are typically negative in patients who only have PSC. One autoantibody, the perinuclear antineutrophil cytoplasmic antibody (pANCA), is positive in ~65% of patients with PSC. Sixty to eighty percent of patients with PSC have inflammatory bowel disease, predominately ulcerative colitis (UC); thus, a colonoscopy is recommended at diagnosis.

Diagnosis The definitive diagnosis of PSC requires cholangiographic imaging. Over the past several years, magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP) has been used as the imaging technique of choice for initial evaluation. Endoscopic retrograde cholangiopancreatography (ERCP) should be performed if the MRCP provided suboptimal images or if there is clinical (newly elevated total bilirubin or worsening pruritus) or MRCP evidence of a dominant stricture. Typical cholangiographic findings in PSC are multifocal stricturing and beading involving both the intrahepatic and extrahepatic biliary tree. These strictures are typically short and with intervening segments of normal or slightly dilated bile ducts that are distributed diffusely, producing the classic beaded appearance. The gallbladder and cystic duct can be involved in up to 15% of cases. Gradually, biliary cirrhosis develops, and patients will progress to decompensated liver disease with all the manifestations of ascites, esophageal variceal hemorrhage, and encephalopathy.

TREATMENT

Primary Sclerosing Cholangitis

There is no specific proven treatment for PSC. Some clinicians use UDCA at "PBC dosages" of 13–15 mg/kg per d with anecdotal improvement, although no study has shown convincing evidence of clinical benefit. A study of high-dose (28–30 mg/kg per d) UDCA found it to be harmful. Endoscopic dilatation of dominant strictures can be helpful, but the ultimate treatment is liver transplantation when decompensated cirrhosis develops. Episodes of cholangitis should be treated with antibiotics. A dreaded complication of PSC is the development of cholangiocarcinoma, which is a relative contraindication to liver transplantation.

CARDIAC CIRRHOSIS

Definition Patients with long-standing right-sided congestive heart failure may develop chronic liver injury and cardiac cirrhosis. This is an increasingly uncommon, if not rare, cause of chronic liver disease given the advances made in the care of patients with heart failure.

Etiology and Pathology In the case of long-term right-sided heart failure, there is an elevated venous pressure transmitted via the inferior vena cava and hepatic veins to the sinusoids of the liver, which become dilated and engorged with blood. The liver becomes enlarged and swollen, and with long-term passive congestion and relative ischemia due to poor circulation, centrilobular hepatocytes can become necrotic, leading to pericentral fibrosis. This fibrotic pattern can extend to the periphery of the lobule outward until a unique pattern of fibrosis causing cirrhosis can occur.

Clinical Features Patients typically have signs of congestive heart failure and will manifest an enlarged firm liver on physical examination. ALP levels are characteristically elevated, and aminotransferases may be normal or slightly increased, with AST usually higher than ALT. It is unlikely that patients will develop variceal hemorrhage or encephalopathy.

Diagnosis The diagnosis is usually made in someone with clear-cut cardiac disease who has an elevated ALP and an enlarged liver. Liver biopsy shows a pattern of fibrosis that can be recognized by an experienced hepatopathologist. Differentiation from Budd-Chiari syndrome (BCS) can be made by seeing extravasation of red blood cells in BCS, but not in cardiac hepatopathy. Veno-occlusive disease, now termed sinusoidal obstructive syndrome, can also affect hepatic outflow and has characteristic features on liver biopsy. Sinusoidal obstructive syndrome can be seen under the circumstances of conditioning for bone marrow transplant with radiation and chemotherapy; it can also be seen with the ingestion of certain herbal teas as well as pyrrolizidine alkaloids. This is typically seen in Caribbean countries and rarely in the United States. Treatment is based on management of the underlying cardiac disease.

OTHER TYPES OF CIRRHOSIS

There are several other less common causes of chronic liver disease that can progress to cirrhosis. These include inherited metabolic liver diseases such as hemochromatosis, Wilson's disease, α_1 antitrypsin (α_1AT) deficiency, and cystic fibrosis. For these disorders, the manifestations of cirrhosis are similar, with some minor variations, to those seen in other patients with other causes of cirrhosis.

Hemochromatosis is an inherited disorder of iron metabolism that results in a progressive increase in hepatic iron deposition, which, over time, can lead to a portal-based fibrosis progressing to cirrhosis, liver failure, and hepatocellular cancer. While the frequency of hemochromatosis is relatively common, with genetic susceptibility occurring in 1 in 250 individuals, the frequency of end-stage manifestations due to the disease is relatively low, and <5% of those patients who are genotypically susceptible will go on to develop severe liver disease from hemochromatosis. Diagnosis is made with serum iron studies showing an elevated transferrin saturation and an elevated ferritin level, along with abnormalities identified by *HFE* mutation analysis. Treatment is straightforward, with regular therapeutic phlebotomy.

Wilson's disease is an inherited disorder of copper homeostasis with failure to excrete excess amounts of copper, leading to an accumulation in the liver. This disorder is relatively uncommon, affecting 1 in 30,000 individuals. Wilson's disease typically affects adolescents and young adults. Prompt diagnosis before end-stage manifestations become irreversible can lead to significant clinical improvement. Diagnosis requires determination of ceruloplasmin levels, which are low; 24-h urine copper levels, which are elevated; typical physical examination findings, including Kayser-Fleischer corneal rings; and characteristic liver biopsy findings. Treatment consists of copper-chelating medications.

α_1AT deficiency results from an inherited disorder that causes abnormal folding of the α_1AT protein, resulting in failure of secretion of that

protein from the liver. It is unknown how the retained protein leads to liver disease. Patients with α_1AT deficiency at greatest risk for developing chronic liver disease have the ZZ phenotype, but only ~10–20% of such individuals will develop chronic liver disease. Diagnosis is made by determining α_1AT levels and phenotype. Characteristic periodic acid–Schiff (PAS)–positive, diastase-resistant globules are seen on liver biopsy. The only effective treatment is liver transplantation, which is curative.

Cystic fibrosis is an uncommon inherited disorder affecting whites of northern European descent. A biliary-type cirrhosis can occur, and some patients derive benefit from the chronic use of UDCA.

MAJOR COMPLICATIONS OF CIRRHOSIS

These include gastroesophageal variceal hemorrhage, splenomegaly, ascites, hepatic encephalopathy, spontaneous bacterial peritonitis (SBP), hepatorenal syndrome (HRS), and hepatocellular carcinoma **(Table 344-2)**. There are also more rare complications in the pulmonary system including hepatopulmonary syndrome and portopulmonary hypertension.

PORTAL HYPERTENSION

Portal hypertension is defined as the elevation of the hepatic venous pressure gradient (HVPG) to >5 mmHg. Portal hypertension is caused by a combination of two simultaneously occurring hemodynamic processes: (1) increased intrahepatic resistance to the passage of blood flow through the liver due to cirrhosis, regenerative nodules, and microthrombi, and (2) increased splanchnic blood flow secondary to vasodilation within the splanchnic vascular bed. In more advanced stages, there is also activation of neurohumoral responses and vasoconstrictive systems resulting in sodium and water retention, increased blood volume, and hyperdynamic circulatory system producing more portal hypertension. There is usually an initial stage of compensated cirrhosis with HVPG between 5 and 10 mmHg that can be asymptomatic and last for ≥10 years, but when clinically significant portal hypertension develops (defined as a HVPG ≥10 mmHg), there is substantial risk of decompensation with variceal bleeding, ascites, or hepatic encephalopathy. With decompensation, median mortality is <2 years. *Variceal hemorrhage* is an immediate life-threatening problem with a 20–30% mortality rate associated with each episode of bleeding. The portal venous system normally drains blood from most of the GI tract including the stomach, small and large intestines, spleen, pancreas, and gallbladder.

The causes of portal hypertension are usually subcategorized as prehepatic, intrahepatic, and posthepatic **(Table 344-3)**. Prehepatic causes of portal hypertension are those affecting the portal venous system before it enters the liver; they include portal vein thrombosis and splenic vein thrombosis. Posthepatic causes encompass those affecting the hepatic veins and venous drainage to the heart; they include BCS and chronic right-sided cardiac congestion. Intrahepatic causes account for >95% of cases of portal hypertension and are represented by the major forms of cirrhosis. Intrahepatic causes of portal hypertension can be further subdivided into presinusoidal, sinusoidal, and postsinusoidal causes. Postsinusoidal causes include veno-occlusive disease, whereas presinusoidal causes include congenital hepatic fibrosis and schistosomiasis. Sinusoidal causes are related to cirrhosis from various causes.

TABLE 344-2 Complications of Cirrhosis

Portal hypertension	Coagulopathy
Gastroesophageal varices	Factor deficiency
Portal hypertensive gastropathy	Fibrinolysis
Splenomegaly, hypersplenism	Thrombocytopenia
Ascites	Bone disease
Spontaneous bacterial peritonitis	Osteopenia
Hepatorenal syndrome	Osteoporosis
Type 1	Osteomalacia
Type 2	Hematologic abnormalities
Hepatic encephalopathy	Anemia
Hepatopulmonary syndrome	Hemolysis
Portopulmonary hypertension	Thrombocytopenia
Malnutrition	Neutropenia

TABLE 344-3 Classification of Portal Hypertension

Prehepatic
Portal vein thrombosis
Splenic vein thrombosis
Massive splenomegaly (Banti's syndrome)
Hepatic
Presinusoidal
Schistosomiasis
Congenital hepatic fibrosis
Sinusoidal
Cirrhosis—many causes
Alcoholic hepatitis
Postsinusoidal
Hepatic sinusoidal obstruction (veno-occlusive syndrome)
Posthepatic
Budd-Chiari syndrome
Inferior vena caval webs
Cardiac causes
Restrictive cardiomyopathy
Constrictive pericarditis
Severe congestive heart failure

Cirrhosis is the most common cause of portal hypertension in the United States, and clinically significant portal hypertension is present in >60% of patients with cirrhosis. Portal vein obstruction may be idiopathic or can occur in association with cirrhosis or with infection, pancreatitis, or abdominal trauma.

Coagulation disorders that can lead to the development of portal vein thrombosis include polycythemia vera; essential thrombocytosis; deficiencies in protein C, protein S, antithrombin III, and factor V Leiden; and abnormalities in the gene-regulating prothrombin production. Some patients may have a subclinical myeloproliferative disorder.

Clinical Features The three primary complications of portal hypertension are gastroesophageal varices with hemorrhage, ascites, and hypersplenism. Thus, patients may present with upper GI bleeding, which, on endoscopy, is found to be due to esophageal or gastric varices; with the development of ascites along with peripheral edema; or with an enlarged spleen with associated reduction in platelets and white blood cells on routine laboratory testing.

ESOPHAGEAL VARICES Over the past decade, it has become common practice to screen known cirrhotics with endoscopy to look for esophageal varices. Such screening studies have shown that approximately one-third of patients with histologically confirmed cirrhosis have varices. Approximately 5–15% of cirrhotics per year develop varices, and it is estimated that the majority of patients with cirrhosis will develop varices over their lifetimes. Furthermore, it is anticipated that roughly one-third of patients with varices will develop bleeding. Several factors predict the risk of bleeding, including the severity of cirrhosis (Child-Pugh class, Model for End-Stage Liver Disease [MELD] score); the height of wedged-hepatic vein pressure; the size of the varix; the location of the varix; and certain endoscopic stigmata, including red wale signs, hematocystic spots, diffuse erythema, bluish color, cherry red spots, or white-nipple spots. Patients with tense ascites are also at increased risk for bleeding from varices.

Diagnosis In patients with cirrhosis who are being followed chronically, the development of portal hypertension is usually revealed by the presence of thrombocytopenia; the appearance of an enlarged spleen; or the development of ascites, encephalopathy, and/or esophageal varices with or without bleeding. In previously undiagnosed patients, any of these features should prompt further evaluation to determine the presence of portal hypertension and liver disease. Varices should

be identified by endoscopy. Contrasted-enhanced abdominal imaging, either by computed tomography (CT) or MRI, can be helpful in demonstrating a nodular liver and in finding changes of portal hypertension with intraabdominal collateral circulation. Rarely, the HVPG is measured by interventional radiology. Patients with a gradient >12 mmHg are at risk for variceal hemorrhage.

TREATMENT

Variceal Hemorrhage

Treatment for esophageal varices as a complication of portal hypertension is divided into two main categories: (1) primary prophylaxis and (2) prevention of rebleeding once there has been an initial variceal hemorrhage. Primary prophylaxis requires routine surveillance by endoscopy of all patients with cirrhosis. Upper endoscopies are recommended at diagnosis of compensated cirrhosis and then every 2 years if the liver disease is active or every 3 years if inactive (alcohol cessation, viral hepatitis eradication). Endoscopy is also recommended at the time of hepatic decompensation. Once varices that are at increased risk for bleeding are identified, usually defined as medium or large varices or small varices with high-risk stigmata or in decompensated cirrhosis, primary prophylaxis can be achieved either through nonselective beta blockade (NSBB) titrated with a goal heart rate of 55–60 beats/min with systolic blood pressure >90 mmHg or by variceal band ligation. Numerous placebo-controlled clinical trials of either propranolol or nadolol show a lower risk of variceal hemorrhage and mortality related to variceal hemorrhage but no clear benefit on overall survival.

Endoscopic variceal ligation (EVL) has been compared to NSBB for primary prophylaxis against variceal bleeding, and EVL appears to have equivalent efficacy. Two more recent trials comparing EVL to carvedilol, a drug with NSBB and anti–α_1-adrenergic properties, showed similar efficacy. Thus, either NSSB or EVL is effective for primary prophylaxis of bleeding, and the choice should be based on patient and physician preference and tolerability. Once primary prophylaxis has been initiated, repeat endoscopy for surveillance of varices is unnecessary.

The approach to patients once they have had a variceal bleed is first to treat the acute bleed, which can be life-threatening, and then to prevent further bleeding. Treatment of acute bleeding requires both fluid and red blood cell replacement to stabilize hemodynamics. A recent randomized trial of restricted transfusion starting when hemoglobin is <7 g/dL with a goal hemoglobin of 7–9 g/dL, compared to a more liberal strategy, resulted in reduced early rebleeding and mortality. This strategy is recommended, although adjustments should be made based on cardiac risks and hemodynamics. Correcting an elevated prothrombin time with fresh frozen plasma is not recommended unless there is evidence of coagulopathy (bleeding at other sites such as IV lines). The use of vasoconstricting agents, usually somatostatin or octreotide, has been shown to improve initial bleeding control and reduce transfusion requirements and all-cause mortality. Prophylactic antibiotics, usually with ceftriaxone, started prior to endoscopy result in reduced infections, recurrent bleeding, and mortality. Balloon tamponade (Sengstaken-Blakemore tube or Minnesota tube) can be used in patients who need stabilization prior to endoscopic therapy or as a bridge to transjugular intrahepatic portosystemic shunt (TIPS) after endoscopic failure. Control of bleeding can be achieved in the vast majority of cases; however, bleeding recurs in the majority of patients if definitive endoscopic therapy has not been instituted. Upper endoscopy is used as first-line treatment to diagnose the cause of the bleeding and to control bleeding acutely with EVL. When esophageal varices extend into the proximal stomach or the bleeding varices are entirely within the stomach, band ligation is often unsuccessful. In these situations, consideration for a TIPS should be made. This technique creates a portosystemic shunt by a percutaneous approach using an expandable metal stent, which is advanced under angiographic guidance to the hepatic veins and then through the substance of the liver to create a direct portocaval shunt. Encephalopathy can occur in as many as 20% of patients after TIPS and is particularly problematic in elderly patients and in patients with preexisting encephalopathy. TIPS is usually reserved for individuals who fail or are unable to receive endoscopic therapy, although there is emerging evidence that patient who are highly selected to be at high risk for rebleeding may also benefit. TIPS can sometimes be used as a bridge to transplantation, and all patients requiring TIPS should be considered for transplant evaluation. Some gastric varices are associated with a splenorenal shunt and can be effectively treated with a balloon occluded retrograde transvenous obliteration (BRTO) of varices sometimes in combination with a TIPS. Prevention of further bleeding is usually accomplished with repeated variceal band ligation until varices are obliterated in combination with NSBB. If recurrent variceal bleeding occurs, then TIPS should be performed for long-term prevention of bleeding. Once a TIPS has been performed, there is no need for further endoscopies for variceal surveillance; however, the TIPS should be periodically monitored with Doppler ultrasound for stenosis. **(Fig. 344-3)**.

PORTAL HYPERTENSIVE GASTROPATHY

Portal hypertensive gastropathy can cause both acute clinical GI bleeding and chronic bleeding resulting in iron-deficiency anemia. It is associated with all causes of portal hypertension and is diagnosed by characteristic endoscopy findings showing a snake skin–like mosaic pattern of gastric mucosa often with central red or brown spots. When there is bleeding, treatment is with NSBB and iron repletion. Refractory bleeding may respond to TIPS.

SPLENOMEGALY AND HYPERSPLENISM

Congestive splenomegaly with hypersplenism is common in patients with portal hypertension and is usually the first indication of portal hypertension. Clinical features include the presence of an enlarged spleen on physical examination and the development of thrombocytopenia and leukopenia in patients who have cirrhosis. Some patients will have significant left-sided and left upper quadrant abdominal pain

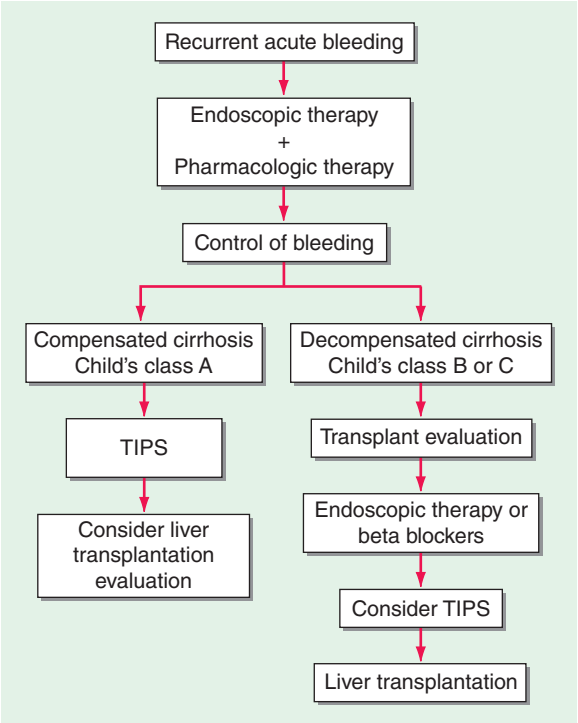

FIGURE 344-3 Management of recurrent variceal hemorrhage. This algorithm describes an approach to management of patients who have recurrent bleeding from esophageal varices. Initial therapy is generally with endoscopic therapy often supplemented by pharmacologic therapy. With control of bleeding, a decision needs to be made as to whether patients should go on to transjugular intrahepatic portosystemic shunt (TIPS; if they are Child's class A) or if they should have TIPS and be considered for transplant (if they are Child's class B or C).

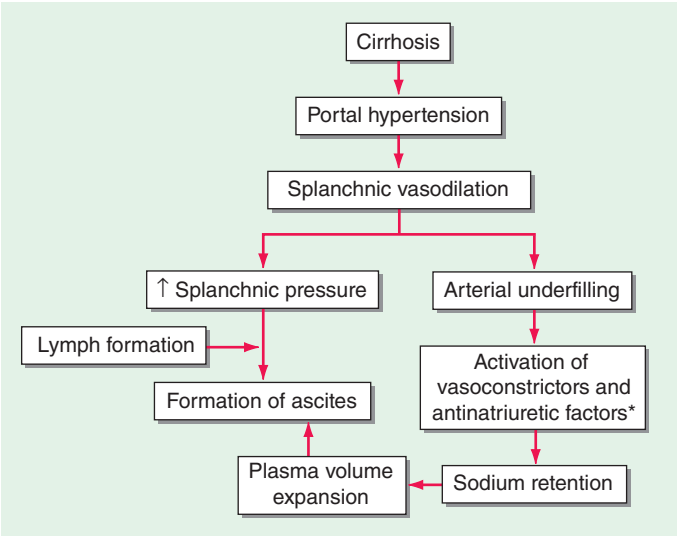

FIGURE 344-4 Development of ascites in cirrhosis. This flow diagram illustrates the importance of portal hypertension with splanchnic vasodilation in the development of ascites. *Antinatriuretic factors include the renin-angiotensin-aldosterone system and the sympathetic nervous system.

related to an enlarged spleen. Splenomegaly itself usually requires no specific treatment.

ASCITES

Definition Ascites is the accumulation of fluid within the peritoneal cavity. Overwhelmingly, the most common cause of ascites is portal hypertension related to cirrhosis; however, clinicians should remember that malignant, infectious, and cardiac causes of ascites can be present as well, and careful differentiation of these other causes is obviously important for patient care.

Pathogenesis The presence of portal hypertension contributes to the development of ascites in patients who have cirrhosis **(Fig. 344-4)**. There is an increase in intrahepatic resistance, causing increased portal pressure, but there is also vasodilation of the splanchnic arterial system, which, in turn, results in an increase in portal venous inflow. Both abnormalities result in increased production of splanchnic lymph. Vasodilating factors such as nitric oxide are responsible for the vasodilatory effect. There is activation of the renin-angiotensin-aldosterone system with the development of hyperaldosteronism and activation of the sympathetic nervous system as a consequence of a homeostatic response caused by underfilling of the arterial circulation secondary to arterial vasodilation in the splanchnic vascular bed. The renal effects of increased aldosterone and activation of the sympathetic nervous system lead to sodium retention causing fluid accumulation and expansion of the extracellular fluid volume, resulting in peripheral edema and ascites. Because the retained fluid is constantly leaking out of the intravascular compartment into the peritoneal cavity, the sensation of vascular filling is not achieved, and the process continues. Hypoalbuminemia from decreased synthetic function in a cirrhotic liver results in reduced plasma oncotic pressure and contributes to the loss of fluid from the vascular compartment into the peritoneal cavity.

Clinical Features Patients typically note an increase in abdominal girth that is often accompanied by the development of peripheral edema. The development of ascites is often insidious, and it is surprising that some patients wait so long and become so distended before seeking medical attention. Patients usually have at least 1–2 L of fluid in the abdomen before they are aware that there is an increase. If ascitic fluid is massive, respiratory function can be compromised, causing dyspnea. Hepatic hydrothorax may also contribute to respiratory symptoms. Patients with massive ascites are often malnourished and have muscle wasting and excessive fatigue and weakness.

Diagnosis Diagnosis of ascites is by physical examination and is often aided by abdominal imaging. Patients will have bulging flanks, may have a fluid wave, or may have the presence of shifting dullness. This is determined by taking patients from a supine position to lying on either their left or right side and noting the movement of the dullness to percussion. Subtle amounts of ascites can be detected by ultrasound or CT scanning. Hepatic hydrothorax is more common on the right side and implicates a rent in the diaphragm with free flow of ascitic fluid into the thoracic cavity.

When patients present with ascites for the first time, it is recommended that a diagnostic paracentesis be performed to characterize the fluid. This should include the determination of total protein and albumin content, blood cell counts with differential, and cultures. In the appropriate setting, amylase may be measured and cytology performed. In patients with cirrhosis, the protein concentration of the ascitic fluid is low, usually <2.5 g/dL. The serum ascites-to-albumin gradient (SAAG), calculated by subtracting the fluid albumin level from the serum albumin level, has replaced the description of exudative or transudative fluid. When the SAAG is >1.1 g/dL, the cause of the ascites is most likely due to portal hypertension; this is usually in the setting of cirrhosis. Cardiac ascites can be identified by SAAG >1.1 g/dL and ascites protein >2.5g/dL. When the SAAG is <1.1 g/dL, infectious or malignant causes of ascites should be considered. When ascitic fluid protein is very low, <1.5 g/dL, patients are at increased risk for developing SBP. A high level of red blood cells in the ascitic fluid usually signifies a traumatic tap but can also rarely occur with hepatocellular cancer or a ruptured omental varix. When the absolute level of polymorphonuclear leukocytes is >250/μL, infection is likely.

TREATMENT

Ascites

Patients with small amounts of ascites can usually be managed with dietary sodium restriction alone. Most average diets in the United States contain 6–8 g of sodium per day, and if patients eat at restaurants or fast-food outlets, the amount of sodium in their diet can exceed this amount. Thus, it is often extremely difficult to get patients to change their dietary habits to ingest 2 g of sodium per day, equivalent to slightly more than three-quarters of a teaspoon of salt, which is the recommended amount. Sodium educational pamphlets are helpful. Often, a simple recommendation is to eat fresh or frozen foods, avoiding canned or processed foods. When a moderate amount of ascites is present, diuretic therapy is usually necessary. Traditionally, spironolactone at 100 mg/d as a single dose is started, and furosemide may be added at 40 mg/d, particularly in patients who have peripheral edema. Failure of the diuretics suggests that patients may not be compliant with a low-sodium diet. If compliance is confirmed and ascitic fluid is not being mobilized, there should be incremental increases in spironolactone to a maximum of 400 mg/d and furosemide to 160 mg/d. If a large amount of ascites is still present on diuretics in patients who are compliant with a low-sodium diet, then they are defined as having *refractory ascites*, and alternative treatment modalities including repeated large-volume paracentesis (LVP) or a TIPS procedure should be considered **(Fig. 344-5)**. After LVP of ≥5 L, IV 25% albumin at a dose of ~8 g/L of removed ascites should be given to prevent circulatory dysfunction. Multiple studies have shown that TIPS, although effective at managing the ascites, does not improve survival. Unfortunately, TIPS is often associated with an increased frequency of hepatic encephalopathy and must be considered carefully on a case-by-case basis. The prognosis for patients with cirrhosis with ascites is poor, and some studies have shown that <50% of patients survive 2 years after the onset of ascites. Thus, there should be consideration for liver transplantation in patients with ascites. Patients with cirrhosis and ascites are at increased risk for renal failure from certain medications including nonsteroidal anti-inflammatory drugs and aminoglycosides; therefore, these medications should generally be avoided. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should be used cautiously with close monitoring of blood pressure and renal function.

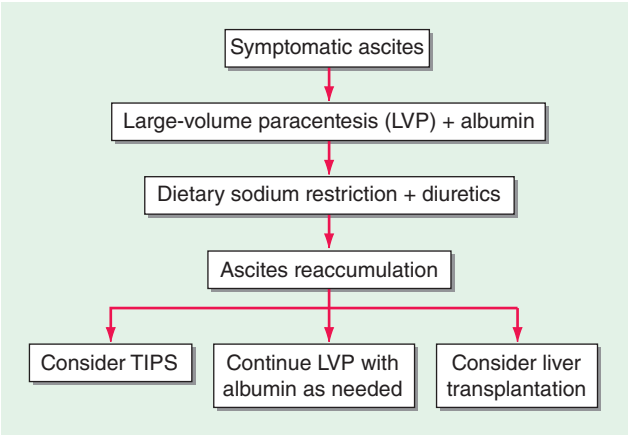

FIGURE 344-5 Treatment of refractory ascites. In patients who develop azotemia in the course of receiving diuretics in the management of their ascites, some will require repeated large-volume paracentesis (LVP), some may be considered for transjugular intrahepatic portosystemic shunt (TIPS), and some would be good candidates for liver transplantation. These decisions are all individualized.

SPONTANEOUS BACTERIAL PERITONITIS

SBP is a common and severe complication of ascites characterized by spontaneous infection of the ascitic fluid without an intraabdominal source. In hospitalized patients with cirrhosis and ascites, SBP can occur in up to 30% of individuals and can have a 25% in-hospital mortality rate. Bacterial translocation is the presumed mechanism for development of SBP, with gut flora traversing the intestine into mesenteric lymph nodes, leading to bacteremia and seeding of the ascitic fluid. The most common organisms are *Escherichia coli* and other gut bacteria; however, gram-positive bacteria, including *Streptococcus viridans*, *Staphylococcus aureus*, and *Enterococcus* spp., can also be found. If more than two organisms are identified, secondary bacterial peritonitis due to a perforated viscus should be considered. The diagnosis of SBP is made when the fluid sample has an absolute neutrophil count >250/μL. Bedside cultures should be obtained by direct injection of ascitic fluid into blood culture bottles. Patients with ascites may present with fever, altered mental status, elevated white blood cell count, abdominal pain or discomfort, and acute kidney injury, or they may present without any of these features. Therefore, it is necessary to have a high degree of clinical suspicion, and peritoneal taps are recommended for most cirrhosis patients hospitalized with ascites and cirrhosis complications or signs of infection. Treatment is commonly with intravenous third-generation cephalosporin for 5 days. In addition, intravenous albumin (1.5 g/kg body weight on day and 1.0 g/kg on day 3) has been shown to reduce the risk of renal failure and to improve survival. In patients with variceal hemorrhage, the frequency of SBP is significantly increased, and prophylaxis against SBP is recommended when a patient presents with upper GI bleeding. Furthermore, in patients who have had an episode (or multiple episodes) of SBP and recovered, quinolone antibiotic prophylaxis should be given to prevent recurrent SBP.

HEPATORENAL SYNDROME

HRS is a form of functional renal failure without renal pathology that occurs in ~10% of patients with advanced cirrhosis or acute liver failure. There are marked disturbances in the arterial renal circulation in patients with HRS; these include an increase in vascular resistance accompanied by a reduction in systemic vascular resistance. The reason for renal vasoconstriction is most likely multifactorial and is poorly understood. The diagnosis is made usually in the presence of a large amount of ascites in patients who have a stepwise progressive increase in creatinine. Type 1 HRS is characterized by a progressive impairment in renal function and a significant reduction in creatinine clearance within 1–2 weeks of presentation. Type 2 HRS is characterized by a reduction in glomerular filtration rate with an elevation of serum creatinine level, but it is stable and is associated with a better outcome than that of type 1 HRS.

HRS requires exclusion of other causes of acute renal failure, most notably volume depletion. Diuretics should be stopped, and infusion of albumin 1 g/kg per day is recommended. Treatment is with vasoconstrictors such as terlipressin (not currently available in North America) or low-dose norepinephrine (requires intensive care unit monitoring). Midodrine, an α-agonist, along with octreotide and intravenous albumin are also commonly used in the United States. The best therapy for HRS is liver transplantation; recovery of renal function is typical in this setting. In patients with either type 1 or type 2 HRS, the prognosis is poor unless transplant can be achieved within a short period of time.

HEPATIC ENCEPHALOPATHY

Portosystemic encephalopathy is a serious complication of chronic liver disease and is broadly defined as an alteration in mental status and cognitive function occurring in the presence of liver failure. In severe acute liver injury, the development of encephalopathy is a requirement for a diagnosis of acute liver failure and can be seen in association with life-threatening brain edema, which is not a feature in chronic liver disease. Encephalopathy is much more commonly seen in patients with chronic liver disease. Gut-derived neurotoxins that are not removed by the liver because of vascular shunting and decreased hepatic mass reach the brain and cause the symptoms known as hepatic encephalopathy. Ammonia levels are typically elevated, but the correlation between severity of liver disease and height of ammonia levels is often poor, and most hepatologists do not rely on ammonia levels to make a diagnosis or follow clinical progress. Other compounds and metabolites that may contribute to the development of encephalopathy include certain false neurotransmitters and mercaptans.

Clinical Features In acute liver failure, changes in mental status can occur rapidly. Brain edema can be seen in these patients, with severe encephalopathy associated with swelling of the gray matter. Cerebral herniation is a feared complication of brain edema in acute liver failure, and treatment to decrease edema is with mannitol and judicious use of intravenous fluids.

In patients with cirrhosis, encephalopathy is often found as a result of certain precipitating events such as hypokalemia, infection, an increased dietary protein load, or volume depletion. Patients may be confused or exhibit a change in personality. They may actually be quite violent and difficult to manage; alternatively, patients may be very sleepy and difficult to rouse. Precipitating events are common, so they should be sought carefully. If patients have ascites, this should be tapped to rule out infection. Evidence of GI bleeding should be sought, and patients should be appropriately hydrated. Electrolytes should be measured and abnormalities corrected. In patients presenting with encephalopathy, asterixis is often present. Asterixis can be elicited by having patients extend their arms and bend their wrists back. Patients who are encephalopathic have a "liver flap"—that is, a sudden forward movement of the wrist. This requires patients to be able to cooperate with the examiner. Alternative causes for altered mental status should also be considered.

The diagnosis of hepatic encephalopathy is clinical and requires an experienced clinician to recognize and put together all the various features. Often when patients have encephalopathy for the first time, they (and/or their caregivers) are unaware of what is transpiring, but once they have been through the experience, they can identify when this is developing in subsequent situations and can often self-medicate to prevent the development or worsening of encephalopathy.

TREATMENT

Hepatic Encephalopathy

Treatment is multifactorial and includes management of the above-mentioned precipitating factors. Sometimes hydration and correction of electrolyte imbalance are all that is necessary. In the past, restriction of dietary protein was used; however, the negative impact of that maneuver on overall nutrition is thought to outweigh the benefit, and it is thus strongly discouraged. The mainstay of

treatment for encephalopathy is to use lactulose, a nonabsorbable disaccharide, which results in colonic acidification. Catharsis ensues, contributing to the elimination of nitrogenous products in the gut that are responsible for the development of encephalopathy. The goal of lactulose therapy is to promote two to three soft stools per day. Patients are asked to titrate their amount of ingested lactulose to achieve the desired effect. Lactulose is usually continued after the initial episode of encephalopathy. Poorly absorbed antibiotics are often used as adjunctive therapies for patients who have a difficult time with lactulose. The alternating administration of neomycin and metronidazole has been used in the past to reduce the individual side effects of each: neomycin for renal insufficiency and ototoxicity and metronidazole for peripheral neuropathy. More recently, rifaximin at 550 mg twice daily has been very effective in preventing recurrent encephalopathy. Zinc supplementation is sometimes helpful and is relatively harmless. The development of encephalopathy in patients with chronic liver disease is a poor prognostic sign, but this complication can be managed in the vast majority of patients.

LIVER-LUNG SYNDROMES

Hepatopulmonary syndrome (HPS) is characterized by arterial hypoxemia in a patient with cirrhosis without significant lung disease. The liver disease causes intrapulmonary vascular dilations resulting in blood shunting past alveoli and significant ventilation-perfusion mismatch. Clinical symptoms include dyspnea and platypnea. HPS is common, occurring in 4–32% of patients with cirrhosis; however, it is often mild. Diagnosis involves demonstrating hypoxemia, without evidence of significant lung disease, and shunt on bubble echocardiography. Treatment is with oxygen supplementation and liver transplantation.

Portopulmonary hypertension (PPHT) is pulmonary hypertension in a patient with portal hypertension. The portal hypertension results in the production of vasoconstrictor substances that affect the pulmonary artery. Many patients are asymptomatic, especially early in the disease; however, they later can develop dyspnea on exertion and fatigue. PPHT is rare, occurring in ~5% of patients with advanced cirrhosis. Diagnosis includes initial identification on echocardiogram and confirmation on right heart catheterization showing elevated mean pulmonary artery pressure, elevated pulmonary vascular resistance, and normal pulmonary capillary wedge pressure. Prognosis is poor, although liver transplantation after effective reduction in pulmonary artery pressure with vasodilatory medications can be effective.

MALNUTRITION IN CIRRHOSIS

Because the liver is principally involved in the regulation of protein and energy metabolism in the body, it is not surprising that patients with advanced liver disease are commonly malnourished. Once patients become cirrhotic, they are more catabolic, and muscle protein is metabolized. There are multiple factors that contribute to the malnutrition of cirrhosis, including poor dietary intake, alterations in gut nutrient absorption, and alterations in protein metabolism. Close attention to food intake is helpful in preventing patients from becoming catabolic. General recommendations include multiple small meals including a late evening snack with total calories of 25–30 kcal per kg of ideal body weight per day and 1.2–1.5 g of protein per kg of ideal body weight per day.

ABNORMALITIES IN COAGULATION

Coagulation disorders in cirrhosis are poorly understood, and typical clinical measures of coagulation, such as the prothrombin time and international normalized ratio, are not reliable measures of clotting ability. There is decreased synthesis of both pro- and anticoagulant factors and thus some rebalancing in coagulation; however, the coagulation cascade can easily tip toward thrombosis or bleeding. In addition, patients may have thrombocytopenia from hypersplenism due to portal hypertension and some platelet dysfunction, which is counterbalanced with increased von Willebrand factor. Adequate thrombin formation can occur with platelet levels from cirrhosis patients >50,000–60,000/L. Synthesis of vitamin K–dependent clotting factors II, VII, IX, and X is diminished in patients with chronic cholestatic syndromes because absorption of vitamin K requires good bile flow. Intravenous or intramuscular vitamin K can quickly correct this abnormality. Overall, the status of coagulation in a cirrhotic patient needs to be judged clinically rather than relying on current laboratory tests.

BONE DISEASE IN CIRRHOSIS

Osteoporosis is common in patients with chronic cholestatic liver disease because of malabsorption of vitamin D and decreased calcium ingestion. The rate of bone resorption exceeds that of new bone formation in patients with cirrhosis, resulting in bone loss. Dual-energy x-ray absorptiometry (DEXA) is a useful method for determining osteoporosis or osteopenia. When a DEXA scan shows osteoporosis, treatment with bisphosphonates is effective.

HEMATOLOGIC ABNORMALITIES IN CIRRHOSIS

Numerous hematologic manifestations of cirrhosis are present, including anemia from a variety of causes including hypersplenism, hemolysis, iron deficiency, and perhaps folate deficiency from malnutrition. Macrocytosis is a common abnormality in red blood cell morphology seen in patients with chronic liver disease, and neutropenia may be a result of hypersplenism.

345 Liver Transplantation

Raymond T. Chung, Jules L. Dienstag

Liver transplantation—the replacement of the native, diseased liver by a normal organ (allograft)—has matured from an experimental procedure reserved for desperately ill patients to an accepted, lifesaving operation applied more optimally in the natural history of end-stage liver disease. The preferred and technically most advanced approach is *orthotopic transplantation*, in which the native organ is removed and the donor organ is inserted in the same anatomic location. Pioneered in the 1960s by Thomas Starzl at the University of Colorado and, later, at the University of Pittsburgh and by Roy Calne in Cambridge, England, liver transplantation is now performed routinely worldwide. Success measured as 1-year survival has improved from ~30% in the 1970s to >90% today. These improved prospects for prolonged survival resulted from refinements in operative technique, improvements in organ procurement and preservation, advances in immunosuppressive therapy, and, perhaps most influentially, more enlightened patient selection and timing. Despite the perioperative morbidity and mortality, the technical

and management challenges of the procedure, and its costs, liver transplantation has become the approach of choice for selected patients whose chronic or acute liver disease is progressive, life-threatening, and unresponsive to medical therapy. Based on the current level of success, the number of liver transplants has continued to grow each year; in 2020, 8906 patients received liver allografts in the United States. Still, the demand for new livers continues to outpace availability; as of 2021, 11,710 patients in the United States were on a waiting list for a donor liver. In response to this drastic shortage of donor organs, many transplantation centers supplement deceased-donor liver transplantation with living-donor transplantation.

INDICATIONS

Potential candidates for liver transplantation are children and adults who, in the absence of contraindications (see below), suffer from severe, irreversible liver disease for which alternative medical or surgical treatments have been exhausted or are unavailable. *Timing of the operation is of critical importance*. Indeed, improved timing and better patient selection are felt to have contributed more to the increased success of liver transplantation in the 1980s and beyond than all the impressive technical and immunologic advances combined. Although the disease should be advanced, and although opportunities for spontaneous or medically induced stabilization or recovery should be allowed, the procedure should be done sufficiently early to give the surgical procedure a fair chance for success. Ideally, transplantation should be considered in patients with end-stage liver disease who are experiencing or have experienced a life-threatening complication of hepatic decompensation or whose quality of life has deteriorated to unacceptable levels. Although patients with well-compensated cirrhosis can survive for many years, many patients with quasi-stable chronic liver disease have much more advanced disease than may be apparent. As discussed below, the better the status of the patient prior to transplantation, the higher will be its anticipated success rate. The decision about *when* to transplant is complex and requires the combined judgment of an experienced team of hepatologists, transplant surgeons, anesthesiologists, and specialists in support services, not to mention the well-informed consent of the patient and the patient's family.

TRANSPLANTATION IN CHILDREN

Indications for transplantation in children are listed in **Table 345-1**. The most common is *biliary atresia*. *Inherited or genetic disorders of metabolism* associated with liver failure constitute another major indication for transplantation in children and adolescents. In Crigler-Najjar disease type I and in certain hereditary disorders of the urea cycle and of amino acid or lactate-pyruvate metabolism, transplantation may be the only way to prevent impending deterioration of central nervous system function, despite the fact that the native liver is structurally normal. Combined heart and liver transplantation has yielded dramatic improvement in cardiac function and in cholesterol levels in children with homozygous familial hypercholesterolemia; combined liver and kidney transplantation has been successful in patients with primary hyperoxaluria type I. In hemophiliacs with transfusion-associated hepatitis and liver failure, liver transplantation has been associated with recovery of normal factor VIII synthesis.

TABLE 345-1 Indications for Liver Transplantation

CHILDREN	ADULTS
Biliary atresia	Primary biliary cholangitis
Neonatal hepatitis	Secondary biliary cirrhosis
Congenital hepatic fibrosis	Primary sclerosing cholangitis
Alagille's syndrome[a]	Autoimmune hepatitis
Byler's disease[b]	Caroli's disease[c]
α_1 Antitrypsin deficiency	Cryptogenic cirrhosis
Inherited disorders of metabolism	Chronic hepatitis with cirrhosis
Wilson's disease	Hepatic vein thrombosis
Tyrosinemia	Fulminant hepatitis
Glycogen storage diseases	Alcohol-associated cirrhosis
Lysosomal storage diseases	Chronic viral hepatitis
Protoporphyria	Primary hepatocellular malignancies
Crigler-Najjar disease type I	Hepatic adenomas
Familial hypercholesterolemia	Nonalcoholic steatohepatitis
Primary hyperoxaluria type I	Familial amyloid polyneuropathy
Hemophilia	

[a]Arteriohepatic dysplasia, with paucity of bile ducts, and congenital malformations, including pulmonary stenosis. [b]Intrahepatic cholestasis, progressive liver failure, and mental and growth retardation. [c]Multiple cystic dilatations of the intrahepatic biliary tree.

TRANSPLANTATION IN ADULTS

Liver transplantation is indicated for end-stage *cirrhosis* of all causes (Table 345-1). In *sclerosing cholangitis* and *Caroli's disease* (multiple cystic dilatations of the intrahepatic biliary tree), recurrent infections and sepsis associated with inflammatory and fibrotic obstruction of the biliary tree may be an indication for transplantation. Because prior biliary surgery complicates and is a relative contraindication for liver transplantation, surgical diversion of the biliary tree has been all but abandoned for patients with sclerosing cholangitis. In patients who undergo transplantation for *hepatic vein thrombosis* (*Budd-Chiari syndrome*), postoperative anticoagulation is essential; underlying myeloproliferative disorders may have to be treated but are not a contraindication to liver transplantation. If a donor organ can be located quickly, before life-threatening complications—including cerebral edema—set in, patients with acute liver failure are candidates for liver transplantation. Currently, alcohol-associated liver disease, chronic hepatitis C, and nonalcoholic fatty liver disease (NAFLD) are the most common indications for liver transplantation, accounting for >40% of all adult candidates who undergo the procedure. Patients with alcohol-associated cirrhosis can be considered as candidates for transplantation if they meet strict criteria for abstinence and reform; however, these criteria still do not prevent recidivism in up to a quarter of cases. In highly selected cases in a limited but growing number of centers, transplantation for severe *acute* alcohol-associated hepatitis has been performed with success; however, because patients with acute alcohol-associated hepatitis are still actively using alcohol and because continued alcohol abuse remains a concern, acute alcohol-associated hepatitis is not a routine indication for liver transplantation. Patients with chronic hepatitis C have early allograft and patient survival comparable to those of other subsets of patients after transplantation; however, reinfection in the donor organ is universal, recurrent hepatitis C had been insidiously progressive, with allograft cirrhosis and failure occurring at a higher frequency beyond 5 years. Fortunately, with the introduction of highly effective direct-acting antiviral (DAA) agents targeting hepatitis C virus (HCV), allograft outcomes have improved substantially. In patients with chronic hepatitis B, in the absence of measures to prevent recurrent hepatitis B, survival after transplantation is reduced by ~10–20%; however, prophylactic use of hepatitis B immune globulin (HBIg) during and after transplantation increases the success of transplantation to a level comparable to that seen in patients with nonviral causes of liver decompensation. Specific oral antiviral drugs (e.g., entecavir, tenofovir disoproxil fumarate, tenofovir alafenamide) **(Chap. 341)** can be used both for prophylaxis against and for treatment of recurrent hepatitis B, facilitating further the management of patients undergoing liver transplantation for end-stage hepatitis B; most transplantation centers rely on antiviral drugs with or without HBIg to manage patients with hepatitis B. Issues of disease recurrence are discussed in more detail below. Patients with nonmetastatic primary hepatobiliary tumors—primary hepatocellular carcinoma (HCC), cholangiocarcinoma, hepatoblastoma, angiosarcoma, epithelioid hemangioendothelioma, and multiple or massive hepatic adenomata—have undergone liver transplantation; however, for some hepatobiliary malignancies, overall survival is significantly lower than that for other categories of liver disease. Most transplantation centers have reported 5-year recurrence-free survival rates in patients with unresectable HCC for single tumors <5 cm in diameter

or for three or fewer lesions all <3 cm comparable to those seen in patients undergoing transplantation for nonmalignant indications. Consequently, liver transplantation is currently restricted to patients whose hepatic malignancies meet these criteria. Expanded criteria for patients with HCC continue to be evaluated. Because the likelihood of recurrent cholangiocarcinoma is very high, only highly selected patients with limited disease are being evaluated for transplantation after intensive chemotherapy and radiation.

CONTRAINDICATIONS

Absolute contraindications for transplantation include life-threatening systemic diseases, uncontrolled extrahepatic bacterial or fungal infections, preexisting advanced cardiovascular or pulmonary disease, multiple uncorrectable life-threatening congenital anomalies, metastatic malignancy, and active drug or alcohol abuse **(Table 345–2)**. Because carefully selected patients in their sixties and even seventies have undergone transplantation successfully, advanced age per se is no longer considered an absolute contraindication; however, in older patients, a more thorough preoperative evaluation should be undertaken to exclude ischemic cardiac disease and other comorbid conditions. Advanced age (>70 years), however, should be considered a *relative contraindication*—that is, a factor to be considered with other relative contraindications. Other relative contraindications include portal vein thrombosis, preexisting renal disease not associated with liver disease (which may prompt consideration of combined liver and kidney transplantation), intrahepatic or biliary sepsis, severe hypoxemia (Po_2 <50 mmHg) resulting from right-to-left intrapulmonary shunts, portopulmonary hypertension with high mean pulmonary artery pressures (>35 mmHg), previous extensive hepatobiliary surgery, any uncontrolled serious psychiatric disorder, and lack of sufficient social supports. Any one of these relative contraindications is insufficient in and of itself to preclude transplantation. For example, the problem of portal vein thrombosis can be overcome by constructing a graft from the donor liver portal vein to the recipient's superior mesenteric vein. Now that combination antiretroviral therapy has dramatically improved the survival of persons with HIV infection **(Chap. 202)**, and because end-stage liver disease caused by chronic hepatitis C and B has emerged as a serious source of morbidity and mortality in the HIV-infected population, liver transplantation has now been performed successfully in selected HIV-positive persons who have excellent control of HIV infection. Selected patients with CD4+ T-cell counts >100/μL and with pharmacologic suppression of HIV viremia have undergone transplantation for end-stage liver disease. HIV-infected persons who have received liver allografts for end-stage liver disease resulting from chronic hepatitis B have experienced survival rates comparable to those of HIV-negative persons undergoing transplantation for the same indication. In contrast, recurrent HCV in the allograft has until recently limited long-term success in persons with HCV-related end-stage liver disease. Again, the availability of DAA agents targeting HCV (see below and **Chap. 341**) is expected has improved allograft outcomes significantly.

TABLE 345-2 Contraindications to Liver Transplantation

ABSOLUTE	RELATIVE
Uncontrolled extrahepatobiliary infection	Age >70
Active, untreated sepsis	Prior extensive hepatobiliary surgery
Uncorrectable, life-limiting congenital anomalies	Portal vein thrombosis
Active substance abuse	Renal failure not attributable to liver disease (consider dual organ transplantation)
Advanced cardiopulmonary disease	Previous extrahepatic malignancy (not including nonmelanoma skin cancer)
Extrahepatobiliary malignancy (not including nonmelanoma malignancy skin cancer)	Severe obesity
Metastatic malignancy to the liver	Severe malnutrition/wasting
Cholangiocarcinoma (except those tumors that fit into protocols)	Medical noncompliance
AIDS	HIV seropositivity with failure to control HIV viremia or CD4 <100/μL
Life-threatening systemic diseases	Intrahepatic sepsis
	Severe hypoxemia secondary to right-to-left intrapulmonary shunts (Po_2 <50 mmHg)
	Severe pulmonary hypertension (mean pulmonary artery pressure >35 mmHg)
	Uncontrolled psychiatric disorder

TECHNICAL CONSIDERATIONS

DECEASED-DONOR SELECTION

Deceased-donor livers for transplantation are procured primarily from victims of head trauma. Organs from brain-dead donors up to age 60 are acceptable if the following criteria are met: hemodynamic stability, adequate oxygenation, absence of bacterial or fungal infection, absence of abdominal trauma, absence of hepatic dysfunction, and serologic exclusion of hepatitis B virus (HBV), HCV, and HIV. Occasionally, organs from donors with hepatitis B and C are used, particularly for recipients with prior hepatitis B and C, respectively. Organs from donors with antibodies to hepatitis B core antigen (anti-HBc) can also be used when the need is especially urgent, and recipients of these organs are treated prophylactically with antiviral drugs. Increasingly, with the early administration of highly effective DAA agents, organs from donors with hepatitis C have been used successfully in previously uninfected recipients. Cardiovascular and respiratory functions are maintained artificially until the liver can be removed. Transplantation of organs procured from deceased donors who have succumbed to cardiac death can be performed successfully under selected circumstances, when ischemic time is minimized and liver histology preserved. Encouraging improvements in normothermic ex vivo liver perfusion techniques may make broader use of these organs possible. Compatibility in ABO blood group and organ size between donor and recipient are important considerations in donor selection; however, ABO-incompatible, split-liver, or reduced-donor-organ allografts can be performed in emergencies or marked donor scarcity. Tissue typing for human leukocyte antigen (HLA) matching is not required, and preformed cytotoxic HLA antibodies do not preclude liver transplantation. Following perfusion with cold electrolyte solution, the donor liver is removed and packed in ice. The use of University of Wisconsin (UW) solution, rich in lactobionate and raffinose, has permitted the extension of cold ischemic time up to 20 h; however, 12 h may be a more reasonable limit. Improved techniques for harvesting multiple organs from the same donor have increased the availability of donor livers, but the availability of donor livers is far outstripped by the demand. Currently in the United States, all donor livers are distributed through a nationwide organ-sharing network (United Network for Organ Sharing [UNOS]) designed to allocate available organs based on regional considerations and recipient acuity. Recipients who have the highest disease severity generally have the highest priority, but allocation strategies that balance highest urgency against best outcomes continue to evolve to distribute deceased-donor organs most effectively. Allocation based on the Child-Turcotte-Pugh (CTP) score, which uses five clinical variables (encephalopathy stage, ascites, bilirubin, albumin, and prothrombin time) and waiting time, has been replaced by allocation based on urgency alone, calculated using the Model for End-Stage Liver Disease (MELD) score. The MELD score is based on a mathematical model that includes bilirubin, creatinine, and prothrombin time expressed as international normalized ratio (INR) **(Table 345-3)**. Neither waiting time (except as a tie breaker between two potential recipients with the same MELD scores) nor posttransplantation outcome is taken into account, but use of the MELD score has been shown to reduce waiting list mortality, to reduce waiting time prior to transplantation, to be the best predictor of pretransplantation mortality, to satisfy the prevailing view that medical need should be the

TABLE 345-3 United Network for Organ Sharing (UNOS) Liver Transplantation Waiting List Criteria

Status 1	Fulminant hepatic failure (including primary graft nonfunction and hepatic artery thrombosis within 7 days after transplantation as well as acute decompensated Wilson's disease)[a]
The Model for End-Stage Liver Disease (MELD)-Na score, on a continuous scale,[b] determines allocation of the remainder of donor organs. This model is based on the following calculation:	
MELD = 3.78 × $\log_e$ bilirubin (mg/100 mL) + 11.2 × $\log_e$ international normalized ratio (INR) + 9.57 × $\log_e$ creatinine (mg/100 mL) + 6.43.[c,d,e]	
MELD-Na = MELD + 1.32 * (137 – Na [meq/L]) – [0.033 * MELD * (137 – Na [meq/L])	
Online calculators to determine MELD scores are available, such as the following: *https://optn.transplant.hrsa.gov/resources/allocation-calculators/meld-calculator/*	

[a]For children <18 years of age, status 1 includes acute or chronic liver failure plus hospitalization in an intensive care unit or inborn errors of metabolism. Status 1 is retained for those persons with fulminant hepatic failure and supersedes the MELD score. [b]The MELD scale is continuous, with 34 levels ranging between 6 and 40 (scores above 40 are categorized as 40). Donor organs usually do not become available unless the MELD score exceeds 20. [c]Patients with stage T2 hepatocellular carcinoma receive 22 disease-specific points. [d]Creatinine is included because renal function is a validated predictor of survival in patients with liver disease. For adults undergoing dialysis twice a week, the creatinine in the equation is set to 4 mg/100 mL. [e]For children <18 years of age, the Pediatric End-Stage Liver Disease (PELD) scale is used. This scale is based on albumin, bilirubin, INR, growth failure, and age. Status 1 is retained.

decisive determinant, and to eliminate both the subjectivity inherent in the CTP scoring system (presence and degree of ascites and hepatic encephalopathy) and the differences in waiting times among different regions of the country. Data indicate that liver recipients with MELD scores <15 experienced higher posttransplantation mortality rates than similarly classified patients who remained on the waiting list. This observation led to the modification of UNOS policy to allocate donor organs to candidates with MELD scores exceeding 15 within the local or regional procurement organization before offering the organ to local patients whose scores are <15. In 2016, the MELD score was modified to incorporate serum sodium, another important predictor of survival in liver transplantation candidates (the MELD-Na score).

The highest priority (status 1) continues to be reserved for patients with fulminant hepatic failure or primary graft nonfunction. Because candidates for liver transplantation who have HCC may not be sufficiently decompensated to compete for donor organs based on urgency criteria alone and because protracted waiting for deceased-donor organs often results in tumor growth beyond acceptable limits for transplantation, such patients are assigned disease-specific MELD points (Table 345–3). Other disease-specific MELD exceptions include portopulmonary hypertension, hepatopulmonary syndrome, familial amyloid polyneuropathy, primary hyperoxaluria (necessitating liver-kidney transplantation), cystic fibrosis liver disease, and highly selected cases of hilar cholangiocarcinoma.

LIVING-DONOR TRANSPLANTATION

Occasionally, especially for liver transplantation in children, one deceased-donor organ can be split between two recipients (one adult and one child). A more viable alternative, transplantation of the right lobe of the liver from a healthy adult donor into an adult recipient, has gained increased popularity. Living-donor transplantation of the left lobe (left lateral segment), introduced in the early 1990s to alleviate the extreme shortage of donor organs for small children, accounts currently for approximately one-third of all liver transplantation procedures in children. Driven by the shortage of deceased-donor organs, living-donor transplantation involving the more sizable right lobe is being considered with increasing frequency in adults; however, living-donor liver transplantation cannot be expected to solve the donor organ shortage; 524 such procedures were done in 2019, representing only ~4% of all liver transplant operations done in the United States.

Living-donor transplantation can reduce waiting time and cold ischemia time; is done under elective, rather than emergency, circumstances; and may be lifesaving in recipients who cannot afford to wait for a deceased donor. The downside, of course, is the risk to the healthy donor (a mean of 10 weeks of medical disability; biliary complications in ~5%; postoperative complications such as wound infection, small-bowel obstruction, and incisional hernias in 9–19%; and even, in 0.2–0.4%, death) as well as the increased frequency of biliary (15–32%) and vascular (10%) complications in the recipient. Potential donors must participate voluntarily without coercion, and transplantation teams should go to great lengths to exclude subtle coercive or inappropriate psychological factors as well as outline carefully to both donor and recipient the potential benefits and risks of the procedure. Donors for the procedure should be 18–60 years old; have a compatible blood type with the recipient; have no chronic medical problems or history of major abdominal surgery; be related genetically or emotionally to the recipient; and pass an exhaustive series of clinical, biochemical, and serologic evaluations to unearth disqualifying medical disorders. The recipient should meet the same UNOS criteria for liver transplantation as recipients of a deceased donor allograft.

SURGICAL TECHNIQUE

Removal of the recipient's native liver is technically difficult, particularly in the presence of portal hypertension with its associated collateral circulation and extensive varices and especially in the presence of scarring from previous abdominal operations. The combination of portal hypertension and coagulopathy (elevated prothrombin time and thrombocytopenia) may translate into large blood product transfusion requirements. After the portal vein and infrahepatic and suprahepatic inferior vena cava are dissected, the hepatic artery and common bile duct are dissected. Then the native liver is removed and the donor organ inserted. During the anhepatic phase, coagulopathy, hypoglycemia, hypocalcemia, and hypothermia are encountered and must be managed by the anesthesiology team. Caval, portal vein, hepatic artery, and bile duct anastomoses are performed in succession, the last by end-to-end suturing of the donor and recipient common bile ducts **(Fig. 345-1)** or by choledochojejunostomy to a Roux-en-Y loop if the recipient common bile duct cannot be used for reconstruction (e.g., in sclerosing cholangitis). A typical transplant operation lasts 8 h, with a range of 6–18 h. Because of excessive bleeding, large volumes of blood, blood products, and volume expanders may be required during surgery; however, blood requirements have fallen sharply with improvements in surgical technique, blood-salvage interventions, and experience.

As noted above, emerging alternatives to orthotopic liver transplantation include split-liver grafts, in which one donor organ is divided and inserted into two recipients, and living-donor procedures, in which part of the left (for children), the left (for children or small adults), or

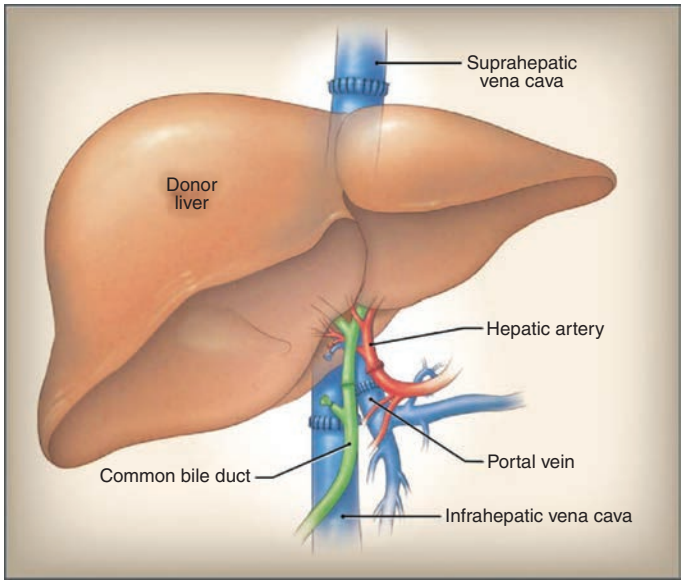

FIGURE 345-1 The anastomoses in orthotopic liver transplantation. The anastomoses are performed in the following sequence: (1) suprahepatic and infrahepatic vena cava, (2) portal vein, (3) hepatic artery, and (4) common bile duct-to-duct anastomosis. *(From JL Dienstag, AB Cosimi: Liver transplantation—a vision realized. N Engl J Med 367:1483, 2012. Copyright © 2012 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

the right (for adults) lobe of the liver is harvested from a living donor for transplantation into the recipient. In the adult procedure, once the right lobe is removed from the donor, the donor right hepatic vein is anastomosed to the recipient right hepatic vein remnant, followed by donor-to-recipient anastomoses of the portal vein and then the hepatic artery. Finally, the biliary anastomosis is performed, duct-to-duct if practical or via Roux-en-Y anastomosis. Heterotopic liver transplantation, in which the donor liver is inserted without removal of the native liver, has met with very limited success and acceptance, except in a very small number of centers. In attempts to support desperately ill patients until a suitable donor organ can be identified, several transplantation centers are studying extracorporeal perfusion with bioartificial liver cartridges constructed from hepatocytes bound to hollow fiber systems and used as temporary hepatic-assist devices, but their efficacy remains to be established. Areas of research with the potential to overcome the shortage of donor organs include hepatocyte transplantation and xenotransplantation with genetically modified organs of nonhuman origin (e.g., swine).

POSTOPERATIVE COURSE AND MANAGEMENT

IMMUNOSUPPRESSIVE THERAPY

The introduction in 1980 of cyclosporine as an immunosuppressive agent contributed substantially to the improvement in survival after liver transplantation. Cyclosporine, a calcineurin inhibitor, blocks early activation of T cells and is specific for T-cell functions that result from the interaction of the T cell with its receptor and that involve the calcium-dependent signal transduction pathway. As a result, the activity of cyclosporine leads to inhibition of lymphokine gene activation, blocking interleukins 2, 3, and 4, tumor necrosis factor α, and other lymphokines. Cyclosporine also inhibits B-cell functions. This process occurs without affecting rapidly dividing cells in the bone marrow, which may account for the reduced frequency of posttransplantation systemic infections. The most common and important side effect of cyclosporine therapy is nephrotoxicity. Cyclosporine causes dose-dependent renal tubular injury and direct renal artery vasospasm. Following renal function is therefore important in monitoring cyclosporine therapy and is perhaps even a more reliable indicator than blood levels of the drug. Nephrotoxicity is reversible and can be managed by dose reduction. Other adverse effects of cyclosporine therapy include hypertension, hyperkalemia, tremor, hirsutism, glucose intolerance, and gingival hyperplasia.

Tacrolimus, a macrolide lactone antibiotic isolated from a Japanese soil fungus, *Streptomyces tsukubaensis*, has the same mechanism of action as cyclosporine but is 10–100 times more potent. Initially applied as "rescue" therapy for patients in whom rejection occurred despite the use of cyclosporine, tacrolimus was shown to be associated with a reduced frequency of acute, refractory, and chronic rejection. Although patient and graft survival are the same with these two drugs, the advantage of tacrolimus in minimizing episodes of rejection, reducing the need for additional glucocorticoid doses, and reducing the likelihood of bacterial and cytomegalovirus (CMV) infection has simplified the management of patients undergoing liver transplantation. In addition, the oral absorption of tacrolimus is more predictable than that of cyclosporine, especially during the early postoperative period when T-tube drainage interferes with the enterohepatic circulation of cyclosporine. As a result, in most transplantation centers, tacrolimus has now supplanted cyclosporine for primary immunosuppression, and many centers rely on oral rather than IV administration from the outset. For transplantation centers that prefer cyclosporine, a better-absorbed microemulsion preparation is available.

Although more potent than cyclosporine, tacrolimus is also more toxic and more likely to be discontinued for adverse events. The toxicity of tacrolimus is similar to that of cyclosporine; nephrotoxicity and neurotoxicity are the most commonly encountered adverse effects, and neurotoxicity (tremor, seizures, hallucinations, psychoses, coma) is more likely and more severe in tacrolimus-treated patients. Both drugs can cause diabetes mellitus, but tacrolimus does not cause hirsutism or gingival hyperplasia. Because of overlapping toxicity between cyclosporine and tacrolimus, especially nephrotoxicity, and because tacrolimus reduces cyclosporine clearance, these two drugs should not be used together. Because 99% of tacrolimus is metabolized by the liver, hepatic dysfunction reduces its clearance; in primary graft nonfunction (when, for technical reasons or because of ischemic damage prior to its insertion, the allograft is defective and does not function normally from the outset), tacrolimus doses have to be reduced substantially, especially in children. Both cyclosporine and tacrolimus are metabolized by the cytochrome P450 IIIA system, and therefore, drugs that induce cytochrome P450 (e.g., phenytoin, phenobarbital, carbamazepine, rifampin) reduce available levels of cyclosporine and tacrolimus, and drugs that inhibit cytochrome P450 (e.g., erythromycin, fluconazole, ketoconazole, clotrimazole, itraconazole, verapamil, diltiazem, danazol, metoclopramide, the HIV protease inhibitor ritonavir, and the HCV protease inhibitors glecaprevir [cyclosporine only] and grazoprevir) increase cyclosporine and tacrolimus blood levels. Indeed, itraconazole is used occasionally to help boost tacrolimus levels. Like azathioprine, cyclosporine and tacrolimus appear to be associated with a risk of lymphoproliferative malignancies (see below), which may occur earlier after cyclosporine or tacrolimus than after azathioprine therapy. Because of these side effects, combinations of cyclosporine or tacrolimus with prednisone and an antimetabolite (azathioprine or mycophenolic acid, see below)—all at reduced doses—are preferable regimens for immunosuppressive therapy.

Mycophenolic acid, a nonnucleoside purine metabolism inhibitor derived as a fermentation product from several *Penicillium* species, is another immunosuppressive drug being used for patients undergoing liver transplantation. Mycophenolate has been shown to be better than azathioprine, when used with other standard immunosuppressive drugs, in preventing rejection after renal transplantation and has been adopted widely as well for use in liver transplantation. The most common adverse effects of mycophenolate are bone marrow suppression and gastrointestinal complaints.

In patients with pretransplantation renal dysfunction or renal deterioration that occurs intraoperatively or immediately postoperatively, tacrolimus or cyclosporine therapy may not be practical; under these circumstances, induction or maintenance of immunosuppression with antithymocyte globulin (ATG; thymoglobulin) or monoclonal antibodies to T cells, OKT3, may be appropriate. Therapy with these agents has been especially effective in reversing acute rejection in the posttransplantation period and is the standard treatment for acute rejection that fails to respond to methylprednisolone boluses. Available data support the use of thymoglobulin induction to delay calcineurin inhibitor use and its attendant nephrotoxicity. IV infusions of thymoglobulin may be complicated by fever and chills, which can be ameliorated by premedication with antipyretics and a low dose of glucocorticoids. Infusions of OKT3 may be complicated by fever, chills, and diarrhea or by pulmonary edema, which can be fatal. Because OKT3 is such a potent immunosuppressive agent, its use is also more likely to be complicated by opportunistic infection or lymphoproliferative disorders; therefore, because of the availability of alternative immunosuppressive drugs, OKT3 is now used sparingly.

Sirolimus, an inhibitor of the mammalian target of rapamycin (mTOR), blocks later events in T-cell activation and is approved for use in kidney transplantation, but it is not formally approved for use in liver transplant recipients because of the reported association with an increased frequency of hepatic artery thrombosis in the first month after transplantation. In patients with calcineurin inhibitor–related nephrotoxicity, conversion to sirolimus has been demonstrated to be effective in preventing rejection with accompanying improvements in renal function. Because of its profound antiproliferative effects, sirolimus has also been suggested to be a useful immunosuppressive agent in patients with a prior or current history of malignancy, such as HCC. Side effects include hyperlipidemia, peripheral edema, oral ulcers, and interstitial pneumonitis. Everolimus is a hydroxyethyl derivative of sirolimus that, when used in conjunction with low-dose tacrolimus, also provides successful protection against acute rejection, with decreased renal impairment compared to that associated with standard

tacrolimus dosing. Everolimus and sirolimus share a similar adverse events profile. The most important principle of immunosuppression is that the ideal approach strikes a balance between immunosuppression and immunologic competence. In general, given sufficient immunosuppression, acute liver allograft rejection is nearly always reversible. On one hand, incompletely treated acute rejection predisposes to the development of chronic rejection, which can threaten graft survival. On the other hand, if the cumulative dose of immunosuppressive therapy is too large, the patient may succumb to opportunistic infection. In hepatitis C, pulse glucocorticoids or OKT3 use accelerates recurrent allograft hepatitis, although the routine use of DAA therapy to clear the allograft of HCV should remove this concern. Further complicating matters, acute rejection can be difficult to distinguish histologically from recurrent hepatitis C. Therefore, immunosuppressive drugs must be used judiciously, with strict attention to the infectious consequences of such therapy and careful confirmation of the diagnosis of acute rejection. In this vein, efforts have been made to minimize the use of glucocorticoids, a mainstay of immunosuppressive regimens, and steroid-free immunosuppression can be achieved in some instances. Patients who undergo liver transplantation for autoimmune diseases such as primary biliary cholangitis, autoimmune hepatitis, and primary sclerosing cholangitis are less likely to achieve freedom from glucocorticoids.

POSTOPERATIVE COMPLICATIONS

Complications of liver transplantation can be divided into nonhepatic and hepatic categories **(Tables 345-4 and 345-5)**. In addition, both immediate postoperative and late complications are encountered. As a rule, patients who undergo liver transplantation have been chronically ill for protracted periods and may be malnourished and wasted. The impact of such chronic illness and the multisystem failure that accompanies liver failure continue to require attention in the postoperative period. Because of the massive fluid losses and fluid shifts that occur during the operation, patients may remain fluid overloaded during the immediate postoperative period, straining cardiovascular reserve; this effect can be amplified in the face of transient renal dysfunction and pulmonary capillary vascular permeability. Continuous monitoring of cardiovascular and pulmonary function, measures to maintain the integrity of the intravascular compartment and to treat extravascular volume overload, and scrupulous attention to potential sources and sites of infection are of paramount importance. Cardiovascular instability may also result from the electrolyte imbalance that may accompany reperfusion of the donor liver as well as from restoration of systemic vascular resistance following implantation. Pulmonary function may be compromised further by paralysis of the right hemidiaphragm associated with phrenic nerve injury. The hyperdynamic state with increased cardiac output that is characteristic of patients with liver failure reverses rapidly after successful liver transplantation.

Other immediate management issues include renal dysfunction. Prerenal azotemia, acute kidney injury associated with hypoperfusion (acute tubular necrosis), and renal toxicity caused by antibiotics, tacrolimus, or cyclosporine are encountered frequently in the postoperative period, sometimes necessitating dialysis. Hemolytic-uremic syndrome can be associated with cyclosporine, tacrolimus, or OKT3. Occasionally, postoperative intraperitoneal bleeding may be sufficient to increase intraabdominal pressure, which, in turn, may reduce renal blood flow; this effect is rapidly reversible when abdominal distention is relieved by exploratory laparotomy to identify and ligate the bleeding site and to remove intraperitoneal clot.

Anemia may also result from acute upper gastrointestinal bleeding or from transient hemolytic anemia, which may be autoimmune, especially when blood group O livers are transplanted into blood group A or B recipients. This autoimmune hemolytic anemia is mediated by donor intrahepatic lymphocytes that recognize red blood cell A or B antigens on recipient erythrocytes. Transient in nature, this process resolves once the donor liver is repopulated by recipient bone marrow–derived lymphocytes; the hemolysis can be treated by transfusing blood group O red blood cells and/or by administering higher doses of glucocorticoids. Transient thrombocytopenia is also commonly encountered. Aplastic anemia, a late occurrence, is rare but has been reported in almost 30% of patients who underwent liver transplantation for acute, severe hepatitis of unknown cause.

TABLE 345-4 Nonhepatic Complications of Liver Transplantation

CATEGORY	COMPLICATION
Cardiovascular instability	Arrhythmias
	Congestive heart failure
	Cardiomyopathy
Pulmonary compromise	Pneumonia
	Pulmonary capillary vascular permeability
	Fluid overload
Renal dysfunction	Prerenal azotemia
	Hypoperfusion injury (acute tubular necrosis)
	Drug nephrotoxicity
	↓ Renal blood flow secondary to ↑ intraabdominal pressure
Hematologic	Anemia secondary to gastrointestinal and/or intraabdominal bleeding
	Hemolytic anemia, aplastic anemia
	Thrombocytopenia
Infection	Bacterial: early, common postoperative infections
	Fungal/parasitic: late, opportunistic infections
	Viral: late, opportunistic infections, recurrent hepatitis
Neuropsychiatric	Seizures
	Metabolic encephalopathy
	Depression
	Difficult psychosocial adjustment
Diseases of donor	Infectious
	Malignant
Malignancy	B-cell lymphoma (posttransplantation lymphoproliferative disorders)
	De novo neoplasms (particularly squamous cell skin carcinoma)

TABLE 345-5 Hepatic Complications of Liver Transplantation

Hepatic Dysfunction Common after Major Surgery	
Prehepatic	Pigment load
	Hemolysis
	Blood collections (hematomas, abdominal collections)
Intrahepatic	
Early	Hepatotoxic drugs and anesthesia
	Hypoperfusion (hypotension, shock, sepsis)
	Benign postoperative cholestasis
Late	Transfusion-associated hepatitis
	Exacerbation of primary hepatic disease
Posthepatic	Biliary obstruction
	↓ Renal clearance of conjugated bilirubin (renal dysfunction)
Hepatic Dysfunction Unique to Liver Transplantation	
Primary graft nonfunction	
Vascular compromise	Portal vein obstruction
	Hepatic artery thrombosis
	Anastomotic leak with intraabdominal bleeding
Bile duct disorder	Stenosis, obstruction, leak
Rejection	
Recurrent primary hepatic disease	

Bacterial, fungal, or viral infections are common and may be life-threatening postoperatively. Early after transplant surgery, common postoperative infections predominate—pneumonia, wound infections, infected intraabdominal collections, urinary tract infections, and IV line infections—rather than opportunistic infections; these infections may involve the biliary tree and liver as well. Beyond the first postoperative month, the toll of immunosuppression becomes evident, and opportunistic infections—CMV, herpes viruses, fungal infections (*Aspergillus*, *Candida*, cryptococcal disease), mycobacterial infections, parasitic infections (*Pneumocystis*, *Toxoplasma*), and bacterial infections (*Nocardia*, *Legionella*, *Listeria*)—predominate. Rarely, early infections represent those transmitted with the donor liver, either infections present in the donor or infections acquired during procurement processing. De novo viral hepatitis infections acquired from the donor organ or, almost unheard of now, from transfused blood products occur after typical incubation periods for these agents (well beyond the first month). Obviously, infections in an immunosuppressed host demand early recognition and prompt management; prophylactic antibiotic therapy is administered routinely in the immediate postoperative period. Use of sulfamethoxazole with trimethoprim reduces the incidence of postoperative *Pneumocystis jirovecii* pneumonia. Antiviral prophylaxis for CMV with ganciclovir should be administered in patients at high risk (e.g., when a CMV-seropositive donor organ is implanted into a CMV-seronegative recipient).

Neuropsychiatric complications include seizures (commonly associated with cyclosporine and tacrolimus toxicity), metabolic encephalopathy, depression, and difficult psychosocial adjustment. Rarely, diseases are transmitted by the allograft from the donor to the recipient. In addition to viral and bacterial infections, malignancies of donor origin have occurred. Posttransplantation lymphoproliferative disorders, especially B-cell lymphoma, are a recognized complication associated with immunosuppressive drugs such as azathioprine, tacrolimus, and cyclosporine (see above). Epstein-Barr virus has been shown to play a contributory role in some of these tumors, which may regress when immunosuppressive therapy is reduced. De novo neoplasms appear at increased frequency after liver transplantation, particularly squamous cell carcinomas of the skin. Routine screening should be performed.

Long-term complications after liver transplantation attributable primarily to immunosuppressive medications include diabetes mellitus and osteoporosis (associated with glucocorticoids and calcineurin inhibitors) as well as hypertension, hyperlipidemia, and chronic renal insufficiency (associated with cyclosporine and tacrolimus). Monitoring and treating these disorders are routine components of posttransplantation care; in some cases, they respond to changes in immunosuppressive regimen, while in others, specific treatment of the disorder is introduced. Data from a large U.S. database showed that the prevalence of renal failure was 18% at year 5 and 25% at year 10 after liver transplantation. Similarly, the high frequency of diabetes, hypertension, hyperlipidemia, obesity, and the metabolic syndrome renders patients susceptible to cardiovascular disease after liver transplantation; although hepatic complications account for most of the mortality after liver transplantation, renal failure and cardiovascular disease are the other leading causes of late mortality after liver transplantation.

HEPATIC COMPLICATIONS

Hepatic dysfunction after liver transplantation is similar to the hepatic complications encountered after major abdominal and cardiothoracic surgery; however, in addition, hepatic complications include primary graft failure, vascular compromise, failure or stricture of the biliary anastomoses, and rejection. As in nontransplantation surgery, postoperative jaundice may result from prehepatic, intrahepatic, and posthepatic sources. *Prehepatic* sources represent the massive hemoglobin pigment load from transfusions, hemolysis, hematomas, ecchymoses, and other collections of blood. *Early intrahepatic* liver injury includes effects of hepatotoxic drugs and anesthesia; hypoperfusion injury associated with hypotension, sepsis, and shock; and benign postoperative cholestasis. *Late intrahepatic* sources of liver injury include exacerbation of primary disease. *Posthepatic* sources of hepatic dysfunction include biliary obstruction and reduced renal clearance of conjugated bilirubin. Hepatic complications unique to liver transplantation include primary graft failure associated with ischemic injury to the organ during harvesting; vascular compromise associated with thrombosis or stenosis of the portal vein or hepatic artery anastomoses; vascular anastomotic leak; stenosis, obstruction, or leakage of the anastomosed common bile duct; recurrence of primary hepatic disorder (see below); and rejection.

TRANSPLANT REJECTION

Despite the use of immunosuppressive drugs, rejection of the transplanted liver still occurs in a proportion of patients, beginning 1–2 weeks after surgery. Clinical signs suggesting rejection are fever, right upper quadrant pain, and reduced bile pigment and volume. Leukocytosis may occur, but the most reliable indicators are increases in serum bilirubin and aminotransferase levels. Because these tests lack specificity, distinguishing among rejection, biliary obstruction, primary graft nonfunction, vascular compromise, viral hepatitis, CMV infection, drug hepatotoxicity, and recurrent primary disease may be difficult. Radiographic visualization of the biliary tree and/or percutaneous liver biopsy often help to establish the correct diagnosis. Morphologic features of acute rejection include a mixed portal cellular infiltrate, bile duct injury, and/or endothelial inflammation ("endothelialitis"); some of these findings are reminiscent of graft-versus-host disease, primary biliary cholangitis, or recurrent allograft hepatitis C. As soon as transplant rejection is suspected, treatment consists of IV methylprednisolone in repeated boluses; if this fails to abort rejection, many centers use thymoglobulin or OKT3. Caution should be exercised when managing acute rejection with pulse glucocorticoids or OKT3 in patients with HCV infection, because of the high risk of triggering recurrent allograft hepatitis C. The availability of DAAs for HCV has effectively obviated this concern.

Chronic rejection is a relatively rare outcome that can follow repeated bouts of acute rejection or that occurs unrelated to preceding rejection episodes. Morphologically, chronic rejection is characterized by progressive cholestasis, focal parenchymal necrosis, mononuclear infiltration, vascular lesions (intimal fibrosis, subintimal foam cells, fibrinoid necrosis), and fibrosis. This process may be reflected as ductopenia—the vanishing bile duct syndrome, which is more common in patients undergoing liver transplantation for autoimmune liver disease. Reversibility of chronic rejection is limited; in patients with therapy-resistant chronic rejection, retransplantation has yielded encouraging results.

OUTCOME

SURVIVAL

The survival rate for patients undergoing liver transplantation has improved steadily since 1983. One-year survival rates have increased from ~70% in the early 1980s to 85–90% from 2003 to the present time. Currently, the 5-year survival rate exceeds 60%. An important observation is the relationship between clinical status before transplantation and outcome. For patients who undergo liver transplantation when their level of compensation is high (e.g., still working or only partially disabled), a 1-year survival rate of >85% is common. For those whose level of decompensation mandates continuous in-hospital care prior to transplantation, the 1-year survival rate is ~70%, whereas for those who are so decompensated that they require life support in an intensive care unit, the 1-year survival rate is ~50%. Since the adoption by UNOS in 2002 of the MELD system for organ allocation, posttransplantation survival has been found to be affected adversely for candidates with MELD scores >25, considered high disease severity. Thus, irrespective of allocation scheme, high disease severity before transplantation corresponds to diminished posttransplantation survival. Another important distinction in survival has been drawn between high- and low-risk patient categories. For patients who do not fit any "high-risk" designations, 1- and 5-year survival rates of 85 and 80%, respectively, have been recorded. In contrast, among patients in high-risk categories—cancer, fulminant hepatitis, age >65, concurrent renal failure, respirator dependence, portal vein thrombosis, and history of a portacaval shunt or multiple right upper quadrant operations—survival statistics fall into the range of 60% at 1 year and 35% at 5 years. Survival after

retransplantation for primary graft nonfunction is ~50%. Causes of failure of liver transplantation vary with time. Failures within the first 3 months result primarily from technical complications, postoperative infections, and hemorrhage. Transplant failures after the first 3 months are more likely to result from infection, rejection, or recurrent disease (such as malignancy or viral hepatitis).

RECURRENCE OF PRIMARY DISEASE

Features of autoimmune hepatitis, primary sclerosing cholangitis, and primary biliary cholangitis overlap with those of rejection or post-transplantation bile duct injury. Whether autoimmune hepatitis and sclerosing cholangitis recur after liver transplantation is controversial; data supporting recurrent autoimmune hepatitis (in up to one-third of patients in some series) are more convincing than those supporting recurrent sclerosing cholangitis. Similarly, reports of recurrent primary biliary cholangitis after liver transplantation have appeared; however, the histologic features of primary biliary cholangitis and chronic rejection are virtually indistinguishable and occur as frequently in patients with primary biliary cholangitis as in patients undergoing transplantation for other reasons. The presence of a florid inflammatory bile duct lesion is highly suggestive of the recurrence of primary biliary cholangitis, but even this lesion can be observed in acute rejection. Hereditary disorders such as Wilson's disease and α_1 antitrypsin deficiency have not recurred after liver transplantation; however, recurrence of disordered iron metabolism has been observed in some patients with hemochromatosis. Hepatic vein thrombosis (Budd-Chiari syndrome) may recur; this can be minimized by treating underlying myeloproliferative disorders and by anticoagulation. Because cholangiocarcinoma recurs almost invariably, few centers now offer transplantation to such patients; however, a few highly selected patients with operatively confirmed stage I or II cholangiocarcinoma who undergo liver transplantation combined with neoadjuvant chemoradiation may experience excellent outcomes. In patients with intrahepatic HCC who meet criteria for transplantation, 1- and 5-year survivals are similar to those observed in patients undergoing liver transplantation for nonmalignant disease. Finally, metabolic disorders such as NAFLD recur frequently, especially if the underlying metabolic predisposition is not altered. The metabolic syndrome occurs commonly after liver transplantation as a result of recurrent NAFLD, immunosuppressive medications, and/or, in patients with hepatitis C related to the impact of HCV infection on insulin resistance, diabetes and fatty liver.

Hepatitis A can recur after transplantation for fulminant hepatitis A, but such acute reinfection has no serious clinical sequelae. In fulminant hepatitis B, recurrence is not the rule; however, in the absence of any prophylactic measures, hepatitis B usually recurs after transplantation for end-stage chronic hepatitis B. Before the introduction of prophylactic antiviral therapy, immunosuppressive therapy sufficient to prevent allograft rejection led inevitably to marked increases in hepatitis B viremia, regardless of pretransplantation levels. Overall graft and patient survival were poor, and some patients experienced a rapid recapitulation of severe injury—severe chronic hepatitis or even fulminant hepatitis—after transplantation. Also recognized in the era before availability of antiviral regimens was *fibrosing cholestatic hepatitis*, rapidly progressive liver injury associated with marked hyperbilirubinemia, substantial prolongation of the prothrombin time (both out of proportion to relatively modest elevations of aminotransferase activity), and rapidly progressive liver failure. This lesion has been suggested to represent a "choking off" of the hepatocyte by an overwhelming density of HBV proteins. Complications such as sepsis and pancreatitis were also observed more frequently in patients undergoing liver transplantation for hepatitis B prior to the introduction of antiviral therapy. The introduction of long-term prophylaxis with HBIg revolutionized liver transplantation for chronic hepatitis B. Preoperative hepatitis B vaccination, preoperative or postoperative interferon (IFN) therapy, or short-term (≤2 months) HBIg prophylaxis has not been shown to be effective, but a retrospective analysis of data from several hundred European patients followed for 3 years after transplantation has shown that long-term (≥6 months) prophylaxis with HBIg is associated with a lowering of the risk of HBV reinfection from ~75 to 35% and a reduction in mortality from ~50 to 20%.

As a result of long-term HBIg use following liver transplantation for chronic hepatitis B, similar improvements in outcome have been observed in the United States, with 1-year survival rates between 75 and 90%. Currently, with HBIg prophylaxis, the outcome of liver transplantation for chronic hepatitis B is indistinguishable from that for chronic liver disease unassociated with chronic hepatitis B; essentially, medical concerns regarding liver transplantation for chronic hepatitis B have been eliminated. Passive immunoprophylaxis with HBIg is begun during the anhepatic stage of surgery, repeated daily for the first 6 postoperative days, and then continued with infusions that are given either at regular intervals of 4–6 weeks or, alternatively, when anti–hepatitis B surface (HBs) levels fall below a threshold of 100 mIU/mL. The current approach in most centers is to continue HBIg indefinitely, which can add ~$20,000 per year to the cost of care; some centers are evaluating regimens that shift to less frequent administration or to IM administration in the late posttransplantation period or, in low-risk patients, maintenance with antiviral therapy (see below) alone. Still, "breakthrough" HBV infection occasionally occurs.

Further improving the outcome of liver transplantation for chronic hepatitis B is the current availability of such antiviral drugs as entecavir, tenofovir disoproxil fumarate, and tenofovir alafenamide **(Chap. 341)**. When these drugs are administered to patients with decompensated liver disease, a proportion improves sufficiently to postpone imminent liver transplantation. In addition, antiviral therapy can be used to prevent recurrence of HBV infection when administered *prior to* transplantation; to treat hepatitis B that recurs *after* transplantation, including in patients who break through HBIg prophylaxis; and to reverse the course of otherwise fatal fibrosing cholestatic hepatitis. Clinical trials have shown that entecavir or tenofovir antiviral therapy reduces the level of HBV replication substantially, sometimes even resulting in clearance of hepatitis B surface antigen (HBsAg); reduces alanine aminotransferase (ALT) levels; and improves histologic features of necrosis and inflammation. Currently, most liver transplantation centers combine HBIg plus one of the high-barrier-to-resistance oral nucleoside (entecavir) or nucleotide analogues (tenofovir). In low-risk patients with no detectable hepatitis B viremia at the time of transplantation, a number of clinical trials have suggested that antiviral prophylaxis can suffice, without HBIg or with a finite duration of HBIg, to prevent recurrent HBV infection of the allograft. In patients documented at the time of liver transplantation to have undetectable HBV DNA in serum and covalently closed circular DNA in the liver (i.e., with low risk for recurrence of HBV infection), a preliminary clinical trial suggested that, after receipt of 5 years of combined therapy, both HBIg and oral-agent therapy can be withdrawn sequentially (over two 6-month periods) with a success rate, as monitored over a median of 6 years after withdrawal, of 90% and an anti-HBs seroconversion rate of 60% (despite transient reappearance of HBV DNA and/or HBsAg in some of these patients).

Antiviral prophylactic approaches applied to patients undergoing liver transplantation for chronic hepatitis B are being used as well for patients without hepatitis B who receive organs from donors with antibody to hepatitis B core antigen (anti-HBc) but do not have HBsAg. Patients who undergo liver transplantation for chronic hepatitis B plus D are less likely to experience recurrent liver injury than patients undergoing liver transplantation for hepatitis B alone; still, such co-infected patients would also be offered standard posttransplantation prophylactic therapy for hepatitis B.

Until recently, the most common indication for liver transplantation was end-stage liver disease resulting from chronic hepatitis C. For patients undergoing liver transplantation for hepatitis C, because of an aggressive natural history of recurrent allograft hepatitis C, graft and patient survival were diminished substantially compared to other indications for transplantation.

The approval over the last decade of several DAA agents and of IFN-free DAA regimens against HCV has had a major impact on the management and outcome of both pretransplantation and posttransplantation HCV infection. Such therapeutic approaches (1) permit

the clearance of viremia in a substantial proportion of decompensated cirrhotics, thereby preventing recurrent allograft infection and even improving the clinical status of most of these patients, delaying or obviating the need for liver replacement; and (2) achieve sustained virologic responses in a much higher proportion of persons with allograft HCV infection, because of improvements in antiviral treatment efficacy and tolerability. Ideally, patients should be treated prior to liver transplantation. This approach has already reduced the numbers of patients referred for liver transplantation and led to delisting of others. A concern, however, is that eradication of HCV infection will reduce the MELD score and lower the priority for a donor organ in some patients who still require transplantation because of continued hepatic decompensation and profound reduction in quality of life. In addition, elimination of HCV infection prior to transplantation would disqualify such patients from accepting donor livers from persons with HCV infection, contracting the potential donor pool and limiting accessibility to donor organs and timely transplantation. Therefore, consideration should be given to postponing DAA therapy in patients with high-MELD HCV-associated end-stage liver disease until after liver transplantation; however, a distinct threshold at which to treat pretransplantation or posttransplantation has not yet been established. Regardless, the approach to treatment should be individualized thoughtfully for each patient, based on such factors as MELD score, time anticipated prior to availability of a donor organ, relative clinical stability, and comorbidities.

DAA combinations that have been used successfully against allograft HCV include ledipasvir, sofosbuvir, and ribavirin; velpatasvir, sofosbuvir, and ribavirin; and grazoprevir and pibrentasvir. (For updated guidelines, see *www.hcvguidelines.org*.) In patients with recurrent HCV infection after liver transplantation, each of these regimens has yielded response rates approaching those seen in compensated nontransplant patient populations.

A small number of allograft recipients have historically succumbed to early HCV-associated liver injury, and a syndrome reminiscent of fibrosing cholestatic hepatitis (see above) has been observed rarely. Currently, however, the routine use of DAA regimens early after transplantation, before the onset of these variant presentations, has already had a profound impact on the frequency of severe recurrent allograft hepatitis C.

Patients who undergo liver transplantation for end-stage alcohol-associated cirrhosis are at risk of resorting to drinking again after transplantation, a potential source of recurrent alcohol-associated liver injury. Currently, alcohol-associated liver disease is the most common indication for liver transplantation, accounting for 30% of all liver transplantation procedures, and most transplantation centers screen candidates carefully for predictors of continued abstinence. Recidivism is more likely in patients whose sobriety prior to transplantation was <6 months. For abstinent patients with alcohol-associated cirrhosis, liver transplantation can be undertaken successfully, with outcomes comparable to those for other categories of patients with chronic liver disease, when coordinated by a team approach that includes substance abuse counseling.

POSTTRANSPLANTATION QUALITY OF LIFE

Full rehabilitation is achieved in most patients who survive the early postoperative months and escape chronic rejection or unmanageable infection. Psychosocial maladjustment interferes with medical compliance in a small number of patients, but most manage to adhere to immunosuppressive regimens, which must be continued indefinitely. In one study, 85% of patients who survived their transplant operations returned to gainful activities. In fact, some women have conceived and carried pregnancies to term after transplantation without demonstrable injury to their infants.

346 Diseases of the Gallbladder and Bile Ducts

Norton J. Greenberger*, Gustav Paumgartner, Daniel S. Pratt

PHYSIOLOGY OF BILE PRODUCTION AND FLOW

BILE SECRETION AND COMPOSITION

Bile formed in hepatocytes is secreted into a complex network of canaliculi, small bile ductules, and larger bile ducts that run with lymphatics and branches of the portal vein and hepatic artery in portal tracts situated between hepatic lobules. These interlobular bile ducts coalesce to form larger septal bile ducts that join to form the right and left hepatic ducts, which in turn, unite to form the common hepatic duct. The common hepatic duct is joined by the cystic duct of the gallbladder to form the common bile duct (CBD), which enters the duodenum (often after joining the main pancreatic duct) through the ampulla of Vater.

Hepatic bile is an isotonic fluid with an electrolyte composition resembling blood plasma. The electrolyte composition of gallbladder bile differs from that of hepatic bile because most of the inorganic anions, chloride, and bicarbonate have been removed by reabsorption across the gallbladder epithelium. As a result of water reabsorption, total solute concentration of bile increases from 3–4 g/dL in hepatic bile to 10–15 g/dL in gallbladder bile.

*Deceased.

Major solute components of bile by moles percent include bile acids (80%), phospholipids (lecithins, cephalins, and sphingomyelin) (16%), and unesterified cholesterol (4.0%). In the lithogenic state, the cholesterol value can be as high as 8–10%. Other constituents include conjugated bilirubin; proteins (all immunoglobulins, albumin, metabolites of hormones, and other proteins metabolized in the liver); electrolytes; mucus; heavy metals; and, often, drugs and their metabolites.

The total daily basal secretion of hepatic bile is ~500–600 mL. Many substances taken up or synthesized by the hepatocyte are secreted into the bile canaliculi. The canalicular membrane forms microvilli and is associated with microfilaments of actin, microtubules, and other contractile elements. Prior to their secretion into the bile, many substances are taken up into the hepatocyte, while others, such as phospholipids, a portion of primary bile acids, and some cholesterol, are synthesized de novo in the hepatocyte. Three mechanisms are important in regulating bile flow: (1) active transport of bile acids from hepatocytes into the bile canaliculi, (2) active transport of other organic anions, and (3) cholangiocellular secretion. The last is a secretin-mediated and cyclic AMP–dependent mechanism that results in the secretion of a bicarbonate-rich fluid into the bile ducts.

Active vectorial trans-hepatocellular movement of bile acids from the portal blood into the bile canaliculi is driven by a set of transport systems at the basolateral (sinusoidal) and the canalicular apical plasma membrane domains of the hepatocyte. Two sinusoidal bile salt uptake systems have been cloned in humans, the Na^+/taurocholate cotransporter (NTCP, SLC10A1) and the organic anion–transporting proteins (OATP1B1/1B3), which also transport a large variety of non–bile salt organic anions. Several ATP-dependent canalicular transport systems, "export pumps" (ATP-binding cassette transport proteins, also known as ABC transporters), have been identified, the most important of which are the bile salt export pump (BSEP, ABCB11); the anionic conjugate export pump (MRP2, ABCC2), which mediates the canalicular excretion of various amphiphilic conjugates formed by phase II conjugation (e.g., bilirubin mono- and diglucuronides and drugs); the multidrug export pump (MDR1, ABCB1) for hydrophobic cationic compounds; and the phospholipid export pump (MDR3, ABCB4). Two hemitransporters, ABCG5/G8, functioning as a couple, constitute the canalicular cholesterol and phytosterol transporter. F1C1 (ATP8B1) is an aminophospholipid transferase ("flippase") essential for maintaining the lipid asymmetry of the canalicular membrane. The canalicular membrane also contains ATP-independent transport systems such as the Cl/HCO_3 anion exchanger isoform 2 (AE2, SLC4A2) for canalicular bicarbonate secretion. For most of these transporters, genetic defects have been identified that are associated with various forms of cholestasis or defects of biliary excretion. F1C1 (ATP8B1) is defective in progressive familial intrahepatic cholestasis type 1 (PFIC1) and benign recurrent intrahepatic cholestasis type 1 (BRIC1) and results in ablation of all other ATP-dependent transporter functions. BSEP (ABCB11) is defective in PFIC2 and BRIC2. Mutations of MRP2 (ABCC2) cause the Dubin-Johnson syndrome, an inherited form of conjugated hyperbilirubinemia **(Chap. 338)**. A defective MDR3 (ABCB4) results in PFIC3. ABCG5/G8, the canalicular half transporters for cholesterol and other neutral sterols, are defective in sitosterolemia. The cystic fibrosis transmembrane regulator (CFTR, ABCC7), located on bile duct epithelial cells but not on canalicular membranes, is defective in cystic fibrosis, which is associated with impaired cholangiocellular pH regulation during ductular bile formation and chronic cholestatic liver disease, occasionally resulting in biliary cirrhosis.

THE BILE ACIDS

The primary bile acids, cholic acid and chenodeoxycholic acid (CDCA), are synthesized in hepatocytes from cholesterol, conjugated with glycine or taurine, and secreted into the bile canaliculus. Secondary bile acids, including deoxycholate and lithocholate, are formed in the colon as bacterial metabolites of the primary bile acids. However, lithocholic acid is much less efficiently absorbed from the colon than deoxycholic acid. Another secondary bile acid, found in low concentration, is ursodeoxycholic acid (UDCA), a stereoisomer of CDCA. In healthy subjects, the ratio of glycine to taurine conjugates in bile is ~3:1.

Bile acids are detergent-like molecules that in aqueous solutions and above a critical concentration of ~2 m*M* form molecular aggregates called *micelles*. Cholesterol alone is sparingly soluble in aqueous environments, and its solubility in bile depends on both the total lipid concentration and the relative molar percentages of bile acids and lecithin. Normal ratios of these constituents favor the formation of solubilizing *mixed micelles*, while abnormal ratios promote the precipitation of cholesterol crystals in bile via an intermediate liquid crystal phase.

In addition to facilitating the biliary excretion of cholesterol, bile acids facilitate the normal intestinal absorption of dietary fats, mainly cholesterol, and fat-soluble vitamins, via a micellar transport mechanism **(Chap. 325)**. Bile acids also serve as a major physiologic driving force for hepatic bile flow and aid in water and electrolyte transport in the small bowel and colon.

Bile acids also function as hormones binding to nuclear (farnesoid X receptor [FXR]) and G protein–coupled (TGR5) receptors that regulate bile acid metabolism and their enterohepatic circulation.

ENTEROHEPATIC CIRCULATION

Bile acids are efficiently conserved under normal conditions. Unconjugated, and to a lesser degree also conjugated, bile acids are absorbed by *passive diffusion* along the entire gut. Quantitatively much more important for bile salt recirculation, however, is the *active transport* mechanism for conjugated bile acids in the distal ileum **(Chap. 325)**. The reabsorbed bile acids enter the portal bloodstream and are taken up rapidly by hepatocytes, reconjugated, and resecreted into bile (enterohepatic circulation).

The normal bile acid pool size is ~2–4 g. During digestion of a meal, the bile acid pool undergoes at least one or more enterohepatic cycles, depending on the size and composition of the meal. Normally, the bile acid pool circulates ~5–10 times daily. Intestinal reabsorption of the pool is ~95% efficient; therefore, daily fecal loss of bile acids is in the range of 0.2–0.4 g. In the steady state, this fecal loss is compensated by an equal daily synthesis of bile acids by the liver, and thus, the size of the bile acid pool is maintained. Bile acids in the intestine stimulate the release of fibroblast growth factor 19 (FGF19), which suppresses the hepatic synthesis of bile acids from cholesterol by inhibiting the rate-limiting enzyme cytochrome P450 7A1 (CYP7A1). FGF19 also promotes gallbladder relaxation. While the loss of bile salts in stool is usually matched by increased hepatic synthesis, the maximum rate of synthesis is ~5 g/d, which may be insufficient to replete the bile acid pool size when there is pronounced impairment of intestinal bile salt reabsorption.

The expression of ABC transporters in the enterohepatic circulation and of the rate-limiting enzymes of bile acid and cholesterol synthesis are regulated in a coordinated fashion by nuclear receptors, which are ligand-activated transcription factors. The hepatic BSEP (ABCB11) is upregulated by the FXR that also represses bile acid synthesis. The expression of the cholesterol transporter, ABCG5/G8, is upregulated by the liver X receptor (LXR), which is an oxysterol sensor.

GALLBLADDER AND SPHINCTERIC FUNCTIONS

In the fasting state, the sphincter of Oddi (SOD) offers a high-pressure zone of resistance to bile flow from the CBD into the duodenum. Its tonic contraction serves to (1) prevent reflux of duodenal contents into the pancreatic and bile ducts and (2) promote filling of the gallbladder. The major factor controlling the evacuation of the gallbladder is the peptide hormone cholecystokinin (CCK), which is released from the duodenal mucosa in response to the ingestion of fats and amino acids. CCK produces (1) powerful contraction of the gallbladder, (2) decreased resistance of the SOD, and (3) enhanced flow of biliary contents into the duodenum.

Hepatic bile is "concentrated" within the gallbladder by energy-dependent transmucosal absorption of water and electrolytes. Almost the entire bile acid pool may be sequestered in the gallbladder following an overnight fast for delivery into the duodenum with the first meal of the day. The normal capacity of the gallbladder is ~30 mL.

CONGENITAL ANOMALIES

Anomalies of the biliary tract are not uncommon and include abnormalities in number, size, and shape (e.g., agenesis of the gallbladder, duplications, rudimentary or oversized "giant" gallbladders, and diverticula). *Phrygian cap* is a clinically innocuous entity in which a partial or complete septum (or fold) separates the fundus from the body. Anomalies of position or suspension are not uncommon and include left-sided gallbladder, intrahepatic gallbladder, retrodisplacement of the gallbladder, and "floating" gallbladder. The latter condition predisposes to acute torsion, volvulus, or herniation of the gallbladder.

GALLSTONES

Epidemiology and Pathogenesis Gallstones are quite prevalent in most Western countries. Gallstone formation increases after age 50. In the United States, the prevalence is highest in Native Americans followed by Hispanics, non-Hispanic whites, and black Americans. The prevalence is higher in women than men across all ages.

Gallstones form because of abnormal bile composition. They are divided into two major types: cholesterol stones and pigment stones. Cholesterol stones account for >90% of all gallstones in Western industrialized countries. Cholesterol gallstones usually contain >50% cholesterol monohydrate plus an admixture of calcium salts, bile pigments, proteins, and fatty acids. Pigment stones are composed primarily of calcium bilirubinate; they contain <20% cholesterol and are classified into "black" and "brown" types, the latter forming secondary to chronic biliary infection.

CHOLESTEROL STONES AND BILIARY SLUDGE Cholesterol is essentially water-insoluble and requires aqueous dispersion into either micelles or vesicles, both of which require the presence of a second lipid to solubilize the cholesterol. Cholesterol and phospholipids are secreted into bile as unilamellar bilayered vesicles, which are converted into mixed micelles consisting of bile acids, phospholipids, and cholesterol by the action of bile acids. If there is an excess of cholesterol in relation to phospholipids and bile acids, unstable, cholesterol-rich vesicles remain, which aggregate into large multilamellar vesicles from which cholesterol crystals precipitate **(Fig. 346-1)**.

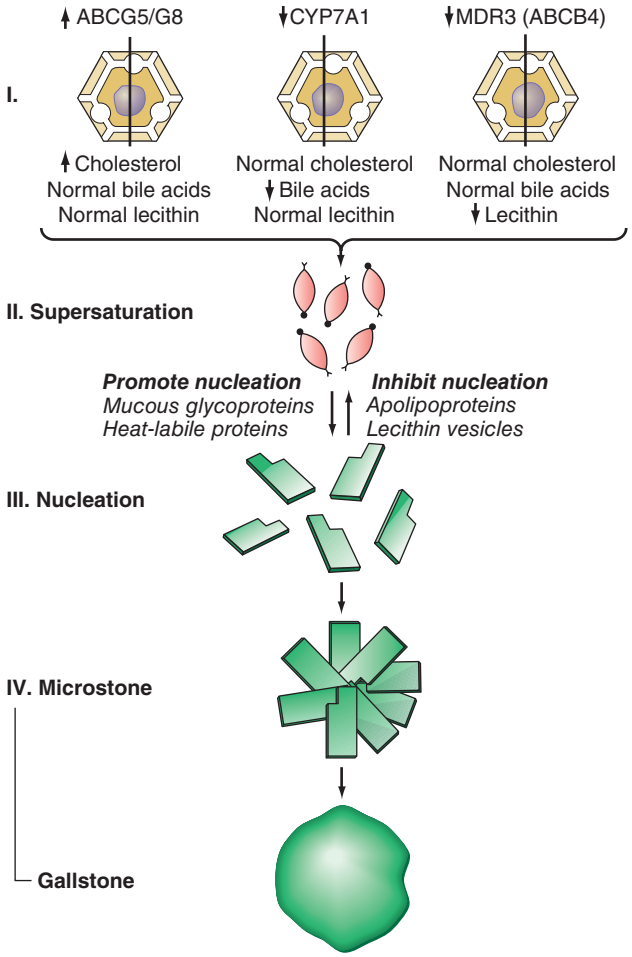

FIGURE 346-1 Scheme showing pathogenesis of cholesterol gallstone formation. Conditions or factors that increase the ratio of cholesterol to bile acids and phospholipids (lecithin) favor gallstone formation. ABCB4, ATP-binding cassette transporter; ABCG5/8, ATP-binding cassette (ABC) transporter G5/G8; CYP7A1, cytochrome P450 7A1; MDR3, multidrug resistance protein 3, also called phospholipid export pump.

There are several important mechanisms in the formation of lithogenic (stone-forming) bile. The most important is increased biliary secretion of cholesterol. This may occur in association with obesity, the metabolic syndrome, high-caloric and cholesterol-rich diets, or drugs (e.g., clofibrate) and may result from increased activity of hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme of hepatic cholesterol synthesis, and increased hepatic uptake of cholesterol from blood. In patients with gallstones, dietary cholesterol *increases* biliary cholesterol secretion. This does not occur in non-gallstone patients on high-cholesterol diets. In addition to environmental factors such as high-caloric and cholesterol-rich diets, genetic factors play an important role in gallstone disease. A large study of symptomatic gallstones in Swedish twins provided strong evidence for a role of genetic factors in gallstone pathogenesis. Genetic factors accounted for 25%, shared environmental factors for 13%, and individual environmental factors for 62% of the phenotypic variation among monozygotic twins. A single nucleotide polymorphism of the gene encoding the hepatic cholesterol transporter ABCG5/G8 has been found in 21% of patients with gallstones, but only in 9% of the general population. It is thought to cause a gain of function of the cholesterol transporter and to contribute to cholesterol hypersecretion. A high prevalence of gallstones is found among first-degree relatives of gallstone carriers and in certain ethnic populations such as American Indians, Chilean Indians, and Chilean Hispanics. A common genetic trait has been identified for some of these populations by mitochondrial DNA analysis. In some patients, impaired hepatic conversion of cholesterol to bile acids may also occur, resulting in an increase of the lithogenic cholesterol/bile acid ratio. Although most cholesterol stones have a polygenic basis, there are rare monogenic (Mendelian) causes. Mutations in the *CYP7A1* gene have been described that result in a deficiency of the enzyme cholesterol 7-hydroxylase, which catalyzes the initial step in cholesterol catabolism and bile acid synthesis. The homozygous state is associated with hypercholesterolemia and gallstones. Because the phenotype is expressed in the heterozygote state, mutations in the *CYP7A1* gene may contribute to the susceptibility to cholesterol gallstone disease in the population. Mutations in the *MDR3* (ABCB4) gene, which encodes the phospholipid export pump in the canalicular membrane of the hepatocyte, may cause defective phospholipid secretion into bile, resulting in cholesterol supersaturation of bile and formation of cholesterol gallstones in the gallbladder and in the bile ducts. Thus, an excess of biliary cholesterol in relation to bile acids and phospholipids is primarily due to hypersecretion of cholesterol, but hyposecretion of bile acids or phospholipids may contribute. An additional disturbance of bile acid metabolism that is likely to contribute to supersaturation of bile with cholesterol is enhanced conversion of cholic acid to deoxycholic acid, with replacement of the cholic acid pool by an expanded deoxycholic acid pool. It may result from enhanced dehydroxylation of cholic acid and increased absorption of newly formed deoxycholic acid. An increased deoxycholate secretion is associated with hypersecretion of cholesterol into bile.

While supersaturation of bile with cholesterol is an important prerequisite for gallstone formation, it is generally not sufficient by itself to produce cholesterol precipitation in vivo. Most individuals with supersaturated bile do not develop stones because the time required for cholesterol crystals to nucleate and grow is longer than the time bile remains in the gallbladder.

An important mechanism is *nucleation* of cholesterol monohydrate crystals, which is greatly accelerated in human lithogenic bile. Accelerated nucleation of cholesterol monohydrate in bile may be due to either

an *excess of pronucleating factors* or a *deficiency of antinucleating factors*. Mucin and certain nonmucin glycoproteins, principally immunoglobulins, appear to be pronucleating factors, while apolipoproteins A-I and A-II and other glycoproteins appear to be antinucleating factors. Pigment particles may possibly play a role as nucleating factors. In a genome-wide analysis of serum bilirubin levels, the uridine diphosphate-glucuronyltransferase 1A1 (*UGT1A1*) Gilbert's syndrome gene variant was associated with the presence of gallstone disease. Because most gallstones associated with the *UGT1A1* variant were cholesterol stones, this finding points to the role of pigment particles in the pathogenesis of gallbladder stones. Cholesterol monohydrate crystal nucleation and crystal growth probably occur within the mucin gel layer. Vesicle fusion leads to liquid crystals, which, in turn, nucleate into solid cholesterol monohydrate crystals. Continued growth of the crystals occurs by direct nucleation of cholesterol molecules from supersaturated unilamellar or multilamellar biliary vesicles.

A third important mechanism in cholesterol gallstone formation is *gallbladder hypomotility*. If the gallbladder emptied all supersaturated or crystal-containing bile completely, stones would not be able to grow. A high percentage of patients with gallstones exhibits abnormalities of gallbladder emptying. Ultrasonographic studies show that gallstone patients display an increased gallbladder volume during fasting and after a test meal (residual volume) and that fractional emptying after gallbladder stimulation is decreased. The incidence of gallstones is increased in conditions associated with infrequent or impaired gallbladder emptying such as fasting, parenteral nutrition, or pregnancy and in patients using drugs that inhibit gallbladder motility.

Biliary sludge is a thick, mucous material that, upon microscopic examination, reveals lecithin-cholesterol liquid crystals, cholesterol monohydrate crystals, calcium bilirubinate, and mucin gels. Biliary sludge typically forms a crescent-like layer in the most dependent portion of the gallbladder and is recognized by characteristic echoes on ultrasonography (see below). The presence of biliary sludge implies two abnormalities: (1) the normal balance between gallbladder mucin secretion and elimination has become deranged, and (2) nucleation of biliary solutes has occurred. That biliary sludge may be a precursor form of gallstone disease is evident from several observations. In one study, 96 patients with gallbladder sludge were followed prospectively by serial ultrasound studies. In 18%, biliary sludge disappeared and did not recur for at least 2 years. In 60%, biliary sludge disappeared and reappeared; in 14%, gallstones (8% asymptomatic, 6% symptomatic) developed; and in 6%, severe biliary pain with or without acute pancreatitis occurred. In 12 patients, cholecystectomies were performed, 6 for gallstone-associated biliary pain and 3 in symptomatic patients with sludge but without gallstones who had prior attacks of pancreatitis; the latter did not recur after cholecystectomy. It should be emphasized that biliary sludge can develop with disorders that cause gallbladder hypomotility; that is, surgery, burns, total parenteral nutrition, pregnancy, and oral contraceptives—all of which are associated with gallstone formation. However, the presence of biliary sludge implies supersaturation of bile with either cholesterol or calcium bilirubinate.

Two other conditions are associated with cholesterol-stone or biliary-sludge formation: pregnancy and rapid weight reduction through a very-low-calorie diet. There appear to be two key changes during pregnancy that contribute to a "cholelithogenic state": (1) a marked increase in cholesterol saturation of bile during the third trimester and (2) sluggish gallbladder contraction in response to a standard meal, resulting in impaired gallbladder emptying. That these changes are related to pregnancy per se is supported by several studies that show reversal of these abnormalities quite rapidly after delivery. During pregnancy, gallbladder sludge develops in 20–30% of women and gallstones in 5–12%. Although biliary sludge is a common finding during pregnancy, it is usually asymptomatic and often resolves spontaneously after delivery. Gallstones, which are less common than sludge and frequently associated with biliary colic, may also disappear after delivery because of spontaneous dissolution related to bile becoming unsaturated with cholesterol postpartum.

Approximately 10–20% of persons with rapid weight reduction achieved through very-low-calorie dieting develop gallstones. In a study involving 600 patients who completed a 3-month, 520-kcal/d diet, UDCA in a dosage of 600 mg/d proved highly effective in preventing gallstone formation; gallstones developed in only 3% of UDCA recipients, compared to 28% of placebo-treated patients. In obese patients treated by gastric banding, 500 mg/d of UDCA reduced the risk of gallstone formation from 30 to 8% within a follow-up of 6 months.

To summarize, cholesterol gallstone disease occurs because of several defects, which include (1) bile supersaturation with cholesterol, (2) nucleation of cholesterol monohydrate with subsequent crystal retention and stone growth, and (3) abnormal gallbladder motor function with delayed emptying and stasis. Other important factors known to predispose to cholesterol-stone formation are summarized in **Table 346-1**.

PIGMENT STONES Black pigment stones are composed of either pure calcium bilirubinate or polymer-like complexes with calcium and mucin glycoproteins. They are more common in patients who have chronic hemolytic states (with increased conjugated bilirubin in bile); cirrhosis, especially related to alcohol; Gilbert's syndrome; or cystic fibrosis. Gallbladder stones in patients with ileal diseases, ileal resection, or ileal bypass generally are also black pigment stones.

TABLE 346-1 Predisposing Factors for Cholesterol and Pigment Gallstone Formation

Cholesterol Stones

1. Demographic/genetic factors: Prevalence highest in North American Indians, Chilean Indians, and Chilean Hispanics, greater in Northern Europe and North America than in Asia, lowest in Japan; familial disposition; hereditary aspects
2. Obesity, metabolic syndrome: Normal bile acid pool and secretion but increased biliary secretion of cholesterol
3. Rapid weight loss: Mobilization of tissue cholesterol leads to increased biliary cholesterol secretion while enterohepatic circulation of bile acids is decreased
4. Female sex hormones
   a. Estrogens stimulate hepatic lipoprotein receptors, increase uptake of dietary cholesterol, and increase biliary cholesterol secretion
   b. Natural estrogens, other estrogens, and oral contraceptives lead to decreased bile salt secretion and decreased conversion of cholesterol to cholesteryl esters
5. Pregnancy: Impaired gallbladder emptying caused by progesterone combined with the influence of estrogens, which increase biliary cholesterol secretion
6. Increasing age: Increased biliary secretion of cholesterol, decreased size of bile acid pool, decreased secretion of bile salts
7. Gallbladder hypomotility leading to stasis and formation of sludge
   a. Total parenteral nutrition
   b. Fasting
   c. Pregnancy
   d. Drugs such as octreotide
8. Clofibrate therapy: Increased biliary secretion of cholesterol
9. Decreased bile acid secretion
   a. Genetic defect of the *CYP7A1* gene
10. Decreased phospholipid secretion: Genetic defect of the *MDR3* gene
11. Miscellaneous
    a. High-calorie, high-fat diet
    b. Spinal cord injury

Pigment Stones

1. Demographic/genetic factors: Asia, rural setting (presumed due to increased prevalence of parasitic biliary infections; the incidence has been dropping with time)
2. Chronic hemolysis (example: sickle cell disease)
3. Alcohol related liver cirrhosis
4. Ineffective erythropoiesis (example: pernicious anemia)
5. Cystic fibrosis
6. Chronic biliary tract infection, parasite infections
7. Increasing age
8. Ileal disease, ileal resection or bypass

Enterohepatic recycling of bilirubin in ileal disease states contributes to their pathogenesis. Brown pigment stones are composed of calcium salts of unconjugated bilirubin with varying amounts of cholesterol and protein. They are caused by the presence of increased amounts of unconjugated, insoluble bilirubin in bile that precipitates to form stones. Deconjugation of an excess of soluble bilirubin mono- and diglucuronides may be mediated by endogenous β-glucuronidase but may also occur by spontaneous hydrolysis. Sometimes, the enzyme is also produced when bile is chronically infected by bacteria, and such stones are brown. Pigment stone formation is frequent in Asia and is often associated with parasitic infections in the gallbladder and biliary tree (Table 346-1).

Diagnosis Procedures of potential use in the diagnosis of cholelithiasis and other diseases of the gallbladder are detailed in **Table 346-2**. Ultrasonography of the gallbladder is very accurate in the identification of cholelithiasis and has replaced oral cholecystography (OCG) **(Fig. 346-2*A*)**. Stones as small as 1.5 mm in diameter may be confidently identified provided that firm criteria are used (e.g., acoustic "shadowing" of opacities that are within the gallbladder lumen and that change with the patient's position [by gravity]). In major medical centers, the false-negative and false-positive rates for ultrasound in gallstone patients are ~2–4%. Biliary sludge is material of low echogenic activity that typically forms a layer in the most dependent position of the gallbladder. This layer shifts with postural changes but fails to produce acoustic shadowing; these two characteristics distinguish sludges from gallstones. Ultrasound can also be used to assess the emptying function of the gallbladder.

TABLE 346-2 Diagnostic Evaluation of the Gallbladder

DIAGNOSTIC ADVANTAGES	DIAGNOSTIC LIMITATIONS	COMMENT
Ultrasound		
Rapid Accurate identification of gallstones (>95%) Simultaneous scanning of GB, liver, bile ducts, pancreas "Real-time" scanning allows assessment of GB volume, contractility Not limited by jaundice, pregnancy May detect very small stones	Bowel gas Massive obesity Ascites	Procedure of choice for detection of stones
Plain Abdominal X-Ray		
Low cost Readily available	Relatively low yield Contraindicated in pregnancy	Pathognomonic findings in: calcified gallstones, limey bile, porcelain GB, emphysematous cholecystitis, gallstone ileus
Cholescintigraphy (HIDA, DISIDA, etc.)		
Accurate identification of cystic duct obstruction Simultaneous assessment of bile ducts	Contraindicated in pregnancy Serum bilirubin >103–205 μmol/L (6–12 mg/dL) Cholecystogram of low resolution	Indicated for confirmation of suspected acute cholecystitis; less sensitive and less specific in chronic cholecystitis; useful in the diagnosis of acalculous cholecystopathy, especially if given with CCK to assess GB emptying

Abbreviations: CCK, cholecystokinin; DISIDA, diisopropyl iminodiacetic acid; GB, gallbladder; HIDA, hydroxyl iminodiacetic acid.

The plain abdominal film may detect gallstones containing sufficient calcium to be radiopaque (10–15% of cholesterol and ~50% of pigment stones). Plain radiography may also be of use in the diagnosis of emphysematous cholecystitis, porcelain gallbladder, limey bile, and gallstone ileus.

OCG was historically a useful procedure for the diagnosis of gallstones but has been replaced by ultrasound and is now regarded as obsolete. It may be used to assess the patency of the cystic duct and gallbladder emptying function. Further, OCG can also delineate the size and number of gallstones and determine whether they are calcified, useful information if medical dissolution is being considered.

Radiopharmaceuticals such as ^{99m}Tc-labeled *N*-substituted iminodiacetic acids (HIDA and DISIDA) are rapidly extracted from the blood and are excreted into the biliary tree in high concentration even in the presence of mild to moderate serum bilirubin elevations. Failure to image the gallbladder in the presence of biliary ductal visualization may indicate cystic duct obstruction, acute or chronic cholecystitis, or surgical absence of the organ. Such scans have application in the diagnosis of acute cholecystitis and may play a role in the detection of a postcholecystectomy bile leak.

Symptoms of Gallstone Disease Gallstones usually produce symptoms by causing inflammation or obstruction following their migration into the cystic duct or CBD. The most specific and characteristic symptom of gallstone disease is biliary colic that is a constant and often long-lasting pain (see below). Obstruction of the cystic duct or CBD by a stone produces increased intraluminal pressure and distention of the viscus that cannot be relieved by repetitive biliary contractions. The resultant visceral pain is characteristically a severe, steady ache or fullness in the epigastrium or right upper quadrant (RUQ) of the abdomen with frequent radiation to the interscapular area, right scapula, or shoulder.

Biliary colic begins quite suddenly and may persist with severe intensity for 30 min to 5 h, subsiding gradually or rapidly. It is steady rather than intermittent, as would be suggested by the word *colic*, which must be regarded as a misnomer, although it is in widespread use. An episode of biliary pain persisting beyond 5 h should raise the suspicion of acute cholecystitis (see below). Nausea and vomiting frequently accompany episodes of biliary pain. An elevated level of serum bilirubin and/or alkaline phosphatase suggests a common duct stone. Fever or chills (rigors) with biliary pain usually imply a complication, that is, cholecystitis, pancreatitis, or cholangitis. Complaints of short-lasting, vague epigastric fullness, dyspepsia, eructation, or flatulence, especially following a fatty meal, should not be confused with biliary pain. Such symptoms are frequently elicited from patients with or without gallstone disease but are not specific for biliary calculi. Biliary colic may be precipitated by eating a fatty meal, by consumption of a large meal following a period of prolonged fasting, or by eating a normal meal; it is frequently nocturnal, occurring within a few hours of retiring.

Natural History Gallstone disease discovered in an asymptomatic patient or in a patient whose symptoms are not referable to cholelithiasis is a common clinical problem. Sixty to 80% of persons with asymptomatic gallstones remain asymptomatic over follow-up periods of up to 25 years. The probability of developing symptoms within 5 years after diagnosis is 2–4% per year and decreases in the years thereafter to 1–2%. The yearly incidence of complications is about 0.1–0.3%. Patients remaining asymptomatic for 15 years were found to be unlikely to develop symptoms during further follow-up, and most patients who did develop complications from their gallstones experienced *prior* warning symptoms. Similar conclusions apply to diabetic patients with silent gallstones. Decision analysis has suggested that (1) the cumulative risk of death due to gallstone disease while on expectant management is small, and (2) prophylactic cholecystectomy is not warranted.

Complications requiring cholecystectomy are much more common in gallstone patients who have developed symptoms of biliary pain. Patients found to have gallstones at a young age are more likely to develop symptoms from cholelithiasis than are patients >60 years at the time of initial diagnosis. Patients with diabetes mellitus and gallstones

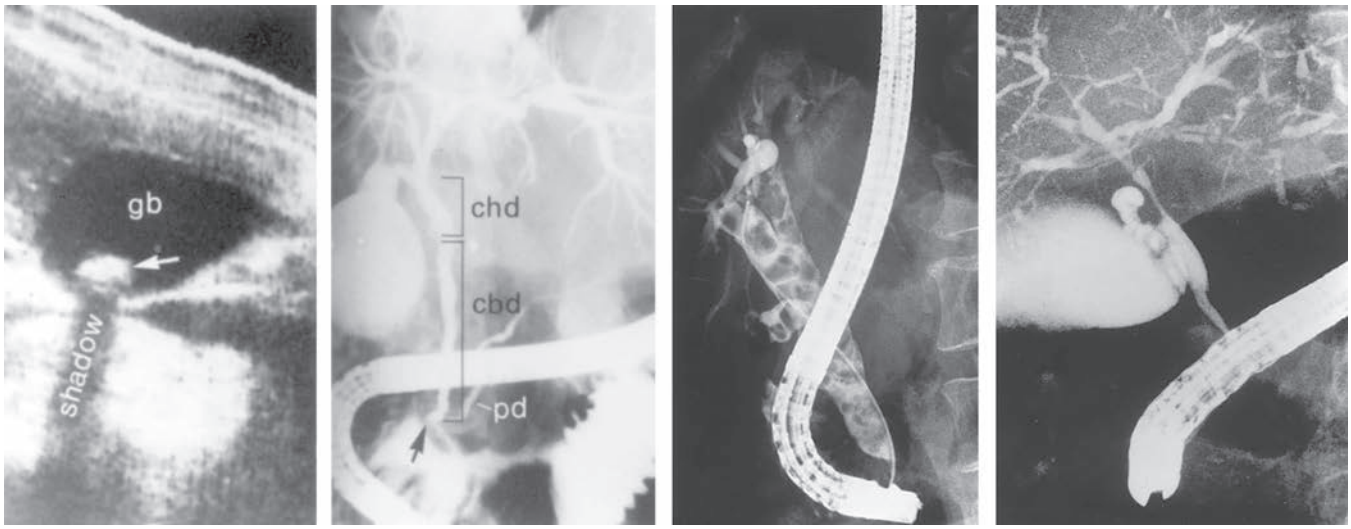

FIGURE 346-2 Examples of ultrasound and radiologic studies of the biliary tract. ***A.*** An ultrasound study showing a distended gallbladder (GB) containing a single large stone (*arrow*), which casts an acoustic shadow. ***B.*** Endoscopic retrograde cholangiopancreatogram (ERCP) showing normal biliary tract anatomy. In addition to the endoscope and large vertical gallbladder filled with contrast dye, the common hepatic duct (CHD), common bile duct (CBD), and pancreatic duct (PD) are shown. The *arrow* points to the ampulla of Vater. ***C.*** Endoscopic retrograde cholangiogram (ERC) showing choledocholithiasis. The biliary tract is dilated and contains multiple radiolucent calculi. ***D.*** ERCP showing sclerosing cholangitis. The CBD shows areas that are strictured and narrowed.

may be somewhat more susceptible to septic complications, but the magnitude of risk of septic biliary complications in diabetic patients is incompletely defined.

TREATMENT

Gallstones

SURGICAL THERAPY

In asymptomatic gallstone patients, the risk of developing symptoms or complications requiring surgery is quite small (see above). Thus, a recommendation for cholecystectomy in a patient with gallstones should probably be based on assessment of three factors: (1) the presence of symptoms that are frequent enough or severe enough to interfere with the patient's general routine; (2) the presence of a prior complication of gallstone disease, that is, history of acute cholecystitis, pancreatitis, gallstone fistula, etc.; or (3) the presence of an underlying condition predisposing the patient to increased risk of gallstone complications (e.g., a previous attack of acute cholecystitis regardless of current symptomatic status). Patients with very large gallstones (>3 cm in diameter) and patients harboring gallstones in a congenitally anomalous gallbladder might also be considered for prophylactic cholecystectomy. Although young age is a worrisome factor in asymptomatic gallstone patients, few authorities would now recommend routine cholecystectomy in young patients with silent stones. Laparoscopic cholecystectomy is a minimal-access approach for the removal of the gallbladder together with its stones. Its advantages include a markedly shortened hospital stay, minimal disability, and decreased cost, and it is the procedure of choice for most patients referred for elective cholecystectomy.

From several studies involving >4000 patients undergoing laparoscopic cholecystectomy, the following key points emerge: (1) complications develop in ~4% of patients, (2) conversion to laparotomy occurs in 5%, (3) the death rate is remarkably low (i.e., <0.1%), and (4) the rate of bile duct injuries is low (i.e., 0.2–0.6%) and comparable with open cholecystectomy. These data indicate why laparoscopic cholecystectomy has become the "gold standard" for treating symptomatic cholelithiasis.

MEDICAL THERAPY—GALLSTONE DISSOLUTION

In carefully selected patients with a functioning gallbladder and with radiolucent stones <10 mm in diameter, complete dissolution can be achieved in ~50% of patients within 6 months to 2 years. For good results within a reasonable time period, this therapy should be limited to radiolucent stones <5 mm in diameter. The dose of UDCA should be 10–15 mg/kg per d. Stones >10 mm in size rarely dissolve. Pigment stones are not responsive to UDCA therapy. Probably ≤10% of patients with *symptomatic* cholelithiasis are candidates for such treatment. However, in addition to the vexing problem of recurrent stones (30–50% over 3–5 years of follow-up), there is also the factor of taking a drug for up to 2 years and perhaps indefinitely. The advantages and success of laparoscopic cholecystectomy have largely reduced the role of gallstone dissolution to patients who wish to avoid or are not candidates for elective cholecystectomy. However, patients with cholesterol gallstone disease who develop recurrent choledocholithiasis after cholecystectomy should be on long-term treatment with UDCA.

ACUTE AND CHRONIC CHOLECYSTITIS

Acute Cholecystitis Acute inflammation of the gallbladder wall usually follows obstruction of the cystic duct by a stone. Inflammatory response can be evoked by three factors: (1) *mechanical inflammation* produced by increased intraluminal pressure and distention with resulting ischemia of the gallbladder mucosa and wall, (2) *chemical inflammation* caused by the release of lysolecithin (due to the action of phospholipase on lecithin in bile) and other local tissue factors, and (3) *bacterial inflammation*, which may play a role in 50–85% of patients with acute cholecystitis. The organisms most frequently isolated by culture of gallbladder bile in these patients include *Escherichia coli*, *Klebsiella* spp., *Streptococcus* spp., and *Clostridium* spp.

Acute cholecystitis often begins as an attack of biliary pain that progressively worsens. Approximately 60–70% of patients report having experienced prior attacks that resolved spontaneously. As the episode progresses, however, the pain of acute cholecystitis becomes more generalized in the right upper abdomen. As with biliary colic, the pain of cholecystitis may radiate to the interscapular area, right scapula, or shoulder. Peritoneal signs of inflammation such as increased pain with jarring or on deep respiration may be apparent. The patient is anorectic and often nauseated. Vomiting is relatively common and may produce symptoms and signs of vascular and extracellular volume depletion. Jaundice is unusual early in the course of acute cholecystitis but may occur when edematous inflammatory changes involve the bile ducts and surrounding lymph nodes.

A low-grade fever is characteristically present, but shaking chills or rigors are not uncommon. The RUQ of the abdomen is almost

invariably tender to palpation. An enlarged, tense gallbladder is palpable in 25–50% of patients. Deep inspiration or cough during subcostal palpation of the RUQ usually produces increased pain and inspiratory arrest (Murphy's sign). Localized rebound tenderness in the RUQ is common, as are abdominal distention and hypoactive bowel sounds from paralytic ileus, but generalized peritoneal signs and abdominal rigidity are usually lacking, in the absence of perforation.

The diagnosis of acute cholecystitis is usually made on the basis of a characteristic history and physical examination. The triad of sudden onset of RUQ tenderness, fever, and leukocytosis is highly suggestive. Typically, leukocytosis in the range of 10,000–15,000 cells per microliter with a left shift on differential count is found. The serum bilirubin is mildly elevated (<85.5 μmol/L [5 mg/dL]) in fewer than half of patients, whereas about one-fourth have modest elevations in serum aminotransferases (usually less than a fivefold elevation). Ultrasound will demonstrate calculi in 90–95% of cases and is useful for detection of signs of gallbladder inflammation including thickening of the wall, pericholecystic fluid, and dilatation of the bile duct. The radionuclide (e.g., HIDA) biliary scan may be confirmatory if bile duct imaging is seen without visualization of the gallbladder.

Approximately 75% of patients treated medically have remission of acute symptoms within 2–7 days following hospitalization. In 25%, however, a complication of acute cholecystitis will occur despite conservative treatment (see below). In this setting, prompt surgical intervention is required. Of the 75% of patients with acute cholecystitis who undergo remission of symptoms, ~25% will experience a recurrence of cholecystitis within 1 year, and 60% will have at least one recurrent bout within 6 years. In view of the natural history of the disease, acute cholecystitis is best treated by early surgery whenever possible. Mirizzi's syndrome is a rare complication in which a gallstone becomes impacted in the cystic duct or neck of the gallbladder causing compression of the CBD, resulting in CBD obstruction and jaundice. Ultrasound shows gallstone(s) lying outside the hepatic duct. Endoscopic retrograde cholangiopancreatography (ERCP) **(Fig. 346-2*B*)**, percutaneous transhepatic cholangiography (PTC), or magnetic resonance cholangiopancreatography (MRCP) will usually demonstrate the characteristic extrinsic compression of the CBD. Surgery consists of removing the cystic duct, diseased gallbladder, and impacted stone. The preoperative diagnosis of Mirizzi's syndrome is important to avoid CBD injury.

ACALCULOUS CHOLECYSTITIS In 5–14% of patients with acute cholecystitis, calculi obstructing the cystic duct are not found at surgery. In >50% of such cases, an underlying explanation for acalculous inflammation is not found. An increased risk for the development of acalculous cholecystitis is especially associated with prolonged fasting, with serious trauma or burns, in the postpartum period following prolonged labor, and with orthopedic and other nonbiliary major surgical operations in the postoperative period. It may possibly complicate periods of prolonged parenteral hyperalimentation. For some of these cases, biliary sludge in the cystic duct may be responsible. Other precipitating factors include vasculitis, obstructing adenocarcinoma of the gallbladder, diabetes mellitus, torsion of the gallbladder, "unusual" bacterial infections of the gallbladder (e.g., *Leptospira*, *Streptococcus*, *Salmonella*, or *Vibrio cholerae*), and parasitic infestation of the gallbladder. Acalculous cholecystitis may also be seen with a variety of other systemic disease processes (e.g., sarcoidosis, cardiovascular disease, tuberculosis, syphilis, actinomycosis).

Although the clinical manifestations of acalculous cholecystitis are indistinguishable from those of calculous cholecystitis, the setting of acute gallbladder inflammation complicating severe underlying illness is characteristic of acalculous disease. Ultrasound or computed tomography (CT) examinations demonstrating a large, tense, static gallbladder without stones and with evidence of poor emptying over a prolonged period may be diagnostically useful in some cases. The complication rate for acalculous cholecystitis exceeds that for calculous cholecystitis. Successful management of acute acalculous cholecystitis appears to depend primarily on early diagnosis and surgical intervention, with meticulous attention to postoperative care.

ACALCULOUS CHOLECYSTOPATHY Disordered motility of the gallbladder can produce recurrent biliary pain in patients without gallstones. Infusion of an octapeptide of CCK can be used to measure the gallbladder ejection fraction during cholescintigraphy. The surgical findings have included abnormalities such as chronic cholecystitis, gallbladder muscle hypertrophy, and/or a markedly narrowed cystic duct. Some of these patients may well have had antecedent gallbladder disease. The following criteria can be used to identify patients with acalculous cholecystopathy: (1) recurrent episodes of typical RUQ pain characteristic of biliary tract pain, (2) abnormal CCK cholescintigraphy demonstrating a gallbladder ejection fraction of <40%, and (3) infusion of CCK reproducing the patient's pain. An additional clue would be the identification of a large gallbladder on ultrasound examination. Importantly, it should be noted that SOD dysfunction can also give rise to recurrent RUQ pain and CCK-scintigraphic abnormalities.

EMPHYSEMATOUS CHOLECYSTITIS So-called emphysematous cholecystitis is thought to begin with acute cholecystitis (calculous or acalculous) followed by ischemia or gangrene of the gallbladder wall and infection by gas-producing organisms. Bacteria most frequently cultured in this setting include anaerobes, such as *Clostridium welchii* or *C. perfringens*, and aerobes, such as *E. coli*. This condition occurs most frequently in elderly men and in patients with diabetes mellitus. The clinical manifestations are essentially indistinguishable from those of nongaseous cholecystitis. The diagnosis is usually made on plain abdominal film by finding gas within the gallbladder lumen, dissecting within the gallbladder wall to form a gaseous ring, or in the pericholecystic tissues. The morbidity and mortality rates with emphysematous cholecystitis are considerable. Prompt surgical intervention coupled with appropriate antibiotics is mandatory.

Chronic Cholecystitis Chronic inflammation of the gallbladder wall is almost always associated with the presence of gallstones and is thought to result from repeated bouts of subacute or acute cholecystitis or from persistent mechanical irritation of the gallbladder wall by gallstones. The presence of bacteria in the bile occurs in >25% of patients with chronic cholecystitis. The presence of infected bile in a patient with *chronic* cholecystitis undergoing elective cholecystectomy probably adds little to the operative risk. Chronic cholecystitis may be asymptomatic for years, which may progress to symptomatic gallbladder disease or to acute cholecystitis or may present with complications (see below).

Complications of Cholecystitis • **EMPYEMA AND HYDROPS** Empyema of the gallbladder usually results from progression of acute cholecystitis with persistent cystic duct obstruction to superinfection of the stagnant bile with a pus-forming bacterial organism. The clinical picture resembles that of cholangitis with high fever; severe RUQ pain; marked leukocytosis; and often, prostration. Empyema of the gallbladder carries a high risk of gram-negative sepsis and/or perforation. Emergency surgical intervention with proper antibiotic coverage is required as soon as the diagnosis is suspected.

Hydrops or mucocele of the gallbladder may also result from prolonged obstruction of the cystic duct, usually by a large solitary calculus. In this instance, the obstructed gallbladder lumen is progressively distended, over a period of time, by mucus (mucocele) or by a clear transudate (hydrops) produced by mucosal epithelial cells. A visible, easily palpable, nontender mass sometimes extending from the RUQ into the right iliac fossa may be found on physical examination. The patient with hydrops of the gallbladder frequently remains asymptomatic, although chronic RUQ pain may also occur. Cholecystectomy is indicated, because empyema, perforation, or gangrene may complicate the condition.

GANGRENE AND PERFORATION Gangrene of the gallbladder results from ischemia of the wall and patchy or complete tissue necrosis. Underlying conditions often include marked distention of the gallbladder, vasculitis, diabetes mellitus, empyema, or torsion resulting in arterial occlusion. Gangrene usually predisposes to perforation of the gallbladder, but perforation may also occur in chronic cholecystitis without premonitory warning symptoms. *Localized perforations*

are usually contained by the omentum or by adhesions produced by recurrent inflammation of the gallbladder. Bacterial superinfection of the walled-off gallbladder contents results in abscess formation. Most patients are best treated with cholecystectomy, but some seriously ill patients may be managed with cholecystostomy and drainage of the abscess. *Free perforation* is less common but is associated with a mortality rate of ~30%. Such patients may experience a sudden transient relief of RUQ pain as the distended gallbladder decompresses; this is followed by signs of generalized peritonitis.

FISTULA FORMATION AND GALLSTONE ILEUS Fistula formation into an adjacent organ adherent to the gallbladder wall may result from inflammation and adhesion formation. Fistulas into the duodenum are most common, followed in frequency by those involving the hepatic flexure of the colon, stomach or jejunum, abdominal wall, and renal pelvis. Clinically "silent" biliary-enteric fistulas occurring as a complication of acute cholecystitis have been found in up to 5% of patients undergoing cholecystectomy. Asymptomatic cholecystoenteric fistulas may sometimes be diagnosed by finding gas in the biliary tree on plain abdominal films. Barium contrast studies or endoscopy of the upper gastrointestinal tract or colon may demonstrate the fistula. Treatment in the symptomatic patient usually consists of cholecystectomy, CBD exploration, and closure of the fistulous tract.

Gallstone ileus refers to mechanical intestinal obstruction resulting from the passage of a large gallstone into the bowel lumen. The stone customarily enters the duodenum through a cholecystoenteric fistula at that level. The site of obstruction by the impacted gallstone is usually at the ileocecal valve, provided that the more proximal small bowel is of normal caliber. Most patients do not give a history of either prior biliary tract symptoms or complaints suggestive of acute cholecystitis or fistula formation. Large stones, >2.5 cm in diameter, are thought to predispose to fistula formation by gradual erosion through the gallbladder fundus. Diagnostic confirmation may occasionally be found on the plain abdominal film (e.g., small-intestinal obstruction with gas in the biliary tree [pneumobilia] and a calcified, ectopic gallstone) or following an upper gastrointestinal series (cholecystoduodenal fistula with small-bowel obstruction at the ileocecal valve). Laparotomy with stone extraction (or propulsion into the colon) remains the procedure of choice to relieve obstruction. Evacuation of large stones within the gallbladder should also be performed. In general, the gallbladder and its attachment to the intestines should be left alone.

LIMEY (MILK OF CALCIUM) BILE AND PORCELAIN GALLBLADDER Calcium salts in the lumen of the gallbladder in sufficient concentration may produce calcium precipitation and diffuse, hazy opacification of bile or a layering effect on plain abdominal roentgenography. This so-called limey bile, or milk of calcium bile, is usually clinically innocuous, but cholecystectomy is often performed, especially when it occurs in a hydropic gallbladder. In the entity called *porcelain gallbladder*, calcium salt deposition within the wall of a chronically inflamed gallbladder may be detected on the plain abdominal film. In the past, cholecystectomy was advised in all patients with porcelain gallbladder because there was felt to be a high incidence of carcinoma of the gallbladder associated with this condition, an association challenged by a number of studies. Two patterns of gallbladder wall calcification have now been appreciated: complete intramural calcification and selective mucosal calcification. The incidence of cancer in those with selective intramural calcification is higher than those with complete mucosal wall calcification, but the risk is very small. As such, the need for cholecystectomy for porcelain gallbladder is not absolute; close surveillance in these patients is also acceptable.

TREATMENT

Acute Cholecystitis

MEDICAL THERAPY

Although surgical intervention remains the mainstay of therapy for acute cholecystitis and its complications, a period of in-hospital stabilization may be required before cholecystectomy. Oral intake is eliminated, nasogastric suction may be indicated, extracellular volume depletion and electrolyte abnormalities are repaired, and analgesia is provided. Intravenous antibiotic therapy is indicated in patients with severe acute cholecystitis, even though bacterial superinfection of bile may not have occurred in the early stages of the inflammatory process. Antibiotic therapy is guided by the most common organisms likely to be present including *E. coli*, *Klebsiella*, *Enterococcus*, *Enterobacter*, and *Streptococcus*. Effective antibiotics include piperacillin plus tazobactam, imipenem, meropenem, ceftriaxone plus metronidazole, and levofloxacin plus metronidazole **(Chap. 161)**. Postoperative complications of wound infection, abscess formation, and sepsis are reduced in antibiotic-treated patients.

SURGICAL THERAPY

The optimal timing of surgical intervention in patients with acute cholecystitis depends on stabilization of the patient. The clear trend is toward earlier surgery, and this is due in part to requirements for shorter hospital stays. Urgent (emergency) cholecystectomy or percutaneous cholecystostomy is probably appropriate in most patients in whom a complication of acute cholecystitis such as empyema, emphysematous cholecystitis, or perforation is suspected or confirmed. Patients with uncomplicated acute cholecystitis should undergo early elective laparoscopic cholecystectomy, ideally within 48–72 h after diagnosis. The complication rate is not increased in patients undergoing early as opposed to delayed (>6 weeks after diagnosis) cholecystectomy. Delayed surgical intervention is probably best reserved for (1) patients in whom the overall medical condition imposes an unacceptable risk for early surgery and (2) patients in whom the diagnosis of acute cholecystitis is in doubt. Thus, early cholecystectomy (within 72 h) is the treatment of choice for most patients with acute cholecystitis. Mortality figures for emergency cholecystectomy in most centers range from 1 to 3%, whereas the mortality risk for early elective cholecystectomy is ~0.5% in patients under age 60. Of course, the operative risks increase with age-related diseases of other organ systems and with the presence of long- or short-term complications of gallbladder disease. Seriously ill or debilitated patients with cholecystitis may be managed with percutaneous drainage (a cholecystostomy tube), transpapillary drainage (an endoscopically placed transpapillary drainage catheter via the cystic duct), or transmural drainage (an endoscopically placed covered, lumen-apposing stent). Elective cholecystectomy may then be done at a later date.

Postcholecystectomy Complications Early complications following cholecystectomy include atelectasis and other pulmonary disorders, abscess formation (often subphrenic), external or internal hemorrhage, biliary-enteric fistula, and bile leaks. Jaundice may indicate absorption of bile from an intraabdominal collection following a biliary leak or mechanical obstruction of the CBD by retained calculi, intraductal blood clots, or extrinsic compression.

Overall, cholecystectomy is a very successful operation that provides total or near-total relief of preoperative symptoms in 75–90% of patients. The most common cause of persistent postcholecystectomy symptoms is an overlooked symptomatic nonbiliary disorder (e.g., reflux esophagitis, peptic ulceration, pancreatitis, or—most often—irritable bowel syndrome). In a small percentage of patients, however, a disorder of the extrahepatic bile ducts may result in persistent symptomatology. These so-called postcholecystectomy syndromes may be due to (1) biliary strictures, (2) retained biliary calculi, (3) cystic duct stump syndrome, (4) stenosis or dyskinesia of the SOD, or (5) bile salt–induced diarrhea or gastritis.

CYSTIC DUCT STUMP SYNDROME In the absence of cholangiographically demonstrable retained stones, symptoms resembling biliary pain or cholecystitis in the postcholecystectomy patient have frequently been attributed to disease in a long (>1 cm) cystic duct remnant (cystic duct stump syndrome). Careful analysis, however, reveals that postcholecystectomy complaints are attributable to other causes in almost all patients in whom the symptom complex was originally thought to result from the existence of a long cystic duct stump.

Accordingly, considerable care should be taken to investigate the possible role of other factors in the production of postcholecystectomy symptoms before attributing them to cystic duct stump syndrome.

SOD STENOSIS, SOD DYSKINESIA, AND BILIARY DYSKINESIA Symptoms of biliary colic accompanied by signs of recurrent, intermittent biliary obstruction may be produced by acalculous cholecystopathy, SOD stenosis, or SOD dyskinesia. SOD stenosis is thought to result from acute or chronic inflammation of the papilla of Vater or from glandular hyperplasia of the papillary segment. Five criteria have been used to define SOD stenosis: (1) upper abdominal pain, usually RUQ or epigastric; (2) abnormal liver tests; (3) dilatation of the CBD upon MRCP or ERCP examination; (4) delayed (>45 min) drainage of contrast material from the duct; and (5) increased basal pressure of the SOD. After exclusion of acalculous cholecystopathy, treatment consists of endoscopic or surgical sphincteroplasty to ensure wide patency of the distal portions of both the bile and pancreatic ducts. The greater the number of the preceding criteria present, the greater is the likelihood that a patient does have a degree of SOD sufficient to justify correction. The factors usually considered as indications for sphincterotomy include (1) prolonged duration of symptoms, (2) lack of response to symptomatic treatment, (3) presence of severe disability, and (4) the patient's choice of sphincterotomy over surgery (given a clear understanding on his or her part of the risks involved in both procedures).

Biliary SOD disorders are characterized by three criteria: (1) biliary pain, (2) absence of bile duct stones or other abnormalities, and (3) elevated liver enzymes or a dilated CBD, but not both. In this setting, either hepatobiliary scintigraphy or SOD manometry can support the diagnosis. Importantly, the presence of both elevated liver enzymes and a dilated CBD should raise the question of obstruction. Proposed mechanisms to account for SOD dysfunction include spasm of the sphincter, denervation sensitivity resulting in hypertonicity, and abnormalities in the sequencing or frequency rates of the sphincteric-contraction waves. When thorough evaluation has failed to demonstrate another cause for the pain and when cholangiographic and manometric criteria suggest a diagnosis of SOD dyskinesia, medical treatment with nitrites or anticholinergics to attempt pharmacologic relaxation of SOD has been proposed but not evaluated in detailed studies. Endoscopic biliary sphincterotomy (EBS) or surgical sphincterotomy may be indicated in patients who fail to respond to a 2- to 3-month trial of medical therapy, especially if SOD pressures are elevated. Approximately 45% of such patients have long-term pain relief after EBS. EBS has become the procedure of choice for removing bile duct stones and for other biliary and pancreatic problems.

BILE SALT–INDUCED DIARRHEA AND GASTRITIS Postcholecystectomy patients may develop symptoms of dyspepsia, which have been attributed to duodenogastric reflux of bile. However, firm data linking these symptoms to bile gastritis after surgical removal of the gallbladder are lacking. Cholecystectomy induces persistent changes in gut transit, and these changes effect a noticeable modification of bowel habits. Cholecystectomy shortens gut transit time by accelerating passage of the fecal bolus through the colon with marked acceleration in the right colon, thus causing an increase in colonic bile acid output and a shift in bile acid composition toward the more diarrheagenic secondary bile acids, that is, deoxycholic acid. Diarrhea that is severe enough, that is, three or more watery movements per day, can be classified as postcholecystectomy diarrhea, and this occurs in 5–10% of patients undergoing elective cholecystectomy. Treatment with bile acid–sequestering agents such as cholestyramine or colestipol is often effective in ameliorating troublesome diarrhea.

THE HYPERPLASTIC CHOLECYSTOSES

The term *hyperplastic cholecystoses* is used to denote a group of disorders of the gallbladder characterized by excessive proliferation of normal tissue components.

Adenomyomatosis is characterized by a benign proliferation of gallbladder surface epithelium with glandlike formations, extramural sinuses, transverse strictures, and/or fundal nodule ("adenoma" or "adenomyoma") formation.

Cholesterolosis is characterized by abnormal deposition of lipid, especially cholesteryl esters, within macrophages in the lamina propria of the gallbladder wall. In its diffuse form ("strawberry gallbladder"), the gallbladder mucosa is brick red and speckled with bright yellow flecks of lipid. The localized form shows solitary or multiple "cholesterol polyps" studding the gallbladder wall. Cholesterol stones of the gallbladder are found in nearly half the cases. Cholecystectomy is only indicated in adenomyomatosis or cholesterolosis when biliary symptoms are present.

The prevalence of gallbladder polyps in the adult population is 1–4% with a marked male predominance. Types of gallbladder polyps include cholesterol polyps, adenomyomas, inflammatory polyps, and adenomas (rare). No significant changes have been found over a 5-year period in asymptomatic patients with gallbladder polyps <6 mm and few changes in polyps 7–9 mm. Cholecystectomy is recommended in symptomatic patients as well as in asymptomatic patients >50 years whose polyps are >10 mm or associated with gallstones or polyp growth on serial ultrasonography.

DISEASES OF THE BILE DUCTS

CONGENITAL ANOMALIES

Biliary Atresia and Hypoplasia Atretic and hypoplastic lesions of the extrahepatic and large intrahepatic bile ducts are the most common biliary anomalies of clinical relevance encountered in infancy. The clinical picture is one of severe obstructive jaundice during the first month of life, with pale stools. When biliary atresia is suspected on the basis of clinical, laboratory, and imaging findings, the diagnosis is confirmed by surgical exploration and operative cholangiography. Approximately 10% of cases of biliary atresia are treatable with Roux-en-Y choledochojejunostomy, with the Kasai procedure (hepatic portoenterostomy) being attempted in the remainder in an effort to restore some bile flow. Most patients, even those having successful biliary-enteric anastomoses, eventually develop chronic cholangitis, extensive hepatic fibrosis, and portal hypertension.

Choledochal Cysts Cystic dilatation may involve the free portion of the CBD, that is, choledochal cyst, or may present as diverticulum formation in the intraduodenal segment. In the latter situation, chronic reflux of pancreatic juice into the biliary tree can produce inflammation and stenosis of the extrahepatic bile ducts, leading to cholangitis or biliary obstruction. Because the process may be gradual, ~50% of patients present with onset of symptoms after age 10. The diagnosis may be made by ultrasound, abdominal CT, MRCP, or cholangiography. Only one-third of patients show the classic triad of abdominal pain, jaundice, and an abdominal mass. Ultrasonographic detection of a cyst separate from the gallbladder should suggest the diagnosis of choledochal cyst, which can be confirmed by demonstrating the entrance of extrahepatic bile ducts into the cyst. Surgical treatment involves excision of the "cyst" and biliary-enteric anastomosis. Patients with choledochal cysts are at increased risk for the subsequent development of cholangiocarcinoma.

Congenital Biliary Ectasia Dilatation of intrahepatic bile ducts may involve either the major intrahepatic radicles (Caroli's disease), the inter- and intralobular ducts (congenital hepatic fibrosis), or both. In Caroli's disease, clinical manifestations include recurrent cholangitis, abscess formation in and around the affected ducts, and, often, brown pigment gallstone formation within portions of ectatic intrahepatic biliary radicles. Ultrasound, MRCP, and CT are of great diagnostic value in demonstrating cystic dilatation of the intrahepatic bile ducts. Treatment with ongoing antibiotic therapy is usually undertaken in an effort to limit the frequency and severity of recurrent bouts of cholangitis. Progression to secondary biliary cirrhosis with portal hypertension, extrahepatic biliary obstruction, cholangiocarcinoma, or recurrent episodes of sepsis with hepatic abscess formation is common.

CHOLEDOCHOLITHIASIS

Pathophysiology and Clinical Manifestations Passage of gallstones into the CBD occurs in ~10–15% of patients with cholelithiasis.

The incidence of common duct stones increases with increasing age of the patient, so up to 25% of elderly patients may have calculi in the common duct at the time of cholecystectomy. Undetected duct stones are left behind in ~1–5% of cholecystectomy patients. The overwhelming majority of bile duct stones are cholesterol stones formed in the gallbladder, which then migrate into the extrahepatic biliary tree through the cystic duct. Primary calculi arising de novo in the ducts are usually brown pigment stones developing in patients with (1) hepatobiliary parasitism or chronic, recurrent cholangitis; (2) congenital anomalies of the bile ducts (especially Caroli's disease); (3) dilated, sclerosed, or strictured ducts; or (4) an *MDR3* (ABCB4) gene defect leading to impaired biliary phospholipids secretion (low phospholipid–associated cholesterol cholelithiasis). Common duct stones may remain asymptomatic for years, may pass spontaneously into the duodenum, or (most often) may present with biliary colic or a complication.

Complications • **CHOLANGITIS** Cholangitis may be acute or chronic, and symptoms result from inflammation, which usually is caused by at least partial obstruction to the flow of bile. Bacteria are present on bile culture in ~75% of patients with acute cholangitis early in the symptomatic course. The characteristic presentation of acute cholangitis involves biliary pain, jaundice, and spiking fevers with chills (Charcot's triad). Blood cultures are frequently positive, and leukocytosis is typical. *Nonsuppurative acute cholangitis* is most common and may respond relatively rapidly to supportive measures and to treatment with antibiotics. In *suppurative acute cholangitis*, however, the presence of pus under pressure in a completely obstructed ductal system leads to symptoms of severe toxicity—mental confusion, bacteremia, and septic shock. Response to antibiotics alone in this setting is relatively poor, multiple hepatic abscesses are often present, and the mortality rate approaches 100% unless prompt endoscopic or surgical relief of the obstruction and drainage of infected bile are carried out. Endoscopic management of bacterial cholangitis is as effective as surgical intervention. ERCP with endoscopic sphincterotomy is safe and the preferred initial procedure for both establishing a definitive diagnosis and providing effective therapy.

OBSTRUCTIVE JAUNDICE Gradual obstruction of the CBD over a period of weeks or months usually leads to initial manifestations of jaundice or pruritus without associated symptoms of biliary colic or cholangitis. Painless jaundice may occur in patients with choledocholithiasis but is much more characteristic of biliary obstruction secondary to malignancy of the head of the pancreas, bile ducts, or ampulla of Vater.

In patients whose obstruction is secondary to choledocholithiasis, associated chronic calculous cholecystitis is very common, and the gallbladder in this setting may be unable to distend. The absence of a palpable gallbladder in most patients with biliary obstruction from duct stones is the basis for Courvoisier's law, that is, that the presence of a palpably enlarged gallbladder suggests that the biliary obstruction is secondary to an underlying malignancy rather than to calculous disease. Biliary obstruction causes progressive dilatation of the intrahepatic bile ducts as intrabiliary pressures rise. Hepatic bile flow is suppressed, and reabsorption and regurgitation of conjugated bilirubin into the bloodstream lead to jaundice accompanied by dark urine (bilirubinuria) and light-colored (acholic) stools.

CBD stones should be suspected in any patient with cholecystitis whose serum bilirubin level is >85.5 μmol/L (5 mg/dL). The maximum bilirubin level is seldom >256.5 μmol/L (15.0 mg/dL) in patients with choledocholithiasis unless concomitant hepatic or renal disease or another factor leading to marked hyperbilirubinemia exists. Serum bilirubin levels ≥342.0 μmol/L (20 mg/dL) should suggest the possibility of neoplastic obstruction. The serum alkaline phosphatase level is almost always elevated in biliary obstruction. A rise in alkaline phosphatase often precedes clinical jaundice and may be the only abnormality in routine liver function tests. There may be a two- to tenfold elevation of serum aminotransferases, especially in association with acute obstruction. Following relief of the obstructing process, serum aminotransferase elevations usually return rapidly to normal, while the serum bilirubin level may take 1–2 weeks to return to normal. The alkaline phosphatase level usually falls slowly, lagging behind the decrease in serum bilirubin.

PANCREATITIS The most common associated entity discovered in patients with nonalcoholic acute pancreatitis is biliary tract disease. Biochemical evidence of pancreatic inflammation complicates acute cholecystitis in 15% of cases and choledocholithiasis in >30%, and the common factor appears to be the passage of gallstones through the common duct. Coexisting pancreatitis should be suspected in patients with symptoms of cholecystitis who develop (1) back pain or pain to the left of the abdominal midline, (2) prolonged vomiting with paralytic ileus, or (3) a pleural effusion, especially on the left side. Surgical treatment of gallstone disease is usually associated with resolution of the pancreatitis.

SECONDARY BILIARY CIRRHOSIS Secondary biliary cirrhosis may complicate prolonged or intermittent duct obstruction with or without recurrent cholangitis. Although this complication may be seen in patients with choledocholithiasis, it is more common in cases of prolonged obstruction from stricture or neoplasm. Once established, secondary biliary cirrhosis may be progressive even after correction of the obstructing process, and increasingly severe hepatic cirrhosis may lead to portal hypertension or to hepatic failure and death. Prolonged biliary obstruction may also be associated with clinically relevant deficiencies of the fat-soluble vitamins A, D, E, and K.

Diagnosis and Treatment The diagnosis of choledocholithiasis is made by cholangiography **(Table 346-3)**, either preoperatively by endoscopic retrograde cholangiogram (ERC) **(Fig. 346-2*C*)** or MRCP or intraoperatively at the time of cholecystectomy. As many as 15% of patients undergoing cholecystectomy will prove to have CBD stones. When CBD stones are suspected prior to laparoscopic cholecystectomy, preoperative ERCP with endoscopic papillotomy and stone extraction is the preferred approach. It not only provides stone clearance but also defines the anatomy of the biliary tree in relationship to the cystic duct. CBD stones should be suspected in gallstone patients who have any of the following risk factors: (1) a history of jaundice or pancreatitis, (2) abnormal tests of liver function, and (3) ultrasonographic or MRCP evidence of a dilated CBD or stones in the duct. Alternatively, if intraoperative cholangiography reveals retained stones, postoperative ERCP can be carried out. The need for preoperative ERCP is expected to decrease further as laparoscopic techniques for bile duct exploration improve.

The widespread use of laparoscopic cholecystectomy and ERCP has decreased the incidence of complicated biliary tract disease and the need for choledocholithotomy and T-tube drainage of the bile ducts. EBS followed by spontaneous passage or stone extraction is the treatment of choice in the management of patients with common duct stones, especially in elderly or poor-risk patients.

TRAUMA, STRICTURES, AND HEMOBILIA

Most benign strictures of the extrahepatic bile ducts result from surgical trauma and occur in about 1 in 500 cholecystectomies. Strictures may present with bile leak or abscess formation in the immediate postoperative period or with biliary obstruction or cholangitis as long as 2 years or more following the inciting trauma. The diagnosis is established by percutaneous or endoscopic cholangiography. Endoscopic brushing of biliary strictures may be helpful in establishing the nature of the lesion and is more accurate than bile cytology alone. When positive exfoliative cytology is obtained, the diagnosis of a neoplastic stricture is established. This procedure is especially important in patients with primary sclerosing cholangitis (PSC) who are predisposed to the development of cholangiocarcinomas. Successful operative correction of non-PSC bile duct strictures by a skillful surgeon with duct-to-bowel anastomosis is usually possible, although mortality rates from surgical complications, recurrent cholangitis, or secondary biliary cirrhosis are high.

Hemobilia may follow traumatic or operative injury to the liver or bile ducts, intraductal rupture of a hepatic abscess or aneurysm of the hepatic artery, biliary or hepatic tumor hemorrhage, or mechanical complications of choledocholithiasis or hepatobiliary parasitism. Diagnostic procedures such as liver biopsy, PTC, and transhepatic biliary

TABLE 346-3 Diagnostic Evaluation of the Bile Ducts

DIAGNOSTIC ADVANTAGES	DIAGNOSTIC LIMITATIONS	CONTRAINDICATIONS	COMPLICATIONS	COMMENT
Ultrasound				
Rapid Simultaneous scanning of GB, liver, bile ducts, pancreas Accurate identification of dilated bile ducts Not limited by jaundice, pregnancy Guidance for fine-needle biopsy	Bowel gas Massive obesity Ascites Barium Partial bile duct obstruction Poor visualization of distal CBD	None	None	Initial procedure of choice in investigating possible biliary tract obstruction
Computed Tomography				
Simultaneous scanning of GB, liver, bile ducts, pancreas Accurate identification of dilated bile ducts, masses Not limited by jaundice, gas, obesity, ascites High-resolution image Guidance for fine-needle biopsy	Extreme cachexia Movement artifact Ileus Partial bile duct obstruction	Pregnancy	Reaction to iodinated contrast, if used	Indicated for evaluation of hepatic or pancreatic masses or for assessing for complications related to gallstones (pancreatitis) Procedure of choice in investigating possible biliary obstruction if diagnostic limitations limit US
Magnetic Resonance Cholangiopancreatography				
Noninvasive modality for visualizing pancreatic and biliary ducts Has excellent sensitivity for bile duct dilatation, biliary stricture, and intraductal abnormalities Can identify pancreatic duct dilatation or stricture, pancreatic duct stenosis, and pancreas divisum	Cannot offer therapeutic intervention High cost	Claustrophobia Certain metals (iron)	None	First choice to assess for choledocholithiasis given comparable sensitivity and specificity to ERCP
Endoscopic Retrograde Cholangiopancreatography				
Simultaneous pancreatography Best visualization of distal biliary tract Bile or pancreatic cytology Endoscopic sphincterotomy and stone removal Biliary manometry	Gastroduodenal obstruction Roux-en-Y biliary-enteric anastomosis	Pregnancy Acute pancreatitis Severe cardiopulmonary disease	Pancreatitis Cholangitis, sepsis Infected pancreatic pseudocyst Perforation (rare) Hypoxemia, aspiration	Cholangiogram of choice if there is believed to be a need for intervention: Diagnosed or high clinical probability of choledocholithiasis Biliary stricture requiring sampling and stenting Need for sphincterotomy such as Sphincter of Oddi dysfunction
Percutaneous Transhepatic Cholangiogram				
Best when bile ducts dilated Best visualization of proximal biliary tract May be used to obtain bile cytology/culture Allows for percutaneous transhepatic drainage	Nondilated or sclerosed ducts	Pregnancy Uncorrectable coagulopathy Massive ascites Hepatic abscess	Bleeding Hemobilia Bile peritonitis Bacteremia, sepsis	Indicated for the drainage of obstructed and infected ducts when ERCP is contraindicated or failed
Endoscopic Ultrasound				
Most sensitive method to detect ampullary stones and exclude pathology in the head of the pancreas				Excellent for detecting choledocholithiasis

Abbreviations: CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography; GB, gallbladder; US, hepatobiliary ultrasound.

drainage catheter placement may also be complicated by hemobilia. Patients often present with a classic triad of biliary pain, obstructive jaundice, and melena or occult blood in the stools. The diagnosis is sometimes made by cholangiographic evidence of blood clot in the biliary tree, but selective angiographic verification may be required. Although minor episodes of hemobilia may resolve without intervention, arteriography and transcatheter embolization or surgical ligation of the bleeding vessel may be required.

EXTRINSIC COMPRESSION OF THE BILE DUCTS

Partial or complete biliary obstruction may be produced by extrinsic compression of the ducts. The most common cause of this form of obstructive jaundice is carcinoma of the head of the pancreas. Biliary obstruction may also occur as a complication of either acute or chronic pancreatitis or involvement of lymph nodes in the porta hepatis by lymphoma or metastatic carcinoma. The latter should be distinguished from cholestasis resulting from massive replacement of the liver by tumor.

HEPATOBILIARY PARASITISM

Infestation of the biliary tract by adult helminths or their ova may produce a chronic, recurrent pyogenic cholangitis with or without multiple hepatic abscesses, ductal stones, or biliary obstruction. This condition is relatively rare but does occur in inhabitants of southern China and

elsewhere in Southeast Asia. The organisms most commonly involved are trematodes or flukes, including *Clonorchis sinensis*, *Opisthorchis viverrini* or *Opisthorchis felineus*, and *Fasciola hepatica*. The biliary tract also may be involved by intraductal migration of adult *Ascaris lumbricoides* from the duodenum or by intrabiliary rupture of hydatid cysts of the liver produced by *Echinococcus* spp. The diagnosis is made by cholangiography and the presence of characteristic ova on stool examination. When obstruction is present, the treatment of choice is laparotomy under antibiotic coverage, with common duct exploration and a biliary drainage procedure.

SCLEROSING CHOLANGITIS

PSC is characterized by a progressive, inflammatory, sclerosing, and obliterative process affecting the extrahepatic and/or the intrahepatic bile ducts. PSC is strongly associated with inflammatory bowel disease, especially ulcerative colitis.

Immunoglobulin G4 (IgG4)–associated cholangitis is a biliary disease of unknown etiology that presents with biochemical and cholangiographic features indistinguishable from PSC, is often associated with autoimmune pancreatitis and other fibrosing conditions, and is characterized by elevated serum IgG4 and infiltration of IgG4-positive plasma cells in bile ducts and liver tissue. All patients diagnosed with sclerosing cholangitis should have a serum IgG4 level checked to rule out IgG4 disease as a cause of secondary sclerosing cholangitis, particularly if they do not have inflammatory bowel disease. Glucocorticoids are the initial treatment of choice. Relapse is common after steroid withdrawal, especially with proximal strictures. Long-term treatment with glucocorticoids and/or steroid-sparing agents such as azathioprine may be needed after relapse or for inadequate response **(Chap. 348)**.

Patients with PSC often present with signs and symptoms of chronic or intermittent biliary obstruction: RUQ abdominal pain, pruritus, jaundice, or acute cholangitis. Late in the course, complete biliary obstruction, secondary biliary cirrhosis, hepatic failure, or portal hypertension with bleeding varices may occur. The diagnosis is established by finding multifocal, diffusely distributed strictures with intervening segments of normal or dilated ducts, producing a beaded appearance on cholangiography **(Fig. 346-2*D*)**. The cholangiographic techniques of choice in suspected cases are MRCP and ERCP. When a diagnosis of sclerosing cholangitis has been established, causes of secondary sclerosing should be considered. Patients with PSC should undergo testing for associated diseases, especially inflammatory bowel disease, if that diagnosis has not already been established.

Small duct PSC is defined by the presence of chronic cholestasis and hepatic histology consistent with PSC in a patient with IBD, but with normal findings on cholangiography. Small duct PSC is found in ~5% of patients with PSC and may represent an earlier stage of PSC associated with a significantly better long-term prognosis. However, such patients may progress to classic PSC and/or end-stage liver disease with consequent necessity of liver transplantation.

In patients with AIDS, cholangiopancreatography may demonstrate a broad range of biliary tract changes as well as pancreatic duct obstruction and occasionally pancreatitis **(Chap. 202)**. Further, biliary tract lesions in AIDS include infection and cholangiopancreatographic changes of sclerosing cholangitis. Changes noted include (1) diffuse involvement of intrahepatic bile ducts alone, (2) involvement of both intra- and extrahepatic bile ducts, (3) ampullary stenosis, (4) stricture of the intrapancreatic portion of the CBD, and (5) pancreatic duct involvement. Associated infectious organisms include *Cryptosporidium*, *Mycobacterium avium-intracellulare*, cytomegalovirus, *Microsporidia*, and *Isospora*. ERCP sphincterotomy can provide significant pain reduction in patients with AIDS-associated papillary stenosis.

TREATMENT

Primary Sclerosing Cholangitis

There is no proven medical therapy for PSC. Therapy to treat pruritus associated with PSC includes cholestyramine, rifampin, and naltrexone. Antibiotics are useful when bacterial cholangitis complicates the clinical picture. Vitamin D and calcium supplementation may be used as initial therapy to help prevent the loss of bone mass frequently seen in patients with chronic cholestasis. In cases where high-grade biliary obstruction (dominant strictures) has occurred, balloon dilatation is preferred over stenting due to the higher complication rate associated with stenting including pancreatitis and cholangitis. Only rarely is surgical intervention indicated. PSC is a progressive disease with a median survival of 12–18 years following the diagnosis, regardless of therapy. Four variables (age, serum bilirubin level, histologic stage, and splenomegaly) predict survival in patients with PSC and serve as the basis for a risk score. PSC is a common indication for liver transplantation.

Section 4 Disorders of the Pancreas

347 Approach to the Patient with Pancreatic Disease

Somashekar G. Krishna, Darwin L. Conwell, Phil A. Hart

GENERAL CONSIDERATIONS

Globally, pancreatic disorders, including acute and chronic pancreatitis, pancreatic cysts, and pancreatic cancer, are challenging to manage and associated with a high burden on health care resources. The relationships between these diseases continues to be poorly understood, but there is encouraging progress. Acute pancreatitis is one of the most common reasons for hospitalizations in gastroenterology, and there is increasing evidence of long-term sequelae including diabetes, exocrine pancreas insufficiency, and pancreas cancer. Chronic pancreatitis, an irreversible disease of the pancreas, is associated with poor quality of life, largely related to abdominal pain, and associated exocrine insufficiency. Pancreatic cysts, mostly incidental, are increasingly detected on cross-sectional abdominal imaging studies. Although a small number and specific types of pancreatic cysts can progress to pancreatic cancer, diagnostic uncertainty can introduce unwanted anxiety to patients and treating physicians. Meanwhile, with persistently high mortality rates, the incidence of pancreatic adenocarcinoma is increasing and is the seventh leading cause of cancer-related death in the industrialized world and the third most common in the United States.

As emphasized in **Chap. 348**, the etiologies and clinical manifestations of pancreatitis are quite varied. Although it is well-appreciated that acute pancreatitis is frequently secondary to biliary tract disease and alcohol abuse, it can also be caused by drugs, genetic mutations, and trauma. In ~30% of patients with acute pancreatitis and 25–40% of patients with chronic pancreatitis, the etiology is initially unexplained.

The global pooled incidence of acute pancreatitis is ~33.7 cases (95% confidence interval [CI], 23.3–48.8) with 1.16 deaths (95% CI, 0.85–1.6) per 100,000 person-years. The global pooled incidence of chronic pancreatitis is ~9.6 cases (95% CI, 7.9–11.8) with 0.09 attributable deaths (95% CI, 0.02–0.5) per 100,000 person-years. In the

United States, the number of patients admitted to the hospital with acute pancreatitis is increasing, with estimated rates of almost 300,000 annually, whereas the number of patients hospitalized for chronic pancreatitis is decreasing, with recent estimates of ~13,000 admissions per year. Chronic pancreatitis has an annual prevalence of 42–73 cases per 100,000 adults in the United States, although higher prevalence rates (0.04–5%) have been noted among adults at autopsy. Together, acute and chronic pancreatic disease costs an estimated $3 billion annually in health care expenditures.

The diagnosis of acute pancreatitis is generally clearly defined based on a combination of laboratory, imaging, and clinical symptoms. The diagnosis of chronic pancreatitis, especially in mild disease, is hampered by the relative inaccessibility of the pancreas to direct examination and the nonspecificity of the abdominal pain associated with chronic pancreatitis. Many patients with chronic pancreatitis do not have elevated blood amylase or lipase levels. Some patients with chronic pancreatitis develop signs and symptoms of exocrine pancreatic insufficiency (EPI), and thus, objective evidence for pancreatic disease can be demonstrated. However, there is a very large reservoir of pancreatic exocrine function. More than 90% of the pancreas must be damaged before maldigestion of fat and protein is manifested. Noninvasive, indirect tests of pancreatic exocrine function (e.g., fecal elastase) are much more likely to give abnormal results in patients with obvious advanced pancreatic disease (i.e., pancreatic calcification, steatorrhea, or diabetes mellitus) than in patients with occult disease. Invasive, direct tests of pancreatic secretory function (e.g., secretin stimulation test) are the most sensitive and specific tests to detect early chronic pancreatic disease when imaging is equivocal or normal.

The increasing utilization of cross-sectional imaging modalities with their improved resolution has contributed to a high prevalence (2–5% with computed tomography [CT] scans, 20–30% with magnetic resonance imaging [MRI]) of incidentally detected pancreatic cysts. The most common cyst type encountered is an intraductal papillary mucinous neoplasm (IPMN), which is classified as a precancerous mucinous cyst. In the absence of high-risk features, radiographic surveillance is typically recommended **(Fig. 347-1)**. Mucinous cystic neoplasms (MCNs) are a less commonly encountered mucinous cyst. Among the neoplastic cysts, serous cystadenomas have a negligible risk of progression to malignancy. Other infrequent neoplastic cysts include neuroendocrine tumors and solid pseudopapillary neoplasms. The most commonly encountered benign cyst is a pseudocyst, which can occur in patients with a history of acute or chronic pancreatitis. It is often difficult to accurately predict the risk of malignant transformation of precancerous pancreatic cysts, and there is an increasing number of patients on imaging surveillance protocols burdening the health care systems in the industrialized world.

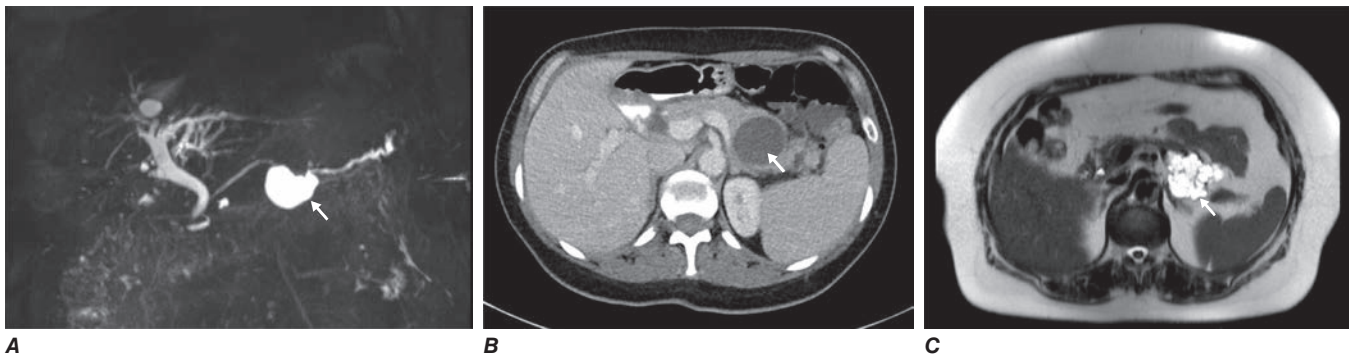
TESTS USEFUL IN THE DIAGNOSIS OF PANCREATIC DISEASE

Several tests are of value in the evaluation of pancreatic disease. Examples of specific tests and their usefulness in the diagnosis of acute and chronic pancreatitis are summarized in **Table 347-1** and **Fig. 347-2**. At some institutions, pancreatic function tests are available and performed if the diagnosis of chronic pancreatitis remains a possibility after noninvasive tests (i.e., ultrasound, CT Scan, MRI with magnetic resonance cholangiopancreatography [MRCP]) or invasive tests (i.e., endoscopic retrograde cholangiopancreatography [ERCP], endoscopic ultrasound [EUS]) have given normal or inconclusive results. In this regard, tests using *direct* stimulation of the pancreas with secretin are the most sensitive.

Pancreatic Enzymes in Body Fluids The serum amylase and lipase levels are widely used as screening tests for acute pancreatitis in the patient with acute abdominal pain or back pain. Lipase is very specific for the pancreas, and values greater than three times the upper limit of normal (3× ULN) in combination with epigastric pain strongly suggest the diagnosis of acute pancreatitis. In acute pancreatitis, the serum amylase and lipase are usually elevated within 24 h of onset and remain so for 3–7 days. Levels usually return to normal within 7 days unless there is pancreatic ductal disruption, ductal obstruction, or pseudocyst formation. Approximately 85% of patients with acute pancreatitis have threefold or greater elevated serum lipase and amylase levels. The values may be normal if (1) there is a delay (2–5 days) before blood samples are obtained, (2) the underlying disorder is chronic pancreatitis rather than acute pancreatitis, or (3) hypertriglyceridemia is present. Patients with hypertriglyceridemia and acute pancreatitis have been found to have spuriously low levels of amylase and perhaps lipase activity. In the absence of objective evidence of pancreatitis by abdominal ultrasound, contrast-enhanced CT scan, MRI with MRCP, or EUS, mild to moderate elevations of amylase and/or lipase are not helpful in making a diagnosis of chronic pancreatitis.

It should be noted that the serum amylase can be elevated in other conditions **(Table 347-2)**, in part because the enzyme is found in many organs. In addition to the pancreas and salivary glands, small quantities of amylase are found in the tissues of the fallopian tubes, lung, thyroid, and tonsils and can be produced by various tumors (carcinomas of the lung, esophagus, breast, and ovary). Isoamylase determinations do not accurately distinguish elevated blood amylase levels from pancreatic or nonpancreatic sources. In patients with unexplained hyperamylasemia, the measurement of macroamylase can avoid numerous tests in patients with this rare disorder.

Elevation of ascitic fluid amylase occurs in acute pancreatitis as well as in (1) ascites due to disruption of the main pancreatic duct or a leaking pseudocyst and (2) other abdominal disorders that simulate pancreatitis



A B C

FIGURE 347-1 ***A.*** Side-branch intraductal papillary mucinous neoplasm (magnetic resonance imaging [MRI] with magnetic resonance cholangiopancreatography [MRCP]). T2-weighted MRCP image demonstrates a dominant, lobulated, hyperintense cystic structure (*arrow*) within the posterior body of the pancreas. The pancreatic duct upstream from the cyst is dilated and irregular. Endoscopic ultrasound and fine-needle aspiration of cyst fluid were consistent with a mucinous cyst. Surgical histopathology revealed an infiltrating moderately differentiated adenocarcinoma, 0.3 cm, arising in a background of an intraductal papillary mucinous neoplasm (IPMN). ***B.*** Mucinous cystic neoplasm (computed tomography [CT] scan). In the tail of the pancreas, there is a well-circumscribed hypodense cyst (*arrow*) without any nodular enhancing components. Endoscopic ultrasound and fine-needle aspiration of cyst fluid were suggestive of a mucinous cyst. Surgical histopathology revealed a mucinous cystic neoplasm (3.4 cm) with low-grade dysplasia. The stroma of the cyst demonstrated diffuse positivity for progesterone receptor and focal positivity for CD10 (ovarian stroma), confirming the diagnosis. ***C.*** Serous cystadenoma (MRI). A lobulated microcystic cyst (*arrow*) is observed in the tail of the pancreas. Neither a communication with the main pancreatic duct nor intracystic soft tissue enhancing nodular components were observed. However, the cyst continued to increase in size and a distal pancreatectomy was performed. Histopathology revealed a serous microcystic adenoma. *(Courtesy of Dr. Z.K. Shah, The Ohio State University Wexner Medical Center; with permission.)*

TABLE 347-1 Tests Useful in the Diagnosis of Acute and Chronic Pancreatitis and Pancreatic Neoplasms

TEST	PRINCIPLE	COMMENT
Pancreatic Enzymes in Body Fluids		
Serum lipase	Pancreatic inflammation leads to increased serum enzyme levels	Enzyme measurement of choice for the diagnosis of acute pancreatitis; increased specificity if the level is more than three times the upper limit of normal (3× ULN)
Amylase		
1. Serum	Pancreatic inflammation leads to increased serum enzyme levels	Simple; increased specificity if the level is >3× ULN; may be falsely normal in patients with hypertriglyceridemic pancreatitis
2. Urine	Renal clearance of amylase is increased in acute pancreatitis	Infrequently used
3. Ascitic fluid	Disruption of gland or main pancreatic duct leads to increased amylase concentration	Can help establish source of ascites; false positives occur with intestinal obstruction and perforated ulcer; can also measure lipase
4. Pleural fluid	Exudative pleural effusion with pancreatitis	False positives occur with carcinoma of the lung and esophageal perforation
Studies Pertaining to Pancreatic Structure		
Radiologic and radionuclide tests		
1. Plain film of the abdomen or upper gastrointestinal x-rays	Can demonstrate large calcifications in chronic pancreatitis	Infrequently used
2. Ultrasonography (US)	Can provide limited information on edema, inflammation, calcification, pseudocysts, and mass lesions	Simple, noninvasive; sequential studies quite feasible; useful in diagnosis of gallstones; pancreas visualization limited by interference from overlying bowel gas
3. Computed tomography (CT) scan	Permits detailed visualization of pancreas and surrounding structures, pancreatic fluid collection, pseudocyst; assessment of necrosis or interstitial disease	Useful in the diagnosis of pancreatic calcification, dilated pancreatic ducts, and pancreatic tumors; may not be able to distinguish between inflammatory and neoplastic mass lesions; multiphasic CT scans are the preferred imaging modality for staging pancreatic cancer; IV contrast is needed for characterization of most features
4. Magnetic resonance imaging (MRI) and cholangiopancreatography (MRCP)	Permits noninvasive detailed evaluation of the pancreatic parenchyma, biliary and pancreatic ducts, adjacent soft tissues, and vascular structures.	Has mostly replaced ERCP for diagnostic assessment of the pancreatic duct; more sensitive than CT scan for detection of mild pancreatitis, necrosis, choledocholithiasis, pancreatic ductal abnormalities, and cystic neoplasms; no exposure to ionizing radiation
5. Endoscopic ultrasonography (EUS) and fine-needle aspiration/biopsy (FNA/B)	High-frequency transducer used with EUS produces very-high-resolution images permitting focused evaluation of pancreatic parenchyma and biliary and pancreatic ducts, and FNA/B provides targeted tissue acquisition	Can be used to assess gallstones, choledocholithiasis, chronic pancreatitis, pancreatic masses, and cystic neoplasms; FNA/B facilitates diagnostic and therapeutic management of pancreatic diseases
6. Endoscopic retrograde cholangiopancreatography (ERCP)	Cannulation of pancreatic and/or common bile duct permits visualization of pancreaticobiliary ductal system	Primarily a therapeutic procedure; invasive with risks for iatrogenic complications
Tests of Exocrine Pancreatic Function		
Direct stimulation of the pancreas with analysis of duodenal contents		
1. Secretin test	Secretin leads to increased output of pancreatic juice and HCO_3^-; pancreatic secretory response is related to the functional mass of pancreatic tissue; involves duodenal intubation and fluoroscopic placement of gastroduodenal tube	Sensitive to detect occult disease; poorly defined normal enzyme response; large secretory reserve capacity of the pancreas; rarely performed
2. Endoscopic pancreatic function test (ePFT)	Secretin-stimulated collection of pancreatic juice performed during upper endoscopy; replaces need for tube placement in the duodenum	Sensitive to detect occult disease; high negative predictive value for chronic pancreatitis; requires sedation
3. EUS-ePFT	Combines endosonographic evaluation of the pancreas and endoscopic collection of pancreatic juice	Single endoscopic evaluation of pancreatic structure and function
4. Secretin-stimulated MRCP	Combines imaging evaluation of the pancreas and a semiquantitative estimation of pancreatic juice output in the duodenum	Improved visualization of pancreatic ductal anatomy; functional evaluation is less accurate than ePFT; noninvasive
Measurement of intraluminal digestion products		
1. Stool fat determination	Lack of lipolytic enzymes brings about impaired fat digestion; quantitative 72-h stool collection and estimation are more reliable than qualitative analysis of a random stool sample	Reliable reference standard for defining severity of fat malabsorption; does not distinguish between pancreatic and nonpancreatic cause of malabsorption
Measurement of pancreatic enzymes in feces		
1. Fecal elastase	Pancreatic secretion of proteolytic enzymes; not degraded in intestine	Diagnostic accuracy is highest when the pretest probability is high and the value is <100 μg/g; false positives will occur in patients with nonformed stools

(e.g., intestinal obstruction, intestinal infarction, or perforated peptic ulcer). Elevation of pleural fluid amylase can occur in acute pancreatitis, chronic pancreatitis, carcinoma of the lung, and esophageal perforation. Lipase is the single best enzyme to measure for the diagnosis of acute pancreatitis. It is important to acknowledge that levels are often mildly elevated in the setting of renal disease, so determining whether a patient with renal failure and abdominal pain has pancreatitis remains a challenging clinical problem. One study found that serum amylase levels were elevated in patients with renal dysfunction only when creatinine clearance was <0.8 mL/s (<50 mL/min). In such patients, the serum

	• **Clinical signs and symptoms suggestive of chronic pancreatic disease:** abdominal pain, nausea, weight loss, steatorrhea, malabsorption, history of alcohol abuse, recurrent pancreatitis, fatty-food intolerance • Perform history, physical examination, review of laboratory studies; consider fecal elastase measurement
Step 1	• **Contrast-enhanced CT scan** • *CP diagnostic criteria*: calcifications in combination with atrophy and/or dilated duct • Diagnostic criteria met; no further imaging needed • Inconclusive or nondiagnostic results; continue to step 2
Step 2	• **MRI and MRCP, with or without secretin enhancement (sMRCP)** • *CP diagnostic criteria*: Cambridge class III,[a] dilated duct, atrophy of gland, filling defects in duct suggestive of stones • Diagnostic criteria met; no further imaging needed • Inconclusive or nondiagnostic results; continue to step 3
Step 3	• **EUS with quantification of parenchymal and ductal criteria** • *CP diagnostic criteria*: ≥5 EUS CP criteria • Diagnostic criteria met; no further imaging needed • Inconclusive or nondiagnostic results; continue to step 4
Step 4	• **Pancreas function test (with secretin)—endoscopic (ePFT) collection method preferred; consider combining ePFT with EUS** • *CP diagnostic criteria*: peak [bicarbonate] <80 mEq/L • Diagnostic criteria met; no further imaging needed • Inconclusive or nondiagnostic results require monitoring of signs and symptoms and repeat testing in 6 months–1 year

FIGURE 347-2 A stepwise diagnostic approach to the patient with suspected chronic pancreatitis (CP). Endoscopic ultrasonography (EUS) and magnetic resonance imaging (MRI) with secretin-stimulated magnetic resonance cholangiopancreatography (sMRCP/MRCP) are appropriate diagnostic alternatives to endoscopic retrograde cholangiopancreatography (ERCP). CT, computed tomography; ePFT, endoscopic pancreas function test. [a]Cambridge classification of pancreatic duct findings: class 0: normal—visualization of complete normal ductal anatomy; class I: equivocal—normal main duct, 1–3 abnormal side branches; class II: mild—normal main duct, >3 abnormal side branches; class III—dilated and irregular main duct, >3 abnormal side branches, small (<10 mm) cysts; class IV—irregular main duct, intraductal calculi, strictures, obstruction with dilation, or large (> 10 mm) cysts.

amylase level was invariably <500 IU/L in the absence of objective evidence of acute pancreatitis. In that study, serum lipase and trypsin levels paralleled serum amylase values. With these limitations in mind, the recommended screening test for acute pancreatitis in renal disease is serum lipase, but a high index of clinical suspicion is needed based on symptoms. Elevations in serum lipase >3× ULN due to nonpancreatic etiology can be observed in hepatobiliary or gastrointestinal malignancies, septicemia, liver cirrhosis, systemic lupus erythematosus, severe head injury, chronic alcoholism, diabetes mellitus, and post-ERCP without any associated evidence of pancreatitis.

Studies Pertaining to Pancreatic Structure • **RADIOLOGIC TESTS** Plain films of the abdomen rarely provide useful information related to pancreatic disease and have been superseded by more detailed imaging studies (ultrasound, EUS, CT, and MRI with MRCP).

Ultrasonography (US) can provide important information in the initial emergency ward evaluation of patients with acute pancreatitis, chronic pancreatitis, pseudocysts, and pancreatic adenocarcinoma. Sonographic changes can indicate the presence of edema, inflammation, and calcification (not obvious on plain films of the abdomen), as well as gallstones, biliary dilation, pseudocysts, and mass lesions. In acute pancreatitis, the pancreas is characteristically enlarged. In pancreatic pseudocyst, the usual appearance is primarily that of a smooth, round fluid collection. Pancreatic adenocarcinoma distorts the usual landmarks, and mass lesions >3.0 cm are usually detected as localized, solid lesions. US is often the initial investigation for most patients with suspected pancreatic disease. However, obesity and excess intestinal bowel gas can interfere with pancreatic imaging, limiting its sensitivity.

CT with intravenous contrast is the best imaging study for the assessment of complications of acute and chronic pancreatitis. It is especially useful in the detection of pancreatic and peripancreatic acute fluid collections, fluid-containing lesions such as pseudocysts, walled-off necrosis **(see Chap. 348, Figs. 348-1, 348-2, and 348-4)**, and pancreatic neoplasms. Acute pancreatitis is characterized by (1) enlargement of the pancreas, (2) distortion of the pancreatic contour with peripancreatic stranding of adjacent fat tissue, and/or (3) the presence of pancreatic fluid that has a different attenuation coefficient than normal pancreas. When possible, CT scans should ideally be performed with oral and intravenous contrast to detect areas of pancreatic necrosis. The major benefit of CT scan in acute pancreatitis is the diagnosis of pancreatic necrosis in patients not responding to conservative management within 72 h. It may take 48–72 h to develop perfusion defects indicative of pancreatic necrosis. Therefore, if acute pancreatitis is confirmed with serology and physical examination findings, CT scan in the first 3 days is not recommended to minimize risk of contrast-induced nephropathy and unnecessary health care costs. Improved imaging technology and increased resolution are facilitated by multiphasic CT scans using multidetector technology (MDCT) in which a pancreas protocol consisting of dual-phase scanning with intravenous contrast is utilized for the detection and staging of pancreatic cancers. While the sensitivity of MDCT for detecting smaller (≤2 cm) lesions is lower, the reported overall sensitivity for pancreatic cancers is 76–97%. The contraindications to using intravenous contrast include renal failure (serum creatinine >2 mg/dL) and a history of severe allergic reaction to iodinated contrast agents. In situations where EUS is not available, CT-guided percutaneous aspiration or biopsy of a pancreatic mass can be performed. Prior to the major advance of EUS-guided fine-needle aspiration (FNA), CT-guided biopsy was utilized in the preceding decades and is regarded as a safe procedure.

MRI and MRCP provide excellent imaging of the bile duct, pancreatic duct, and pancreas parenchyma in both acute pancreatitis and chronic pancreatitis. MRI is better than transabdominal US and CT scans and comparable to EUS in the detection of choledocholithiasis. Similar to CT, MRI can evaluate for the severity of acute pancreatitis. Moreover, T2-weighted MRI of fluid collections can differentiate necrotic debris from fluid in suspected walled-off necrosis, and T1 imaging can diagnose hemorrhage in suspected pseudoaneurysm rupture. In chronic pancreatitis, secretin-enhanced MRCP is a method to enhance the evaluation of major and minor ductal changes. While imaging is comparable to CT for evaluating pancreatic mass lesions, MRI with MRCP is the preferred imaging modality for evaluating pancreatic cystic lesions. Nephrogenic systemic fibrosis has been described in patients with chronic renal failure following exposure to the gadolinium contrast, but incidence rates are extraordinarily low with contemporary contrast agents.

EUS produces high-resolution images of the bile duct, pancreatic parenchyma, and pancreatic duct with a transducer fixed to an

TABLE 347-2 Causes of Hyperamylasemia and Hyperamylasuria

Pancreatic Disease

I. Pancreatitis
  A. Acute
  B. Chronic: ductal obstruction
  C. Complications of pancreatitis
    1. Pancreatic pseudocyst
    2. Ascites caused by pancreatic duct disruption
    3. Pancreatic necrosis
II. Pancreatic trauma
III. Pancreatic adenocarcinoma

Nonpancreatic Disorders

I. Renal insufficiency
II. Salivary gland lesions
  A. Mumps
  B. Calculus
  C. Irradiation sialadenitis
  D. Maxillofacial surgery
III. "Tumor" hyperamylasemia
  A. Carcinoma of the lung, esophagus, breast, or ovary
IV. Macroamylasemia
V. Burns
VI. Diabetes mellitus, particularly when ketoacidosis is present
VII. Pregnancy
VIII. Renal transplantation
IX. Cerebral trauma
X. Drugs: opiates

Other Abdominal Disorders

I. Biliary tract disease: cholecystitis, choledocholithiasis
II. Intraabdominal disease
  A. Perforated or penetrating peptic ulcer
  B. Intestinal obstruction or inflammation
  C. Ruptured ectopic pregnancy
  D. Peritonitis
  E. Aortic aneurysm
  F. Postoperative hyperamylasemia

endoscope that can be directed onto the surface of the pancreas through the stomach or duodenum. EUS is not beneficial for the evaluation of pancreas during acute pancreatitis. It is preferable to perform EUS after the resolution of acute pancreatitis (~4 weeks) to detect any predisposing factors, including malignancy, choledocholithiasis, pancreatic divisum, or ampullary lesions. EUS can be combined with ERCP in a single session and is increasingly preferred for the diagnosis and management of choledocholithiasis in acute pancreatitis and pancreatic neoplasm with biliary obstruction. EUS has been studied as a diagnostic modality for chronic pancreatitis. Criteria for abnormalities on EUS in severe chronic pancreatic disease have been developed. There is general agreement that the presence of five or more of the nine criteria listed in **Table 347-3** is highly predictive of chronic pancreatitis in the correct clinical context. The sensitivity of EUS (81%; 95% CI, 70–89%) to diagnose chronic pancreatitis is comparable to that of MRI/MRCP (78%; 95% CI, 69–85%) and better than CT (75%; 95% CI, 66–83%); however, nonspecific changes are commonly seen in the pancreas that may be attributable to cigarette smoking, diabetes, or normal aging. EUS also facilitates the delivery of nerve-blocking agents via fine-needle injection in patients suffering from pancreatic pain from chronic pancreatitis (celiac plexus block) or cancer (celiac plexus neurolysis). When clinically suspected, EUS imaging is more sensitive than MDCT for the detection of pancreatic malignancy and permits fine-needle aspiration/biopsy (FNA/B). Currently, EUS-guided FNA/B is the diagnostic modality of choice for the acquisition of diagnostic tissue and cyst fluid in patients with pancreatic masses and cystic lesions, respectively.

TABLE 347-3 Endoscopic Ultrasonographic Criteria for Chronic Pancreatitis (Total Criteria = 9)

DUCTAL	PARENCHYMAL
Stones	Echogenic strands
Hyperechoic main duct margins	Echogenic foci
Main duct irregularity	Lobular contour
Main duct dilatation	Cysts
Visible side branches	

Although a pancreatogram during ERCP is the most specific and sensitive test for evaluating the ductal anatomy, EUS and MRI/MRCP have largely replaced ERCP in the diagnostic evaluation of pancreatic disease to avoid the risk of complications. Therefore, ERCP is primarily of therapeutic value after CT, EUS, or MRI and MRCP has detected abnormalities requiring endoscopic treatment. ERCP is the most sensitive modality for the detection of bile duct stones. In the management of acute biliary pancreatitis, ERCP should not be unduly delayed in patients with high clinical suspicion of biliary obstruction. In chronic pancreatitis, ERCP abnormalities in the main pancreatic duct and side branches have been outlined by the Cambridge classification (Fig. 347-2). The presence of ductal stenosis and irregularity can make it difficult to distinguish chronic pancreatitis from pancreatic adenocarcinoma. It is important to be aware that ERCP changes interpreted as indicating chronic pancreatitis actually may be due to the effects of aging on the pancreatic duct, sequelae of a recent attack of acute pancreatitis, or changes secondary to placement of pancreatic duct stent. Although aging may cause impressive ductal alterations, it does not affect the results of pancreatic secretin function tests. Pancreatic adenocarcinoma is characterized by stenosis or obstruction of either the pancreatic duct or the common bile duct; both ductal systems are often abnormal (double-duct sign). When indicated, ERCP permits acquisition of diagnostic tissue as in biopsy of ampullary lesions or biliary brushings for distal bile duct strictures. Elevated serum amylase levels after ERCP have been reported in the majority of patients, and clinical pancreatitis has been reported in 5–10% of patients. Until recently, pancreatic duct stents were commonly placed to prevent post-ERCP pancreatitis. However, recent data suggest that periprocedural administration of rectal indomethacin can decrease the incidence of post-ERCP pancreatitis. Studies are currently underway comparing rectal indomethacin alone versus combination with prophylactic pancreatic duct stents to prevent post-ERCP pancreatitis.

TESTS OF EXOCRINE PANCREATIC FUNCTION

Pancreatic function tests (Table 347-1) can be divided into the following:

1. *Direct stimulation of the pancreas* by IV infusion of secretin followed by collection and measurement of duodenal contents: The secretin test, used to detect diffuse pancreatic disease, is based on the physiologic principle that the pancreatic secretory response is directly related to the functional mass of pancreatic tissue. In the standard assay, secretin is given IV in a dose of 0.2 μg/kg of synthetic human secretin as a bolus. Normal values for the standard secretin test are (1) volume output >2 mL/kg per h, (2) bicarbonate (HCO_3^-) concentration >80 mmol/L, and (3) HCO_3^- output >10 mmol/L in 1 h. The most reproducible measurement, giving the highest level of discrimination between normal subjects and patients with chronic pancreas dysfunction, appears to be the maximal bicarbonate concentration. A cutoff point <80 mmol/L is considered abnormal and suggestive of reduced secretory function that is most commonly observed in early chronic pancreatitis.
2. There may be a dissociation between the results of the secretin test and other tests of absorptive function. For example, patients with chronic pancreatitis often have abnormally low outputs of HCO_3^- after secretin but have normal fecal fat excretion. The secretin test directly measures the secretory capacity of ductular epithelium, whereas fecal fat excretion indirectly reflects intraluminal lipolytic

activity. Steatorrhea does not occur until intraluminal levels of lipase are markedly reduced, underscoring the fact that only small amounts of enzymes are necessary for intraluminal digestive activities. It must be emphasized that an abnormal secretin test result suggests that pancreatic ductal secretory function is abnormal. This is an early abnormality in chronic pancreatitis but should not be considered diagnostic and must be interpreted within the proper clinical context (for example, a patient with recurrent attacks of pancreatitis and persistent abdominal pain and Cambridge 2 changes on imaging)

3. *Measurement of fecal pancreatic enzymes* such as elastase: Measurement of *intraluminal digestion products* (i.e., undigested muscle fibers, stool fat, and fecal nitrogen) is discussed in **Chap. 325**. The amount of human elastase in stool reflects the pancreatic output of this proteolytic enzyme. Decreased fecal elastase-1 (FE-1) activity in stool is a test to detect severe EPI in patients with chronic pancreatitis and cystic fibrosis. FE-1 levels >200 μg/g are normal, levels of 100–200 μg/g are considered mild-moderate EPI, and levels <100 μg/g are severe EPI. Although the test is simple and noninvasive, it can yield false-positive results if stools are not formed and should not generally be used for the evaluation of a patient with diarrhea. False-positive results have also been observed in diabetes and irritable bowel syndrome.

Tests useful in the diagnosis of EPI and the differential diagnosis of malabsorption are also discussed in Chaps. 325 and 348.

BIOCHEMISTRY AND PHYSIOLOGY OF PANCREATIC EXOCRINE SECRETION

GENERAL CONSIDERATIONS

The pancreas secretes 1500–3000 mL of isosmotic alkaline (pH >8) fluid per day containing ~20 enzymes. Pancreatic secretions provide the enzymes and bicarbonate needed to perform the major digestive activity of the gastrointestinal tract and provide an optimal pH for the function of these enzymes.

REGULATION OF PANCREATIC SECRETION

Secretions from the exocrine pancreas are highly regulated by neurohormonal systems in a phasic manner (cephalic, gastric, and intestinal phases). *Gastric acid* is the stimulus for the release of secretin from the duodenal mucosa (S cells), which stimulates the secretion of water and electrolytes from pancreatic ductal cells. Release of cholecystokinin (CCK) from the duodenal and proximal jejunal mucosa (Ito cells) is largely triggered by long-chain fatty acids, essential amino acids (tryptophan, phenylalanine, valine, methionine), and gastric acid itself. CCK evokes an enzyme-rich secretion from acinar cells in the pancreas. The *parasympathetic nervous system* (via the vagus nerve) exerts significant control over pancreatic secretion, particularly during the cephalic phase. Secretion evoked by secretin and CCK depends on the permissive roles of vagal afferent and efferent pathways. This is particularly true for enzyme secretion, whereas water and bicarbonate secretions are heavily dependent on the hormonal effects of secretin and to a lesser extent CCK. Also, vagal stimulation affects the release of vasoactive intestinal peptide (VIP), a secretin agonist. Pancreatic exocrine secretion is also influenced by inhibitory neuropeptides including somatostatin, pancreatic polypeptide, peptide YY, neuropeptide Y, enkephalin, pancreastatin, calcitonin gene–related peptides, glucagon, and galanin. Pancreatic polypeptide and peptide YY may act primarily on nerves outside the pancreas, while somatostatin acts at multiple sites.

WATER AND ELECTROLYTE SECRETION

Bicarbonate is the ion of primary physiologic importance within pancreatic secretion. The ductal cells secrete bicarbonate predominantly derived from plasma (93%) more than from intracellular metabolism (7%). Bicarbonate enters the duct lumen through the sodium bicarbonate cotransporter with depolarization caused by chloride efflux through the cystic fibrosis transmembrane conductance regulator (CFTR). Secretin and VIP bind at the basolateral surface and cause an increase in secondary messenger intracellular cyclic AMP and act on the apical surface of the ductal cells opening the CFTR, which promotes secretion. CCK, acting as a neuromodulator, markedly potentiates the stimulatory effects of secretin. Acetylcholine also plays an important role in ductal cell secretion. Intraluminal bicarbonate secreted from the ductal cells helps neutralize gastric acid, increases the solubility of fatty acids and bile acids, maintains an optimal pH for pancreatic and brush border enzymes, and prevents intestinal mucosal damage.

ENZYME SECRETION

The acinar cell is highly compartmentalized for the production and secretion of pancreatic enzymes. Proteins synthesized by the rough endoplasmic reticulum are processed in the Golgi and then targeted to the appropriate site: zymogen granules, lysosomes, or other cell compartments. The zymogen granules migrate to the apical region of the acinar cell awaiting the appropriate neural or hormonal stimulatory response. The pancreas secretes amylolytic, lipolytic, and proteolytic enzymes into the duct lumen. *Amylolytic enzymes*, such as amylase, hydrolyze starch to oligosaccharides and to the disaccharide maltose. The *lipolytic enzymes* include lipase, phospholipase A_2, and cholesterol esterase. Bile salts inhibit lipase in isolation, but colipase, another constituent of pancreatic secretion, binds to lipase and prevents this inhibition. Bile salts activate phospholipase A and cholesterol esterase. *Proteolytic enzymes* include endopeptidases (trypsin, chymotrypsin), which act on internal peptide bonds of proteins and polypeptides; exopeptidases (carboxypeptidases, aminopeptidases), which act on the free carboxyl- and amino-terminal ends of peptides, respectively; and elastase. The proteolytic enzymes are secreted as inactive zymogen precursors. Ribonucleases (deoxyribonucleases, ribonuclease) are also secreted. *Enterokinase*, an enzyme found in the duodenal mucosa ("brush border"), cleaves the lysine-isoleucine bond of trypsinogen to form trypsin. Trypsin then activates the other proteolytic zymogens and phospholipase A_2 in a cascade. The nervous system initiates pancreatic enzyme secretion. The neurologic stimulation is cholinergic, involving extrinsic innervation by the vagus nerve and subsequent innervation by intrapancreatic cholinergic nerves. The stimulatory neurotransmitters are acetylcholine and gastrin-releasing peptides. These neurotransmitters activate calcium-dependent secondary messenger systems, resulting in the release of zymogens into the pancreas duct. VIP is present in intrapancreatic nerves and potentiates the effect of acetylcholine. In contrast to other species, there are no CCK receptors on acinar cells in humans. CCK in physiologic concentrations stimulates pancreatic secretion by stimulating afferent vagal and intrapancreatic nerves.

AUTOPROTECTION OF THE PANCREAS

Autodigestion of the pancreas is prevented by (1) the packaging of pancreatic proteases in the precursor (proenzyme) form, (2) intracellular calcium homeostasis (low intracellular calcium in the cytosol of the acinar cell promotes the destruction of spontaneously activated trypsin), (3) acid-base balance, and (4) the synthesis of protective protease inhibitors (pancreatic secretory trypsin inhibitor [PSTI] or SPINK1), which can bind and inactivate ~20% of intracellular trypsin activity. Chymotrypsin C can also lyse and inactivate trypsin. These protease inhibitors are found in acinar cells, pancreatic secretions, and the α_1- and α_2-globulin fractions of plasma. Loss of any of these four protective mechanisms leads to premature enzyme activation, autodigestion, and ultimately acute pancreatitis.

ENTEROPANCREATIC AXIS AND FEEDBACK INHIBITION

Pancreatic enzyme secretion is controlled, at least in part, by a negative feedback mechanism induced by the presence of active serine proteases in the duodenum and nutrients in the distal small intestine. For example, perfusion of the duodenal lumen with phenylalanine (stimulates early digestion) causes a prompt increase in plasma CCK levels as well as increased secretion of chymotrypsin and other pancreatic enzymes. However, simultaneous perfusion with trypsin (stimulates late digestion) blunts both responses. Conversely, perfusion of the duodenal lumen with protease inhibitors actually leads to enzyme hypersecretion. Available evidence supports the concept that the duodenum contains a peptide called *CCK-releasing factor* (CCK-RF) that is involved in stimulating CCK release. It appears that serine proteases inhibit pancreatic secretion by inactivating a CCK-releasing peptide in the lumen of the small intestine. Thus, the integrative result of both bicarbonate and enzyme secretion depends on a feedback process for both bicarbonate and pancreatic enzymes. Acidification of the duodenum releases secretin, which stimulates vagal and other neural pathways to activate pancreatic duct cells, which secrete bicarbonate. This bicarbonate then neutralizes the duodenal acid, and the feedback loop is completed. Dietary proteins bind proteases, thereby leading to an increase in free CCK-RF. CCK is then released into the blood in physiologic concentrations, acting primarily through the neural pathways (vagal-vagal). This leads to acetylcholine-mediated pancreatic enzyme secretion. Proteases continue to be secreted from the pancreas until the protein within the duodenum is digested. At this point, pancreatic protease secretion is reduced to basic levels, thus completing this step in the feedback process. Additional hormonal feedback inhibition of pancreatic enzyme secretion occurs via peptide YY and glucagon-like peptide-1 following lipid or carbohydrate exposure to the ileum.

ACUTE PANCREATITIS

GENERAL CONSIDERATIONS

Recent U.S. estimates indicate that acute pancreatitis is the most common inpatient principal gastrointestinal diagnosis, responsible for >250,000 hospitalizations per year. The annual incidence ranges from 15–45/100,000 persons, depending on the distribution of etiologies (e.g., alcohol, gallstones, metabolic factors, drugs [Table 348-1]) and country of study. The median length of hospital stay is 4 days, with a median hospital cost of ~$6000 and a mortality of ~1%. The estimated cost annually approaches $3 billion. Hospitalization rates increase with age and are higher among blacks and men. The age-adjusted rate of hospital discharges with an acute pancreatitis diagnosis increased by 62% between 1988 and 2004. From 2000 to 2009, the rate increased by 30%. Thus, the incidence of acute pancreatitis continues to rise and is associated with substantial health care costs.

ETIOLOGY AND PATHOGENESIS

There are many causes of acute pancreatitis (Table 348-1), and the mechanisms by which each of these conditions triggers pancreatic inflammation have not been fully elucidated. Gallstones and alcohol account for 80–90% of identified cases of acute pancreatitis in the United States. Gallstones continue to be the leading cause of acute pancreatitis in most series (30–60%). The risk of acute pancreatitis in patients with at least one gallstone <5 mm in diameter is fourfold greater than that in patients with larger stones. Alcohol is the second most common cause, responsible for 15–30% of cases in the United States. The incidence of pancreatitis in alcoholics is surprisingly low (5/100,000), indicating that in addition to the amount of alcohol ingested, other factors affect a person's susceptibility to pancreatic injury, such as cigarette smoking and genetic predisposition. Acute pancreatitis occurs in 5–10% of patients following endoscopic retrograde cholangiopancreatography (ERCP); however, this risk can be decreased with proper patient selection and the use of a prophylactic pancreatic duct stent and/or rectal nonsteroidal anti-inflammatory drugs (NSAIDs; indomethacin). Risk factors for post-ERCP pancreatitis include minor papilla sphincterotomy, suspected sphincter of Oddi dysfunction, prior history of post-ERCP pancreatitis, age <60 years, more than two contrast injections into the pancreatic duct, and endoscopist experience.

Hypertriglyceridemia is the cause of acute pancreatitis in 1–4% of cases; serum triglyceride levels are usually >1000 mg/dL. Most patients with hypertriglyceridemic pancreatitis have undiagnosed or uncontrolled diabetes mellitus. An additional subset has an underlying derangement in lipid metabolism, probably unrelated to pancreatitis. Such patients are prone to recurrent episodes of pancreatitis. Any factor (e.g., alcohol or medications, such as oral contraceptives) that causes an abrupt increase in serum triglycerides can potentially precipitate a bout

TABLE 348-1 Causes of Acute Pancreatitis

Common Causes
Gallstones (including microlithiasis)
Alcohol (acute and chronic alcoholism)
Hypertriglyceridemia
Endoscopic retrograde cholangiopancreatography (ERCP), especially after biliary manometry
Idiopathic
Uncommon Causes
Drugs (azathioprine, 6-mercaptopurine, sulfonamides, estrogens, tetracycline, valproic acid, 5-aminosalicylic acid [5-ASA])
Connective tissue disorders and thrombotic thrombocytopenic purpura (TTP)
Pancreatic cancer
Hypercalcemia
Periampullary diverticulum
Pancreas divisum[a]
Hereditary pancreatitis
Cystic fibrosis
Renal failure
Infections (mumps, coxsackievirus, cytomegalovirus, echovirus, parasites)
Autoimmune (e.g., type 1 and type 2)
Trauma (especially blunt abdominal trauma)
Postoperative (abdominal and nonabdominal operations)
Causes to Consider in Patients with Recurrent Bouts of Acute Pancreatitis without an Obvious Etiology
Occult disease of the biliary tree or pancreatic ducts, especially microlithiasis, biliary sludge
Alcohol abuse
Metabolic: Hypertriglyceridemia, hypercalcemia
Anatomic: Pancreas divisum[a]
Pancreatic cancer
Intraductal papillary mucinous neoplasm (IPMN)
Hereditary pancreatitis
Cystic fibrosis
Idiopathic

[a]Pancreas divisum is not believed to cause acute pancreatitis in isolation of another disease precipitant.

of acute pancreatitis. Patients with a deficiency of apolipoprotein CII have an increased incidence of pancreatitis; apolipoprotein CII activates lipoprotein lipase, which is important in clearing chylomicrons from the bloodstream. Although frequently entertained, <2% of cases of acute pancreatitis are drug related. Drugs cause pancreatitis either by a hypersensitivity reaction or by the generation of a toxic metabolite, although in some cases, it is not clear which of these mechanisms is operative (Table 348-1).

Pathologically, acute pancreatitis ranges from *interstitial pancreatitis* (pancreas blood supply maintained), which is generally self-limited, to *necrotizing pancreatitis* (pancreas blood supply interrupted). Autodigestion is a currently accepted pathogenic theory resulting when proteolytic enzymes (e.g., trypsinogen, chymotrypsinogen, proelastase, and lipolytic enzymes such as phospholipase A_2) are activated in the pancreas acinar cell compartment rather than the intestinal lumen. A number of factors (e.g., endotoxins, exotoxins, viral infections, ischemia, oxidative stress, lysosomal calcium, direct trauma) are believed to facilitate premature activation of trypsin. Activated proteolytic enzymes, especially trypsin, not only digest pancreatic and peripancreatic tissues but can also activate other enzymes, such as elastase and phospholipase A_2. Spontaneous activation of trypsin also can occur, resulting in autodigestion.

ACTIVATION OF PANCREATIC ENZYMES IN THE PATHOGENESIS OF ACUTE PANCREATITIS

Several studies have suggested that pancreatitis is a disease that evolves in three phases. The *initial phase* is characterized by intrapancreatic digestive enzyme activation and acinar cell injury. Trypsin activation appears to be mediated by lysosomal hydrolases such as cathepsin B that become colocalized with digestive enzymes in intracellular organelles; it is currently believed that acinar cell injury is the consequence of trypsin activation. The *second phase* of pancreatitis involves the activation, chemoattraction, and sequestration of leukocytes and macrophages in the pancreas, resulting in an enhanced intrapancreatic inflammatory reaction. Neutrophil depletion induced by prior administration of an antineutrophil serum has been shown to reduce the severity of experimentally induced pancreatitis. There is also evidence to support the concept that neutrophils can activate trypsinogen. Thus, intrapancreatic acinar cell activation of trypsinogen could be a two-step process (i.e., an early neutrophil-independent and a later neutrophil-dependent phase). The *third phase* of pancreatitis is due to the effects of activated proteolytic enzymes and cytokines, released by the inflamed pancreas, on distant organs. Activated proteolytic enzymes, especially trypsin, not only digest pancreatic and peripancreatic tissues but also activate other enzymes such as elastase and phospholipase A_2. The active enzymes and cytokines then digest cellular membranes and cause proteolysis, edema, interstitial hemorrhage, vascular damage, coagulation necrosis, fat necrosis, and cellular necrosis in the parenchyma. Cellular injury and death result in the liberation of bradykinin peptides, vasoactive substances, and histamine that can produce vasodilation, increased vascular permeability, and edema with profound effects on other organs. The systemic inflammatory response syndrome (SIRS) and acute respiratory distress syndrome (ARDS), as well as multiorgan failure, may occur as a result of this cascade of local and distant effects.

A number of genetic factors can increase the susceptibility and/or modify the severity of pancreatic injury in acute pancreatitis, recurrent acute pancreatitis, and chronic pancreatitis. All the major genetic susceptibility factors center on the control of trypsin activity within the pancreatic acinar cell, in part because they were identified as candidate genes linked to intrapancreatic trypsin control. Six genetic variants have been identified as being associated with susceptibility to pancreatitis. The genes that have been identified include (1) cationic trypsinogen gene (*PRSS1*), (2) pancreatic secretory trypsin inhibitor (*SPINK1*), (3) the cystic fibrosis transmembrane conductance regulator gene (*CFTR*), (4) the chymotrypsin C gene (*CTRC*), (5) the calcium-sensing receptor (*CASR*), and (6) claudin-2 (*CLDN2*). Among these variants, only *PRSS1* mutations are sufficient to precipitate acute pancreatitis in the absence of other risk factors, whereas the other variants are disease modifiers. Investigations of other genetic variants are currently underway, and new genes will be added to this list in the future.

APPROACH TO THE PATIENT

Abdominal Pain

Abdominal pain is the major symptom of acute pancreatitis. Pain may vary from mild discomfort to severe, constant, and incapacitating distress. Characteristically, the pain, which is steady and boring in character, is located in the epigastrium region and may radiate to the back, chest, flanks, and lower abdomen. Nausea, vomiting, and abdominal distention due to gastric and intestinal hypomotility are also frequent complaints.

Physical examination frequently reveals a distressed and anxious patient. Low-grade fever, tachycardia, and hypotension are common. Shock is not unusual and may result from (1) hypovolemia secondary to exudation of blood and plasma proteins into the retroperitoneal space; (2) increased formation and release of kinin peptides, which cause vasodilation and increased vascular permeability; and (3) systemic effects of proteolytic and lipolytic enzymes released into the circulation. Jaundice occurs infrequently; when present, it may be a consequence of extrinsic compression due to peripancreatic edema or a pancreatic head mass or of intraductal obstruction from a common bile duct stone or sludge. Erythematous skin nodules due to subcutaneous fat necrosis rarely occur. In 10–20% of patients, there are pulmonary findings, including basilar rales, atelectasis, and pleural effusion, the latter most frequently left-sided. Abdominal tenderness and muscle rigidity are present to a variable degree, but compared with the intense pain, these signs may be less impressive. Bowel sounds are usually diminished or absent. An enlarged pancreas from an acute fluid collection, walled-off necrosis, or a pseudocyst may be palpable in the upper abdomen later in the course of the disease (i.e., 4–6 weeks). A faint blue discoloration around the umbilicus (Cullen's sign) may occur as the result of hemoperitoneum, and a blue-red-purple or green-brown discoloration of the flanks (Turner's sign) reflects tissue breakdown of hemoglobin from severe necrotizing pancreatitis with hemorrhage; both findings are rare but reflect an increased clinical severity.

LABORATORY DATA

Serum amylase and lipase values threefold or more above normal are strongly supportive of the diagnosis if alternate etiologies, including gut perforation, ischemia, and infarction, are excluded. However, it should be noted that there is no correlation between the severity of pancreatitis and the degree of serum lipase and amylase elevations or serial trends. After 3–7 days, even with continuing evidence of pancreatitis, total serum amylase values tend to return toward normal. However, pancreatic lipase levels may remain elevated for 7–14 days. It should be recognized that amylase elevations in serum and urine occur in many conditions other than pancreatitis **(see Chap. 347, Table 347-2)**. Importantly, patients with *acidemia* (arterial pH ≤7.32) may have spurious elevations in serum amylase. This finding explains why patients with diabetic ketoacidosis may have marked elevations in serum amylase without any other evidence of acute pancreatitis. On the other hand, serum amylase levels can be spuriously low in the setting of severe hypertriglyceridemia. Serum lipase activity increases in parallel with amylase activity and is more specific than amylase, making it the preferred test. A serum lipase measurement can be instrumental in differentiating a pancreatic or nonpancreatic cause for hyperamylasemia.

Leukocytosis (15,000–20,000 leukocytes/μL) occurs frequently. Patients with more severe disease may show hemoconcentration with hematocrit values >44% and/or prerenal azotemia with a blood urea nitrogen (BUN) level >22 mg/dL resulting from loss of plasma into the retroperitoneal space and peritoneal cavity.

Hemoconcentration may be the harbinger of more severe disease, whereas azotemia is a significant risk factor for mortality. *Hyperglycemia* is common and is due to multiple factors, including

TABLE 348-2 Revised Atlanta Definitions of Morphologic Features of Acute Pancreatitis

	DEFINITION	COMPUTED TOMOGRAPHY FEATURES
Types of Acute Pancreatitis		
Interstitial pancreatitis	Acute inflammation of the pancreatic parenchyma and peripancreatic tissues, but without recognizable tissue necrosis	Pancreatic parenchyma enhancement by IV contrast agent and without peripancreatic necrosis
Necrotizing pancreatitis	Inflammation associated with pancreatic parenchymal and/or peripancreatic necrosis	Lack of pancreatic parenchymal enhancement by IV contrast agent and/or presence of findings of peripancreatic necrosis (see below—ANC and WON)
Morphologic Features		
Acute pancreatic fluid collection	Peripancreatic fluid associated with interstitial edematous pancreatitis with no associated peripancreatic necrosis. This term applies only to areas of peripancreatic fluid seen within the first 4 weeks after onset of interstitial edematous pancreatitis and without the features of a pseudocyst.	Occurs in the setting of interstitial pancreatitis Homogeneous collection with fluid density Confined by normal peripancreatic fascial planes No definable wall encapsulating the collection Adjacent to pancreas (no intrapancreatic extension)
Pancreatic pseudocyst	An encapsulated collection of fluid with a well-defined inflammatory wall usually outside the pancreas with minimal or no necrosis. This entity usually occurs >4 weeks after onset of interstitial edematous pancreatitis.	Well circumscribed, usually round or oval Homogeneous fluid density No solid component Well-defined wall; that is, completely encapsulated Maturation usually requires >4 weeks after onset of acute pancreatitis; occurs after interstitial pancreatitis
Acute necrotic collection (ANC)	A collection containing variable amounts of both fluid and necrosis associated with necrotizing pancreatitis; the necrosis can involve the pancreatic parenchyma and/or the peripancreatic tissues.	Occurs in the setting of acute necrotizing pancreatitis Heterogeneous and nonliquid density of varying degrees in different locations (some appear homogeneous early in their course) No definable wall encapsulating the collection Location—intrapancreatic and/or extrapancreatic
Walled-off necrosis (WON)	A mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has developed a well-defined inflammatory wall. WON usually occurs >4 weeks after onset of acute necrotizing pancreatitis.	Heterogeneous with liquid and nonliquid density with varying degrees of loculations (some may appear homogeneous) Well-defined wall; that is, completely encapsulated Location—intrapancreatic and/or extrapancreatic Maturation usually requires >4 weeks after onset of acute necrotizing pancreatitis

Source: Data from P Banks et al: Gut 62:102, 2013.

decreased insulin release, increased glucagon release, and increased output of adrenal glucocorticoids and catecholamines. *Hypocalcemia* occurs in ~25% of patients, and its pathogenesis is incompletely understood. Although earlier studies suggested that the response of the parathyroid gland to a decrease in serum calcium is impaired, subsequent observations have failed to confirm this phenomenon. Intraperitoneal saponification of calcium by fatty acids in areas of fat necrosis occurs occasionally, with large amounts (up to 6.0 g) dissolved or suspended in ascitic fluid. Such "soap formation" may also be significant in patients with pancreatitis, mild hypocalcemia, and little or no obvious ascites. *Hyperbilirubinemia* (serum bilirubin >4.0 mg/dL) occurs in ~10% of patients. However, jaundice is transient, and serum bilirubin levels return to normal in 4–7 days. Serum alkaline phosphatase and transaminase levels may also be transiently elevated and parallel serum bilirubin values. Elevations of alanine aminotransferase (ALT) >3× the upper limit of normal are strongly associated with a gallstone etiology in patients with acute pancreatitis. Approximately 5–10% of patients have *hypoxemia* (arterial Po_2 ≤60 mmHg), which may herald the onset of ARDS. Finally, the electrocardiogram is occasionally abnormal in acute pancreatitis with ST-segment and T-wave abnormalities simulating myocardial ischemia.

An abdominal ultrasound is recommended in the emergency ward as the initial diagnostic imaging modality and is most useful to evaluate for gallstones and common bile duct dilation.

The Revised Atlanta Criteria have clearly outlined the morphologic features of acute pancreatitis on computed tomography (CT) scan as follows: (1) interstitial pancreatitis, (2) necrotizing pancreatitis, (3) acute pancreatic fluid collection, (4) pancreatic pseudocyst, (5) acute necrotic collection (ANC), and (6) walled-off necrosis (WON) **(Table 348-2 and Fig. 348-1). Radiologic studies useful in the diagnosis of acute pancreatitis are discussed in Chap. 347 and listed in Table 347-1.**

DIAGNOSIS

Any severe acute pain in the abdomen or back should suggest the possibility of acute pancreatitis. The diagnosis is established by two of the following three criteria: (1) typical abdominal pain in the epigastrium that may radiate to the back, (2) threefold or greater elevation in serum lipase and/or amylase, and (3) confirmatory findings of acute pancreatitis on cross-sectional abdominal imaging. Although not required for diagnosis, markers of severity may include hemoconcentration (hematocrit >44%), admission azotemia (BUN >22 mg/dL), SIRS, and signs of organ failure **(Table 348-3)**.

The *differential diagnosis* should include the following disorders: (1) perforated viscus, especially peptic ulcer; (2) acute cholecystitis and biliary colic; (3) acute intestinal obstruction; (4) mesenteric vascular occlusion; (5) renal colic; (6) inferior myocardial infarction; (7) dissecting aortic aneurysm; (8) connective tissue disorders with vasculitis; (9) pneumonia; and (10) diabetic ketoacidosis. It may be difficult to differentiate acute cholecystitis from acute pancreatitis, because an elevated serum amylase may be found in both disorders. Pain of biliary tract origin is more right sided or epigastric than periumbilical or left upper quadrant and can be more severe; ileus is usually absent. Ultrasound is helpful in establishing the diagnosis of cholelithiasis and cholecystitis. Intestinal obstruction due to mechanical factors can be differentiated from pancreatitis by the history of crescendo-decrescendo pain, findings on abdominal examination, and CT of the abdomen showing changes characteristic of mechanical obstruction. Acute mesenteric vascular occlusion is usually suspected in elderly debilitated patients with leukocytosis, abdominal distention, and bloody diarrhea, confirmed by CT or magnetic resonance angiography. Vasculitides secondary to systemic lupus erythematosus and polyarteritis nodosa may be confused with pancreatitis, especially because pancreatitis may develop as a complication of these diseases. Diabetic ketoacidosis is often accompanied by abdominal pain and

TABLE 348-3 Severe Acute Pancreatitis

Risk Factors for Severity
• Age >60 years
• Obesity, BMI >30 kg/m^2
• Comorbid disease (based on Charlson comorbidity index)
Markers of Severity at Admission or within 24 h
• SIRS—defined by presence of 2 or more criteria:
• Core temperature <36° or >38°C
• Heart rate >90 beats/min
• Respirations >20/min or Pco_2 <32 mmHg
• White blood cell count >12,000/μL, <4000/μL, or 10% bands
• APACHE II (≥8 at 24 h)
• Hemoconcentration (hematocrit >44%)
• Admission BUN (>22 mg/dL)
• BISAP score (≥3 present)
• (B) BUN >25 mg/dL
• (I) Impaired mental status
• (S) SIRS: ≥2 of 4 present
• (A) Age >60 years
• (P) Pleural effusion
• Organ failure (Modified Marshall score) (≥1 present):
• Cardiovascular: systolic BP <90 mmHg, heart rate >130 beats/min
• Pulmonary: Pao_2 <60 mmHg
• Renal: serum creatinine >2.0 mg/dL
Markers of Severity during Hospitalization
• Persistent organ failure (≥48 h)
• Pancreatic or extrapancreatic necrosis

Abbreviations: APACHE II, Acute Physiology and Chronic Health Evaluation II; BISAP, Bedside Index of Severity in Acute Pancreatitis; BMI, body mass index; BP, blood pressure; BUN, blood urea nitrogen; SIRS, systemic inflammatory response syndrome.

elevated total serum amylase levels, thus closely mimicking acute pancreatitis; however, the serum lipase level is often not elevated in diabetic ketoacidosis, and pancreas imaging is normal.

CLINICAL COURSE, DEFINITIONS, AND CLASSIFICATIONS

The Revised Atlanta Criteria define (1) phases of acute pancreatitis, (2) severity of acute pancreatitis, and (3) radiographic definitions, as outlined below.

Phases of Acute Pancreatitis Two phases of acute pancreatitis have been defined, early (<2 weeks) and late (>2 weeks), which primarily describe the hospital course of the disease. In the *early phase* of acute pancreatitis, which lasts 1–2 weeks, severity is defined by clinical parameters rather than morphologic findings. Most patients exhibit SIRS, and if this persists, patients are predisposed to organ failure. Three organ systems should be assessed to define organ failure: respiratory, cardiovascular, and renal. Organ failure is defined as a score of 2 or more for one of these three organ systems using the modified Marshall scoring system. Persistent organ failure (>48 h) is the most important clinical finding regarding severity of the acute pancreatitis episode. Organ failure that affects more than one organ is considered multisystem organ failure. CT imaging is usually not needed or recommended during the first 48 h of admission in acute pancreatitis.

The *late phase* is characterized by a protracted course of illness and may require imaging to evaluate for local complications. The critical clinical parameter of severity, as in the early phase, is persistent organ failure. These patients may require supportive measures such as renal dialysis, ventilator support, or need for supplemental nutrition via a nasojejunal or parenteral route. The radiographic feature of greatest importance to recognize in this phase is the development of necrotizing pancreatitis on CT imaging. Necrosis is associated with prolonged hospitalization and, if infected, may require intervention (percutaneous, endoscopic, and/or surgical).

Severity of Acute Pancreatitis Three classes of severity have been defined: mild, moderately severe, and severe. *Mild acute pancreatitis* is without local complications or organ failure. Most patients with interstitial acute pancreatitis have mild pancreatitis. In mild acute pancreatitis, the disease is self-limited and subsides spontaneously, usually within 3–7 days after onset. Oral intake can be resumed if the patient is hungry, has normal bowel function, and is without nausea and vomiting. Typically, a clear or full liquid diet has been recommended for the initial meal; however, a low-fat solid diet is a reasonable choice following recovery from mild acute pancreatitis.

Moderately severe acute pancreatitis is characterized by transient organ failure (i.e., it resolves in <48 h) or local or systemic complications in the absence of persistent organ failure. These patients may or may not have necrosis but may develop a local complication such as a fluid collection that requires a prolonged hospitalization >1 week. As with mild acute pancreatitis, the mortality rate for these patients remains low.

Severe acute pancreatitis is characterized by persistent organ failure (>48 h), involving one or more organs. A CT scan or magnetic resonance imaging (MRI) should be obtained to assess for necrosis and/or complications. If a local complication is encountered, management is dictated by clinical symptoms, evidence of infection, the maturity of fluid collection, and clinical stability of the patient. Prophylactic antibiotics are no longer recommended for severe acute pancreatitis.

Imaging in Acute Pancreatitis Two types of pancreatitis are recognized on imaging as *interstitial* or *necrotizing* based on pancreatic perfusion. CT imaging with IV contrast is best evaluated 3–5 days into hospitalization if patients are not responding to supportive care to assess for local complications such as necrosis. Recent studies report the overutilization of CT imaging within 72 h for acute pancreatitis, including those with a mild severity of disease. The Revised Atlanta Criteria also outline the terminology for local complications and fluid collections along with a CT imaging template to guide reporting of findings. Local morphologic features are summarized in Table 348-2. *Interstitial pancreatitis* occurs in 90–95% of admissions for acute pancreatitis and is characterized by diffuse gland enlargement, homogenous contrast enhancement, and mild inflammatory changes or peripancreatic stranding. Symptoms generally resolve with a week of hospitalization. *Necrotizing pancreatitis* occurs in 5–10% of acute pancreatitis admissions and may not evolve until several days of hospitalization. It is characterized by lack of pancreatic parenchymal enhancement by intravenous contrast agent and/or presence of findings of peripancreatic necrosis. The natural history of pancreatic and peripancreatic necrosis is variable because it may remain solid or liquefy, remain sterile or become infected, and persist or disappear over time. Importantly, those with only extrapancreatic necrosis have a more favorable prognosis than patients with pancreatic necrosis (with or without extrapancreatic necrosis). CT identification of local complications, particularly necrosis, is critical in patients who are not responding to therapy because patients with infected and sterile necrosis are at greatest risk of mortality **(Figs. 348-1 and 348-2)**. The median prevalence of organ failure is >50% in necrotizing pancreatitis, and is perhaps slightly higher in infected versus sterile necrosis. With single-organ system failure, the mortality is 3–10%, but increases to nearly 50% with multiorgan failure.

ACUTE PANCREATITIS MANAGEMENT

The management of patients with acute pancreatitis from the time of diagnosis in the emergency ward to hospital discharge is briefly reviewed, highlighting salient features based on severity and complications. It is important to recognize that 85–90% of cases of acute pancreatitis are self-limited and subside spontaneously, usually within 3–7 days after onset, and do not exhibit organ failure or local complications.

The management of acute pancreatitis begins in the emergency ward. After a diagnosis has been confirmed, early and aggressive fluid resuscitation is critical. Additionally, intravenous analgesics are administered, severity is assessed, and a search for etiologies that may impact acute care is begun. Patients who do not respond to aggressive fluid

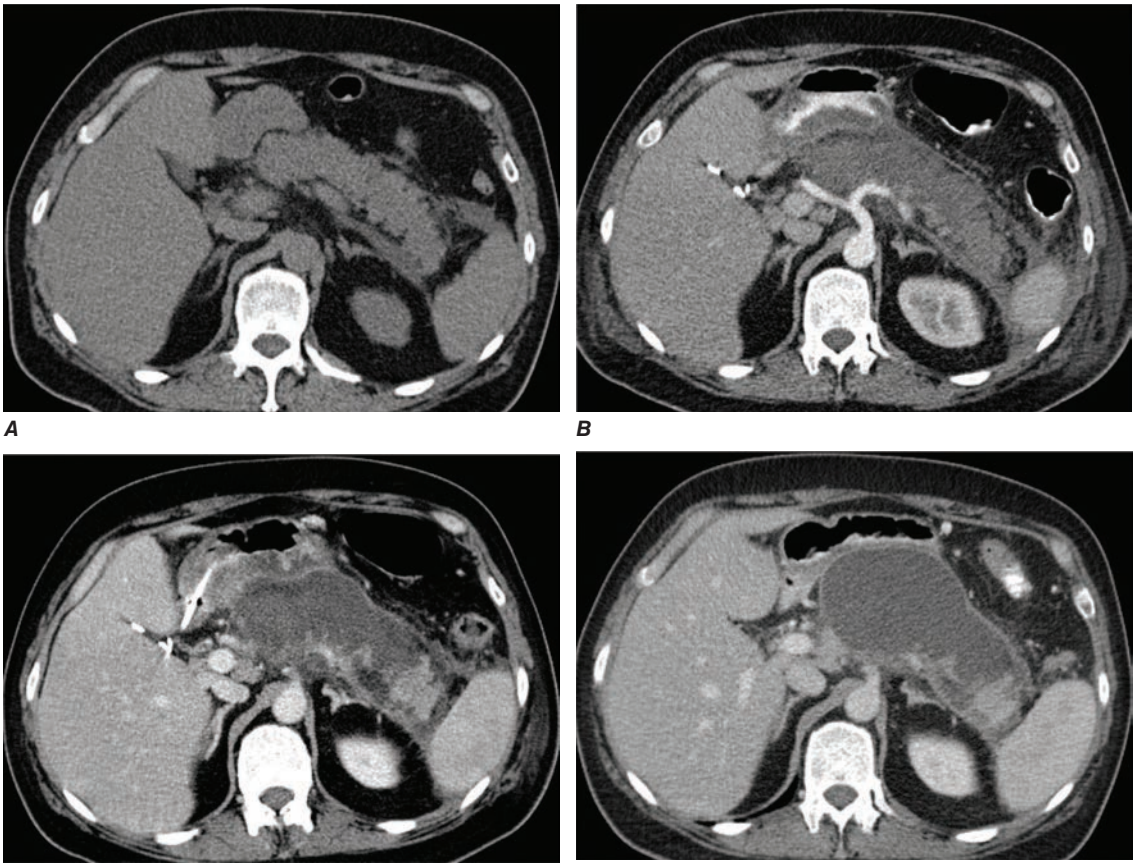

FIGURE 348-1 Evolution of changes of acute necrotizing pancreatitis on computed tomography (CT). ***A.*** CT scan of the abdomen without IV contrast performed on admission for a patient with acute gallstone pancreatitis, showing mild peripancreatic stranding. ***B.*** Contrast-enhanced CT scan of the abdomen performed on the same patient 1 week after admission shows extensive intrapancreatic necrosis, evidenced by the lack of contrast enhancement in the pancreatic body with very minimal enhancement noted at the distal most aspect of the pancreatic tail. ***C.*** Contrast-enhanced CT scan of the abdomen performed on the same patient 2 weeks after admission demonstrates a semiorganized, heterogeneous fluid collection, referred to as an acute necrotic collection. On this image, a small area of viable pancreatic parenchyma is seen at the tail of the pancreas. ***D.*** Contrast-enhanced CT scan of the abdomen performed on the same patient 5 weeks after admission demonstrates a well-encapsulated fluid collection, essentially replacing the pancreas, referred to as walled-off necrosis.

resuscitation in the emergency ward should be considered for admission to a step-down or intensive care unit for aggressive fluid resuscitation, hemodynamic monitoring, and management of any organ failure.

Fluid Resuscitation and Monitoring Response to Therapy The most important treatment intervention for acute pancreatitis is early, aggressive intravenous fluid resuscitation to prevent systemic complications from the secondary systemic inflammatory response. The patient is initially made NPO to minimize nutrient-induced stimulation of the pancreas and is given intravenous narcotic analgesics to control abdominal pain and supplemental oxygen (as needed).

Intravenous fluids of lactated Ringer's or normal saline are initially bolused at 15–20 mL/kg (1050–1400 mL), followed by 2–3 mL/kg per hour (200–250 mL/h), to maintain urine output >0.5 mL/kg per hour. Serial bedside evaluations are required every 6–8 h to assess vital signs, oxygen saturation, and change in physical examination to optimize fluid resuscitation. Lactated Ringer's solution has been shown to

Mortele, Brigham and Women's Hospital; with permission.)*

decrease systemic inflammation (lower C-reactive protein levels from admission) and may be a better crystalloid than normal saline. A *targeted resuscitation strategy* with measurement of hematocrit and BUN every 8–12 h is recommended to ensure adequacy of fluid resuscitation and monitor response to therapy, noting that a less aggressive resuscitation strategy may be needed in milder forms of pancreatitis. A rising BUN during hospitalization is not only associated with inadequate hydration but also higher in-hospital mortality.

A decrease in hematocrit and BUN during the first 12–24 h is strong evidence that sufficient fluids are being administered. Serial measurements and bedside assessment for fluid overload are continued, and fluid rates are maintained at the current rate. Adjustments in fluid resuscitation may be required in patients with cardiac, pulmonary, or renal disease. A rise in hematocrit or BUN during serial measurement should be treated with a repeat volume challenge with a 2-L crystalloid bolus followed by increasing the fluid rate by 1.5 mg/kg per hour. If the BUN or hematocrit fails to respond (i.e., remains elevated or does not decrease) to this bolus challenge and increase in fluid rate, consideration of transfer to an intensive care unit is strongly recommended for hemodynamic monitoring.

Assessment of Severity and Hospital Triage Severity of acute pancreatitis should be determined in the emergency ward to assist in patient triage to a regular hospital ward or step-down unit or direct admission to an intensive care unit. The Bedside Index of Severity in Acute Pancreatitis (BISAP) incorporates five clinical and laboratory parameters obtained within the first 24 h of hospitalization (Table 348-3)—BUN >25 mg/dL, impaired mental status (Glasgow coma scale score <15), SIRS, age >60 years, and pleural effusion on radiography—that can be useful in assessing severity. The presence of three or more of these factors was associated with substantially increased risk for in-hospital mortality among patients with acute pancreatitis. In addition, an elevated hematocrit >44% and admission BUN >22 mg/dL are also associated with more severe acute pancreatitis. Incorporating these indices with the overall patient response to initial fluid resuscitation in the emergency ward can be useful at triaging patients to the appropriate hospital acute care setting.

In general, patients with lower BISAP scores, hematocrits, and admission BUNs tend to respond to initial management and can be safely triaged to a regular hospital ward for ongoing care. If SIRS is not present at 24 h, the patient is unlikely to develop organ failure or necrosis. Therefore, patients with persistent SIRS at 24 h or underlying comorbid illnesses (e.g., chronic obstructive pulmonary disease, congestive heart failure) should be considered for a step-down unit setting if available. Patients with higher BISAP scores and elevations in hematocrit and admission BUN who do not respond to initial fluid resuscitation and exhibit evidence of respiratory failure, hypotension, or organ failure should be considered for direct admission to an intensive care unit.

Special Considerations Based on Etiology A careful history, review of medications, selected laboratory studies (liver profile, serum triglycerides, serum calcium), and an abdominal ultrasound are recommended in the emergency ward to assess for etiologies that may impact acute management. An abdominal ultrasound is the initial imaging modality of choice and will evaluate the gallbladder, common bile duct, and pancreatic head.

GALLSTONE PANCREATITIS Patients with evidence of ascending cholangitis (rising white blood cell count, increasing liver enzymes) should undergo ERCP within 24–48 h of admission. Patients with gallstone pancreatitis are at increased risk of recurrence, and consideration should be given to performing a cholecystectomy during the same admission in mild acute pancreatitis. An alternative for patients who are not surgical candidates would be to perform an endoscopic biliary sphincterotomy before discharge.

HYPERTRIGLYCERIDEMIA Serum triglycerides >1000 mg/dL are associated with acute pancreatitis. Initial therapy should focus on treatment of hyperglycemia with intravenous insulin, which often corrects the hypertriglyceridemia. Adjunct therapies may also include heparin or plasmapheresis, but there is no compelling evidence these measures improve clinical outcomes. Outpatient therapies include control of diabetes if present, administration of lipid-lowering agents, weight loss, and avoidance of drugs that elevate lipid levels.

Other potential etiologies that may impact acute hospital care include *hypercalcemia* and *post-ERCP pancreatitis*. Treatment of hyperparathyroidism or malignancy is effective at reducing serum calcium. Pancreatic duct stenting and rectal indomethacin administration are effective at decreasing pancreatitis after ERCP. Drugs that cause pancreatitis should be discontinued. Multiple drugs have been implicated, but only about 30 have been rechallenged (Class 1A) and found to be causative.

Nutritional Therapy A low-fat solid diet can be administered to subjects with mild acute pancreatitis once they are able to eat. Enteral nutrition should be considered 2–3 days after admission in subjects with more severe pancreatitis instead of total parenteral nutrition (TPN). Enteral feeding maintains gut barrier integrity, limits bacterial translocation, is less expensive, and has fewer complications than TPN. Gastric feeding is safe; the benefits of nasojejunal enteral feeding over gastric feeding remains under investigation.

Management of Local Complications (Table 348-4) Patients exhibiting signs of clinical deterioration despite aggressive fluid resuscitation and hemodynamic monitoring should be assessed for local complications, which may include necrosis, pseudocyst formation, pancreas duct disruption, peripancreatic vascular complications, and extrapancreatic infections. A multidisciplinary team approach is recommended, including gastroenterology, surgery, interventional radiology, and intensive care specialists, and consideration should also be made for transfer to a tertiary pancreas center of excellence.

NECROSIS The management of necrosis requires a multidisciplinary team approach. Percutaneous fine-needle aspiration of necrosis with Gram stain and culture was previously performed to evaluate for infected pancreatic necrosis in those with sustained leukocytosis, fever, or organ failure. However, the current use of this technique varies depending on institutional preference, with many abandoning this diagnostic test to avoid potentially contaminating an otherwise sterile collection, particularly when culture results will not lead to a clinical decision to de-escalate antimicrobial therapy. Even though there is currently no role for *prophylactic antibiotics* in necrotizing pancreatitis, *empiric antibiotics* should be considered in those with clinical decompensation. Prophylactic antibiotics do not lead to improved survival and may promote the development of opportunistic fungal infections. Repeated CT or MRI imaging should also be considered with any change in clinical course to monitor for complications (e.g., thromboses, hemorrhage, abdominal compartment syndrome).

In general, *sterile necrosis* is most often managed conservatively unless complications arise. Once a diagnosis of *infected necrosis* is established and an organism identified, targeted antibiotics should be instituted. Pancreatic drainage and/or debridement (necrosectomy) should be considered for definitive management of *infected necrosis*, but clinical decisions are ultimately influenced by the clinical response since almost two-thirds of patients respond to antibiotic treatment with or without percutaneous drainage. Symptomatic local complications as outlined in the Revised Atlanta Criteria typically require definitive therapy.

A step-up approach (percutaneous or endoscopic transgastric/transduodenal drainage followed, if necessary, by surgical necrosectomy) has been successfully reported by some pancreatic centers. One-third of the patients successfully treated with the step-up approach did not require major abdominal surgery. A randomized trial reported advantages to an initial endoscopic approach compared to an initial surgical necrosectomy approach in select patients requiring intervention for symptomatic WON. Taken together, a more conservative approach to the management of infected pancreatic necrosis has evolved under the close supervision of a multidisciplinary team. If conservative therapy can be safely implemented, it is recommended to do so for 4–6 weeks to allow the pancreatic collections to either resolve or evolve to develop

a more organized boundary (i.e., to "wall off") so that surgical or endoscopic intervention is generally safer and more effective.

PSEUDOCYST The incidence of pseudocyst is low, and most acute collections resolve over time. Less than 10% of patients have persistent fluid collections after 4 weeks that would meet the definition of a pseudocyst. Only symptomatic collections require intervention with endoscopic or surgical drainage.

PANCREATIC DUCT DISRUPTION Pancreatic duct disruption may present with symptoms of increasing abdominal pain or shortness of breath in the setting of an enlarging fluid collection resulting in pancreatic ascites (ascitic fluid has high amylase level). Diagnosis can be confirmed on magnetic resonance cholangiopancreatography (MRCP) or ERCP. Placement of a bridging pancreatic stent for at least 6 weeks is >90% effective at resolving the leak with or without parenteral nutrition and octreotide. Nonbridging stents are less effective (25–50%) but should be considered with parenteral nutrition and octreotide prior to surgical intervention.

PERIVASCULAR COMPLICATIONS Perivascular complications may include *splenic vein thrombosis* with gastric varices and pseudoaneurysms, as well as *portal and superior mesenteric vein thromboses*. *Gastric varices* rarely bleed but can be life-threatening. Similarly, life-threatening bleeding from a ruptured *pseudoaneurysm* can be diagnosed and treated with mesenteric angiography and embolization.

EXTRAPANCREATIC INFECTIONS Hospital-acquired infections occur in up to 20% of patients with acute pancreatitis. Patients should be continually monitored for the development of pneumonia, urinary tract infection, and line infection. Continued culturing of urine, monitoring of chest x-rays, and routine changing of intravenous lines are important during hospitalization.

Follow-Up Care Hospitalizations for moderately severe and severe acute pancreatitis can be prolonged and last weeks to months and often involve periods of intensive care unit admission and outpatient rehabilitation or subacute nursing care. Follow-up evaluation should assess for development of diabetes, exocrine pancreatic insufficiency, recurrent cholangitis, or infected fluid collections. As mentioned previously, cholecystectomy should be performed during the initial hospitalization for acute gallstone pancreatitis with mild clinical severity. For patients with necrotizing gallstone pancreatitis, the timing of cholecystectomy needs to be individualized.

RECURRENT ACUTE PANCREATITIS

Approximately 25% of patients who have had an attack of acute pancreatitis have a recurrence. The two most common etiologic factors are alcohol and cholelithiasis. In patients with recurrent pancreatitis without an obvious cause, the differential diagnosis should encompass occult biliary tract disease, including microlithiasis, hypertriglyceridemia, pancreatic cancer, and hereditary pancreatitis (Table 348-1). In one series of 31 patients diagnosed initially as having idiopathic or recurrent acute pancreatitis, 23 were found to have occult gallstone disease. Thus, approximately two-thirds of patients with recurrent acute pancreatitis without an obvious cause actually have occult gallstone disease due to microlithiasis. Genetic defects as in hereditary pancreatitis and cystic fibrosis mutations can result in recurrent pancreatitis. Other diseases of the biliary tree and pancreatic ducts that can cause acute pancreatitis include choledochocele; ampullary tumors; pancreas divisum; and pancreatic duct stones, stricture, and tumor. Approximately 2–4% of patients with pancreatic cancer present with acute pancreatitis.

PANCREATITIS IN PATIENTS WITH AIDS

The incidence of acute pancreatitis is theoretically increased in patients with AIDS for two reasons: (1) the high incidence of infections involving the pancreas such as infections with cytomegalovirus, *Cryptosporidium*, and the *Mycobacterium avium* complex; and (2) the frequent use by patients with AIDS of medications such as pentamidine, trimethoprim-sulfamethoxazole, and protease inhibitors. The incidence has been markedly reduced due to advances in therapy, including the disuse of didanosine (Chap. 202).

CHRONIC PANCREATITIS AND EXOCRINE PANCREATIC INSUFFICIENCY

PATHOPHYSIOLOGY

Chronic pancreatitis is a disease process characterized by irreversible damage to the pancreas, in contrast to the reversible changes noted

in acute pancreatitis (Table 348-4). The events that initiate and then perpetuate the inflammatory process in the pancreas are becoming more clearly understood. Irrespective of the mechanism of injury, it is becoming apparent that stellate cell activation leads to cytokine expression and production of extracellular matrix proteins that contribute to acute and chronic inflammation and collagen deposition in the pancreas. This condition is defined by the presence of histologic abnormalities, including chronic inflammation, fibrosis, and progressive destruction (atrophy) of both exocrine and endocrine tissue. A number of etiologies have been associated with chronic pancreatitis resulting in the cardinal manifestations of the disease such as abdominal pain, steatorrhea, weight loss, diabetes mellitus, and, less commonly, pancreatic cancer **(Table 348-5)**.

Even in individuals in whom alcohol is believed to be the primary cause of chronic pancreatitis, other factors are likely required for the development and progression of disease, which explains why not all heavy consumers of alcohol develop pancreatic disease. There is also a strong association between smoking and chronic pancreatitis. Cigarette smoke leads to an increased susceptibility to pancreatic autodigestion and predisposes to dysregulation of duct cell CFTR function. Smoking is an independent, dose-dependent risk factor for chronic pancreatitis and recurrent acute pancreatitis. Both continued alcohol and smoking exposure are associated with disease progression, including pancreatic fibrosis and calcifications.

Characterization of pancreatic stellate cells (PSCs) has added insight into the underlying cellular responses behind development of chronic pancreatitis. Specifically, PSCs are believed to play a role in maintaining normal pancreatic architecture that shifts toward fibrogenesis in those who develop chronic pancreatitis. It is believed that alcohol or additional stimuli lead to matrix metalloproteinase–mediated destruction of normal collagen in pancreatic parenchyma, which later allows for pancreatic remodeling. Proinflammatory cytokines, tumor necrosis factor α (TNF-α), interleukin 1 (IL-1), and interleukin 6 (IL-6), as well as oxidant complexes, can induce PSC activity with subsequent new collagen synthesis. In addition to being stimulated by cytokines, oxidants, or growth factors, PSCs also possess transforming growth factor β (TGF-β)–mediated self-activating autocrine pathways that may explain disease progression in chronic pancreatitis even after removal of noxious stimuli.

ETIOLOGIC CONSIDERATIONS

Among adults in the United States, alcoholism is the most common cause of clinically apparent chronic pancreatitis, whereas cystic fibrosis is the most frequent cause in children. As many as 25% of adults in the United States with chronic pancreatitis have the *idiopathic* form, including a subset of patients who do not develop clinical manifestations until later in life (idiopathic late-onset chronic pancreatitis). Recent investigations have indicated that up to 15% of patients with chronic pancreatitis previously classified as having idiopathic pancreatitis may have an underlying genetic predisposition (Table 348-5).

The prototypical genetic defect was identified in the cationic trypsinogen gene (*PRSS1*) by studying several large families with chronic pancreatitis. Additional pathogenic and nonpathogenic mutations have been identified in this gene. The defect prevents the destruction of prematurely activated trypsin and allows it to be resistant to the intracellular protective effect of trypsin inhibitor. It is hypothesized that this continual activation of digestive enzymes within the gland leads to acute injury and, finally, chronic pancreatitis. Since the initial discovery of the *PRSS1* mutation defect, other genetic disease modifiers have been identified (Table 348-5).

The *CFTR* gene functions as a cyclic AMP–regulated chloride channel. In patients with cystic fibrosis, the high concentration of macromolecules can block the pancreatic ducts. It must be appreciated, however, that there is a great deal of heterogeneity in relationship to the *CFTR* gene defect. More than 1700 putative mutations of the *CFTR* gene have been identified. Attempts to elucidate the relationship between the genotype and pancreatic manifestations have been hampered by the large number and different classes of *CFTR* mutations. The ability to detect *CFTR* mutations has led to the recognition that the clinical spectrum of the disease is broader than previously thought. Two studies have clarified the association between mutations of the *CFTR* gene and another monosymptomatic form of cystic fibrosis (i.e., chronic pancreatitis). It is estimated that in patients with idiopathic pancreatitis, the frequency of a single *CFTR* mutation is 11 times the expected frequency and the frequency of two mutant alleles is 80 times the expected frequency. In these studies, patients were adults when the diagnosis of pancreatitis was made; none had any clinical evidence of pulmonary disease, and sweat test results were not diagnostic of cystic fibrosis. The prevalence of such mutations is unclear, and further studies are needed. In addition, the therapeutic and prognostic implication of these findings with respect to managing pancreatitis remains to be determined. *CFTR* mutations are common in the general population, so it is unclear whether the *CFTR* mutation alone can lead to pancreatitis as an autosomal recessive disease. A study evaluated 39 patients with idiopathic chronic pancreatitis to assess the risk associated with these mutations. Patients with two *CFTR* mutations (compound heterozygotes) demonstrated *CFTR* function at a level between that seen in typical cystic fibrosis and cystic fibrosis carriers and had a fortyfold increased risk of pancreatitis. The presence of a separate genetic mutation (*N34S SPINK1*) increased the risk twentyfold. A combination of two *CFTR* mutations and an *N34S SPINK1* mutation increased the risk of pancreatitis 900-fold. Knowledge of the genetic defects and downstream alterations in protein expression has led to the development of novel therapies in children with cystic fibrosis that potentiate the CFTR channel, resulting in improvement in lung function, quality of life, and weight gain. Some studies have shown that use of CFTR modulators

TABLE 348-6 Comparison of the Autoimmune Pancreatitis (AIP) Subtypes

	TYPE 1 AIP	TYPE 2 AIP
Age at diagnosis, mean	Seventh decade	Fifth decade
Male sex	75%	50%
Serum IgG4 elevation	~66%	~25%
Other organ involvement	50%	No[a]
Histologic findings:		
Lymphoplasmacytic Infiltration	++	++
Periductal inflammation	++	++
Storiform fibrosis	++	+
Obliterative phlebitis	++	+
Granulocytic epithelial lesion (GEL)	–	+++
IgG4 tissue staining	Abundant (≥10 cells/hpf)	Scant (<10 cells/hpf)
Response to steroids	~100%	~100%
Risk for relapse	High (20–60%)	Low (<10%)
Associated with IgG4-RD	Yes	No

[a]Inflammatory bowel disease is seen in ~10–20% of patients with idiopathic duct-centric chronic pancreatitis but may also occur in type 1 AIP.

may reduce the frequency of acute pancreatitis in heterozygous carriers. Table 348-5 lists other recognized causes of chronic pancreatitis.

AUTOIMMUNE PANCREATITIS (TABLE 348-6)

Autoimmune pancreatitis (AIP) refers to a form of chronic pancreatitis with distinct histopathology and several unique differences in the clinical phenotype. Currently, two subtypes of AIP are recognized, type 1 AIP and idiopathic duct-centric chronic pancreatitis (IDCP, also referred to as type 2 AIP). Type 1 AIP is identified as the pancreatic manifestation of a multiorgan syndrome currently referred to as IgG4-related disease (Chap. 368). The characteristic histopathologic findings of type 1 AIP include lymphoplasmacytic infiltrate, storiform fibrosis, and abundant IgG4 cells. IDCP is histologically defined by the presence of granulocytic infiltration of the duct wall (termed a granulocytic epithelial lesion [GEL]) but without IgG4-positive cells. Type 1 AIP is often associated with involvement of other organs in the setting of IgG4-related disease, including bilateral submandibular gland enlargement, characteristic renal lesions, retroperitoneal fibrosis, and stricturing of the suprapancreatic biliary tree. In contrast, IDCP is a pancreas-specific disorder that is associated with inflammatory bowel disease in ~10% of patients. AIP is not a common cause of idiopathic recurrent acute pancreatitis.

Jaundice, weight loss, and new-onset diabetes are the most common presenting symptoms. Elevated serum IgG4 levels are supportive of the diagnosis (elevated in two-thirds of patients with type 1 AIP) but have a low positive predictive value when used in isolation of other clinical findings. CT imaging demonstrates abnormalities in the majority of patients with either diffuse or focal enlargement during active disease, unless the gland is atrophic due to previous disease (Fig. 348-3). The presence of an inflammatory rim, termed a capsule sign, is highly specific (but not sensitive) for AIP. ERCP or MRCP reveals strictures in the bile duct in more than one-third of patients with AIP, including some patients with isolated intrahepatic bile duct strictures (type 1 AIP only), which can mimic primary sclerosing cholangitis, and is referred to as IgG4-related sclerosing cholangitis (previously termed IgG4-associated cholangitis).

The Mayo Clinic HISORt criteria provide a helpful mnemonic to remember the key diagnostic features of this disease, including (1) *h*istology; (2) *i*maging; (3) *s*erology (elevated serum IgG4 levels); (4) *o*ther organ involvement; and (5) *r*esponse to glucocorticoid *t*herapy. These diagnostic criteria have been harmonized with those from other countries to develop the International Consensus Diagnostic Criteria for AIP, which are the most widely utilized criteria. Glucocorticoids have shown efficacy in alleviating symptoms, decreasing the size of the pancreas, and reversing histopathologic features in patients with AIP. Patients typically respond dramatically to glucocorticoid therapy within a 2- to 4-week period. Prednisone is usually administered at an initial dose of 40 mg/d for 4 weeks followed by a taper of the daily dosage by 5 mg per week based on monitoring of clinical parameters. Relief of symptoms, liver biochemistries, and abnormal imaging of the pancreas and bile ducts are followed to assess for treatment response. A poor response to glucocorticoids should raise suspicion of an alternate diagnosis, such as pancreatic cancer. A recent multicenter international study examined >1000 patients with AIP. Clinical remission was achieved in 99% of type 1 AIP and 92% of type 2 AIP patients with steroids. However, disease relapse occurred in 31 and 9% of patients with type 1 and type 2 AIP, respectively. Patients with multiple relapses may be managed with an immunomodulator (e.g., azathioprine, 6-mercaptopurine, or mycophenolate mofetil) or B-cell depletion therapy (e.g., rituximab). The appearance of interval cancers following a diagnosis of AIP is uncommon.

Clinical Features of Chronic Pancreatitis Patients with chronic pancreatitis primarily seek medical attention due to abdominal pain or symptoms of maldigestion. The abdominal pain may be quite variable in location, severity, and frequency. The pain can be constant or

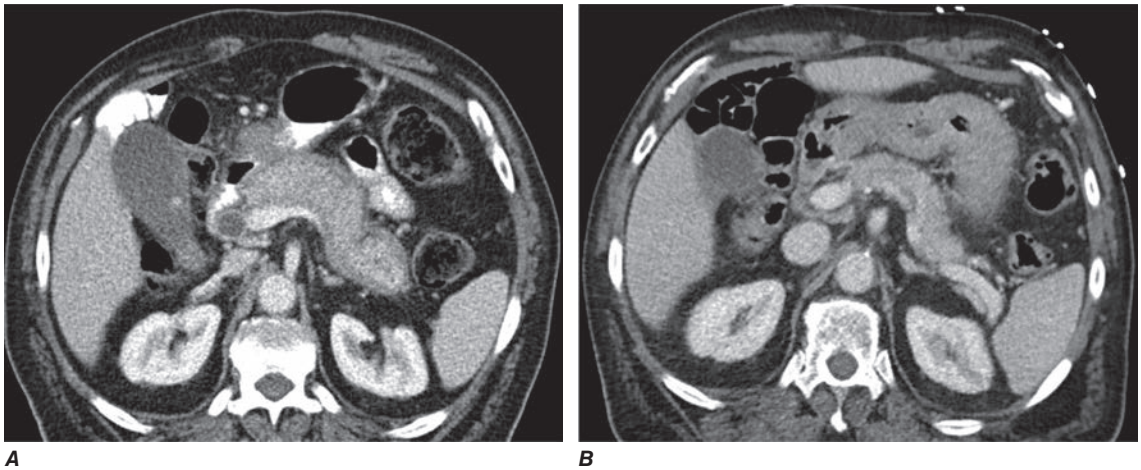

FIGURE 348-3 Imaging features of the pancreatic parenchyma in a patient with type 1 autoimmune pancreatitis on computed tomography (CT). ***A.*** Contrast-enhanced CT scan of the abdomen demonstrates diffuse pancreatic enlargement and a hypoechoic rim (capsule sign) in a patient who presented with jaundice. The serum IgG4 level was elevated to 942 mg/dL (reference range 4–86 mg/dL), so the patient was diagnosed with definitive type 1 autoimmune pancreatitis. ***B.*** Contrast-enhanced CT scan of the abdomen following a treatment course with high-dose steroids demonstrates return to normal size of the pancreas, reappearance of normal lobulations along the margin, and absence of the hypoechoic rim.

intermittent with pain-free intervals. Eating may exacerbate the pain, leading to a fear of eating with consequent weight loss. The spectrum of abdominal pain ranges from mild to quite severe, with narcotic dependence as a frequent consequence. There is often a disparity between the reported severity of abdominal pain and the physical findings, which primarily consist of nonfocal abdominal tenderness. Patients with chronic abdominal pain may or may not experience symptoms of maldigestion, such as chronic diarrhea, steatorrhea, and/or weight loss. Fat-soluble vitamin deficiencies are increasingly recognized. Importantly, there is an exceedingly high prevalence of metabolic bone disease in chronic pancreatitis, with ~65% of patients having either osteopenia or osteoporosis. Patients with chronic pancreatitis have impaired quality of life and develop significant morbidity, requiring frequent use of health care resources.

The diagnosis of early or mild chronic pancreatitis can be challenging because there is no accurate biomarker for the disease. In contrast to acute pancreatitis, the serum amylase and lipase levels are usually not strikingly elevated in chronic pancreatitis. Rather, low serum pancreatic enzyme levels are moderately specific for a diagnosis of chronic pancreatitis but have poor sensitivity. Elevation of serum bilirubin and alkaline phosphatase may indicate cholestasis secondary to common bile duct stricture caused by chronic inflammation or fibrosis. The cumulative prevalence of exocrine pancreatic insufficiency is >80%. The presence of overt steatorrhea in a patient with chronic pancreatitis is highly suggestive of this complication. However, in those with milder symptoms, additional testing, such as a random fecal elastase-1 level (on a formed stool specimen) may be needed to confirm the diagnosis of exocrine pancreatic insufficiency. The radiographic evaluation of a patient with suspected chronic pancreatitis usually proceeds from a noninvasive to more invasive approach. Abdominal CT imaging **(Fig. 348-4)** is the initial modality of choice, followed by MRI, endoscopic ultrasound, and pancreas function testing. In addition to excluding a pseudocyst and pancreatic cancer, CT imaging may show calcifications, dilated pancreatic or biliary ducts, or an atrophic pancreas. Although abdominal CT scanning and MRCP greatly aid in the diagnosis of pancreatic disease, the diagnostic test with the best sensitivity is the hormone stimulation test using secretin. The secretin test becomes abnormal when ≥60% of the pancreatic exocrine function has been lost. This usually correlates well with the onset of chronic abdominal pain. The role of endoscopic ultrasonography (EUS) in diagnosing early chronic pancreatitis is still evolving. A total of nine endosonographic features have been described in chronic pancreatitis. The presence of five or more features is considered diagnostic of chronic pancreatitis. EUS is not a specific enough test for detecting early chronic pancreatitis alone **(Chap. 347)** and may show positive features in patients with diabetes, patients with a history of cigarette smoking, or even in normal aging individuals. Recent data suggest that EUS can be combined with endoscopic pancreatic function testing (EUS-ePFT) during a single endoscopy to screen for chronic pancreatitis in patients with chronic abdominal pain. Diffuse calcifications noted on plain film of the abdomen usually indicate significant damage to the pancreas and are pathognomic for chronic pancreatitis. Although alcohol is by far the most common cause of pancreatic calcification, such calcification may also be noted in hereditary pancreatitis, posttraumatic pancreatitis, idiopathic chronic pancreatitis, and tropical pancreatitis.

Complications of Chronic Pancreatitis There are a number of disease-related complications from chronic pancreatitis in addition to the aforementioned abdominal pain and exocrine pancreatic insufficiency **(Table 348-7)**. The lifetime prevalence of chronic

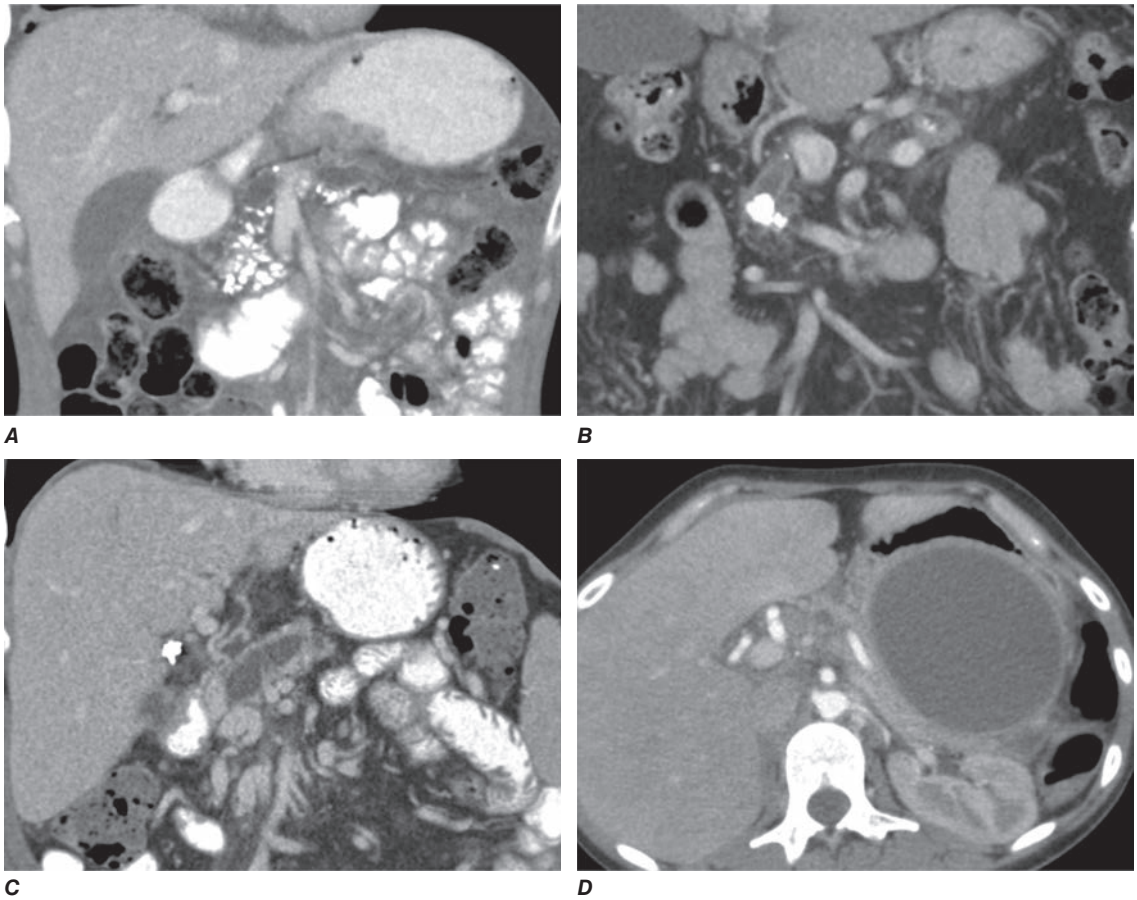

FIGURE 348-4 Distribution of imaging features of chronic pancreatitis on computed tomography (CT). Distinct features of chronic pancreatitis are seen on selected images from contrast-enhanced CT scans of the abdomen from four unique patients, including the following. ***A.*** Numerous punctate calcifications involving the pancreatic parenchyma in the head and body. ***B.*** A moderate-sized calculus visualized in the pancreatic duct with associated ductal dilation. ***C.*** Significant pancreatic duct dilation and adjacent parenchymal atrophy secondary to a pancreatic duct stricture (which is not well seen on this scan). ***D.*** A large unilocular, encapsulated cyst in the tail of the pancreas consistent with a pseudocyst from prior pancreatitis. Note adjacent pancreatic parenchymal atrophy.

TABLE 348-7 Complications of Chronic Pancreatitis

Chronic abdominal pain	Biliary stricture and/or biliary cirrhosis
Exocrine pancreatic insufficiency	Pancreatic duct stricture
Diabetes mellitus	Pseudocyst
Splanchnic venous thrombosis	Pancreatic cancer
Metabolic bone disease (osteoporosis)	

pancreatitis–related diabetes exceeds 80%. Although most patients develop hyperglycemia due to insulin deficiency caused by loss of islet cells, diabetic ketoacidosis and diabetic coma are uncommon. Likewise, end-organ damage (retinopathy, neuropathy, nephropathy) is also uncommon. Nondiabetic retinopathy may be due to vitamin A and/or zinc deficiency. Osteoporosis and osteopenia are increasingly recognized in chronic pancreatitis and likely related to a combination of shared risk factors (e.g., alcohol use, cigarette smoking), vitamin D deficiency, and detrimental effects on the bone from chronic inflammation. Gastrointestinal bleeding may occur from peptic ulceration, gastritis, a pseudocyst eroding into the duodenum, arterial bleeding into the pancreatic duct (hemosuccus pancreaticus), or ruptured varices secondary to splenic vein thrombosis. Jaundice, cholestasis, and biliary cirrhosis may occur from the chronic inflammatory reaction around the intrapancreatic portion of the common bile duct. Twenty years after the diagnosis of chronic calcific pancreatitis, the cumulative risk of pancreatic cancer is 4%. Patients with hereditary *PRSS1* or tropical pancreatitis have an increased risk for pancreatic cancer compared to other forms of chronic pancreatitis.

TREATMENT

Chronic Pancreatitis

There are currently no therapies to reverse or delay the disease progression of chronic pancreatitis, so management is primarily focused on screening for and management of disease-related complications.

STEATORRHEA

The treatment of steatorrhea with pancreatic enzyme replacement therapy is conceptually straightforward, yet complete correction of steatorrhea is uncommon. Enzyme therapy usually brings diarrhea under control and restores absorption of fat to an acceptable level and affects weight gain. Thus, pancreatic enzyme replacement is the cornerstone of therapy. In treating steatorrhea, it is important to use a potent pancreatic formulation that will deliver sufficient lipase into the duodenum to correct maldigestion and decrease steatorrhea. For adult patients with exocrine pancreatic insufficiency, it is generally recommended to start at a dosage of 25,000–50,000 units of lipase taken during each meal; however, the dose may need to be increased up to 100,000 units of lipase depending on the response in symptoms, nutritional parameters, and/or pancreas function test results. Additionally, some may require acid suppression with proton pump inhibitors to optimize the response to pancreatic enzymes. Monitoring nutritional parameters such as fat-soluble vitamins, zinc levels, body weight, and periodic bone mineral density measurement should be considered.

ABDOMINAL PAIN

The management of pain in patients with chronic pancreatitis is challenging due to the complex mechanisms of pancreatitis-related pain. Recent meta-analyses have shown no consistent benefit of enzyme therapy at reducing pain in chronic pancreatitis. Pain relief experienced by patients treated with pancreatic enzymes may be due to improvements in the dyspepsia from maldigestion. One short-term randomized trial showed that pregabalin could decrease pain in chronic pancreatitis and lower pain medication requirement. Other studies using antioxidants have yielded mixed results.

Endoscopic treatment of chronic pancreatitis pain may involve sphincterotomy, pancreatic duct stenting, stone extraction, and drainage of a pancreatic pseudocyst. Therapy directed to the pancreatic duct would seem to be most appropriate in the setting of a dominant stricture, especially if there is an obstructing intraductal stone. The use of endoscopic stenting for patients with chronic pain, but without a dominant stricture, has not been subjected to controlled trials. It is now appreciated that significant complications can occur from stenting (e.g., stent migration, stent occlusion, and stent-induced pancreatic duct strictures). Recent guidelines recommend considering celiac plexus block for treatment of pain in chronic pancreatitis, but recommendations were conditional with very low quality of evidence. Celiac plexus block has not been rigorously studied for chronic pancreatitis and does not provide durable pain relief. It can provide relive in some selected patients, but the a priori identification of those who will respond is difficult. In patients with pancreatic duct dilation, ductal decompression with *surgical therapy* has been the therapy of choice. Among such patients, 80% seem to obtain immediate relief; however, at the end of 3 years, one-half of the patients have recurrence of pain. Two randomized prospective trials comparing endoscopic to surgical therapy for chronic pancreatitis demonstrated that surgical therapy was superior to endoscopy at decreasing pain and improving quality of life in selected patients with dilated ducts and abdominal pain. This would suggest that chronic pancreatitis patients with dilated ducts and pain should be considered for surgical intervention. The role of preoperative stenting prior to surgery as a predictor of response has yet to be proven.

Total pancreatectomy with or without autologous islet cell transplantation has been used in highly selected patients with chronic pancreatitis and abdominal pain refractory to conventional therapy. However, some patients will continue to have pain postoperatively, illustrating the complex nature of pain in patients with chronic pancreatitis. Patients who benefit most from total pancreatectomy have a shorter duration of symptoms and lower pain medication requirements. The role of this procedure remains to be fully defined but may be an option in lieu of ductal decompression surgery or partial pancreatic resection in patients with intractable, painful, small-duct disease or hereditary pancreatitis and particularly as the standard surgical procedures tend to decrease islet cell yield.

HEREDITARY PANCREATITIS

Hereditary pancreatitis (*PRSS1*) is a rare form of pancreatitis with early age of onset that is typically associated with familial aggregation of cases. A genome-wide search using genetic linkage analysis identified the hereditary pancreatitis gene on chromosome 7. Mutations in ion codons 29 (exon 2) and 122 (exon 3) of the cationic trypsinogen gene (*PRSS1*) cause an autosomal dominant form of pancreatitis. The codon 122 mutations lead to a substitution of the corresponding arginine with another amino acid, usually histidine. This substitution, when it occurs, eliminates a fail-safe trypsin self-destruction site necessary to eliminate trypsin that is prematurely activated within the acinar cell. These patients have recurring episodes of acute pancreatitis. Patients frequently develop pancreatic calcification, diabetes mellitus, and steatorrhea; in addition, they have an increased incidence of pancreatic cancer with a cumulative incidence of ~10%. A previous natural history study of hereditary pancreatitis in >200 patients from France reported that abdominal pain started in childhood at age 10 years, steatorrhea developed at age 29 years, diabetes at age 38 years, and pancreatic cancer at age 55 years. Abdominal complaints in relatives of patients with hereditary pancreatitis should raise the question of pancreatic disease.

PANCREATIC ENDOCRINE TUMORS

Pancreatic endocrine tumors are discussed in Chap. 84.

OTHER CONDITIONS

ANNULAR PANCREAS

When the ventral pancreatic anlage fails to migrate correctly to make contact with the dorsal anlage, the result may be a ring of pancreatic tissue encircling the duodenum. Such an annular pancreas may cause intestinal obstruction in the neonate or the adult. Symptoms of

postprandial fullness, epigastric pain, nausea, and vomiting may be present for years before the diagnosis is entertained. The radiographic findings are symmetric dilation of the proximal duodenum with bulging of the recesses on either side of the annular band, effacement but not destruction of the duodenal mucosa, accentuation of the findings in the right anterior oblique position, and lack of change on repeated examinations. The differential diagnosis should include duodenal webs, tumors of the pancreas or duodenum, duodenal ulcer, regional enteritis, and adhesions. Patients with annular pancreas have an increased incidence of pancreatitis and peptic ulcer. Because of these and other potential complications, the treatment is surgical even if the condition has been present for years. Retrocolic duodenojejunostomy is the procedure of choice, although some surgeons advocate Billroth II gastrectomy, gastroenterostomy, and vagotomy.

PANCREAS DIVISUM

Pancreas divisum is present in 7–10% of the population and occurs when the embryologic ventral and dorsal pancreatic anlagen fail to fuse, so that pancreatic drainage is accomplished mainly through the accessory minor papilla. Pancreas divisum is the most common congenital anatomic variant of the human pancreas. Current evidence indicates that this anomaly does not predispose to the development of pancreatitis in the majority of patients who harbor it. However, the combination of pancreas divisum and a small accessory orifice could result in dorsal duct obstruction. The challenge is to identify this subset of patients with dorsal duct pathology. Cannulation of the dorsal duct by ERCP is technically challenging and associated with a very high risk of post-ERCP pancreatitis, so patients with pancreatitis and pancreas divisum should likely be treated with conservative measures. In many of these patients, pancreatitis is idiopathic and unrelated to the pancreas divisum. Endoscopic or surgical intervention is indicated only if pancreatitis recurs and no other cause can be found. It should be stressed that the ERCP/MRCP appearance of pancreas divisum (i.e., a small-caliber ventral duct with an arborizing pattern) may be mistaken as representing an obstructed main pancreatic duct secondary to a mass lesion.

MACROAMYLASEMIA

In macroamylasemia, amylase circulates in the blood in a polymer form too large to be easily excreted by the kidney. Patients with this condition demonstrate an elevated serum amylase value and a low urinary amylase value. The presence of macroamylase can be documented by chromatography of the serum. The prevalence of macroamylasemia is 1.5% of the nonalcoholic general adult hospital population. Usually, macroamylasemia is an incidental finding and is not related to disease of the pancreas or other organs. Macrolipasemia has now been documented in patients with cirrhosis or non-Hodgkin's lymphoma. In these patients, the pancreas appeared normal on ultrasound and CT examination. Lipase was shown to be complexed with immunoglobulin A. Thus, the possibility of *both* macroamylasemia and macrolipasemia should be considered in patients with elevated blood levels of these enzymes.

Acknowledgment

This chapter represents a revised version of chapters by Drs. Norton J. Greenberger (deceased), Phillip P. Toskes (deceased), Peter A. Banks, and Bechien Wu that were in previous editions of Harrison's.

Section 1 The Immune System in Health and Disease

349 Introduction to the Immune System

Barton F. Haynes, Kelly A. Soderberg, Anthony S. Fauci

DEFINITIONS

- *Adaptive immune system*—recently evolved system of immune responses mediated by T and B lymphocytes. Immune responses by these cells are based on specific antigen recognition by clonotypic receptors that are products of genes that rearrange during development and throughout the life of the organism. Additional cells of the adaptive immune system include various types of antigen-presenting cells (APCs).
- *Antibody*—B cell–produced molecules encoded by genes that rearrange during B-cell development consisting of immunoglobulin heavy and light chains that together form the central component of the B-cell receptor (BCR) for antigen. Antibody can exist as B cell–surface antigen-recognition molecules or as secreted molecules in plasma and other body fluids.
- *Antigens*—foreign or self-molecules that are recognized by the adaptive and innate immune systems resulting in immune cell triggering, T-cell activation, and/or B-cell antibody production.
- *Antimicrobial peptides*—small peptides <100 amino acids in length that are produced by cells of the innate immune system and have anti-infectious agent activity.
- *Apoptosis*—the process of *programmed cell death* whereby signaling through various "death receptors" on the surface of cells (e.g., tumor necrosis factor [TNF] receptors, CD95) leads to a signaling cascade that involves activation of the caspase family of molecules and leads to DNA cleavage and cell death. Apoptosis, which does not lead to induction of inordinate inflammation, is to be contrasted with *cell necrosis*, which does lead to induction of inflammatory responses.
- *Autoimmune diseases*—diseases such as systemic lupus erythematosus and rheumatoid arthritis in which cells of the adaptive immune system such as autoreactive T and B cells become overreactive and produce self-reactive T-cell and antibody responses.
- *Autoinflammatory diseases*—hereditary disorders such as hereditary periodic fevers (HPFs) characterized by recurrent episodes of severe inflammation and fever due to mutations in controls of the innate inflammatory response, i.e., the inflammasome (see below and Table 349-5). Patients with HPFs also have rashes, serosal and joint inflammation, and some can have neurologic symptoms. Autoinflammatory diseases are different from autoimmune diseases in that evidence for activation of adaptive immune cells such as autoreactive B cells is not present.
- *Autophagy*—lysosomal degradation pathway mechanism of cells to dispose of intracellular debris and damaged organelles. Autophagy by cells of the innate immune system is used to control intracellular infectious agents such as mycobacteria, in part by initiation of phagosome maturation and enhancing major histocompatibility complex (MHC) class II antigen presentation to CD4 T cells.
- *B-cell receptor for antigen*—complex of surface molecules that rearrange during postnatal B-cell development, made up of surface immunoglobulin (Ig) and associated Ig αβ chain molecules that recognize nominal antigen via Ig heavy- and light-chain variable regions, and signal the B cell to terminally differentiate to make antigen-specific antibody.
- *B lymphocytes*—bone marrow–derived or bursal-equivalent lymphocytes that express surface immunoglobulin (the BCR for antigen) and secrete specific antibody after interaction with antigen.
- *B regulatory cells*—a population of suppressive B cells that aid in the inhibition of inflammation through the release of cytokines such as interleukin (IL) 10.
- *CD classification of human lymphocyte differentiation antigens*—the development of monoclonal antibody technology led to the discovery of a large number of new leukocyte surface molecules. In 1982, the First International Workshop on Leukocyte Differentiation Antigens was held to establish a nomenclature for cell-surface molecules of human leukocytes. From this and subsequent leukocyte differentiation workshops has come the *cluster of differentiation* (CD) classification of leukocyte antigens.
- *CD4 T cell*—T lymphocyte subset that participates in adaptive immunity and helps B cells make antibody.
- *CD8 T cell*—cytotoxic T lymphocyte subset that destroys tumor cells and cells infected with pathogens.
- *Chemokines*—soluble molecules that direct and determine immune cell movement and circulation pathways.
- *Complement*—cascading series of plasma enzymes and effector proteins that function to lyse pathogens and/or target them to be phagocytized by neutrophils and monocyte/macrophage lineage cells of the reticuloendothelial system.
- *Co-stimulatory molecules*—molecules of APCs (such as B7-1 and B7-2 or CD40) that lead to T-cell activation when bound by ligands on activated T cells (such as CD28 or CD40 ligand).
- *Crystallopathies*—nanoparticle- or microparticle-sized deposits of crystals, misfolded proteins, or airborne particulate matter that can stimulate the inflammasome and initiate inflammation and tissue damage.
- *Cytokines*—soluble proteins that interact with specific cellular receptors that are involved in the regulation of the growth and activation of immune cells and mediate normal or pathologic inflammatory and immune responses.
- *Dendritic cells*—myeloid and/or lymphoid lineage APCs of the adaptive immune system. Immature dendritic cells (DCs), or DC precursors, are key components of the innate immune system by responding to infections with production of high levels of cytokines. DCs are key initiators both of innate immune responses via cytokine production and of adaptive immune responses via presentation of antigen to T lymphocytes.
- *Ig Fc receptors*—receptors found on the surface of certain cells including B cells, natural killer (NK) cells, macrophages, neutrophils, and mast cells. Fc receptors bind to antibodies that have attached to invading pathogen-infected cells. They stimulate cytotoxic cells to destroy microbe-infected cells through a mechanism known as antibody-dependent cell-mediated cytotoxicity (ADCC). Examples of important Fc receptors include CD16 (FcγRIIIa), CD23 (FcεR), CD32 (FcγRII), CD64 (FcγRI), and CD89 (FcαR).
- *Inflammasome*—large cytoplasmic complexes of intracellular proteins that link the sensing of microbial products and cellular stress to the proteolytic activation of IL-1β and IL-18 inflammatory cytokines. Activation of molecules in the inflammasome is a key step in the response of the innate immune system for intracellular recognition of microbial and other danger signals in both health and pathologic states.
- *Innate immune system*—ancient immune recognition system of host cells bearing germline-encoded pattern recognition receptors (PRRs) that recognize pathogens and trigger a variety of mechanisms of pathogen elimination. Cells of the innate immune system include NK cell lymphocytes, monocytes/macrophages, DCs, neutrophils, basophils, eosinophils, tissue mast cells, and epithelial cells.

- *Innate lymphoid cells (ILCs)*—lymphocytes that do not express the type of diversified antigen receptors on T cell and B cells. ILC1s, ILC2s, and ILC3s are tissue resident cells and functionally are analogous to CD4 T_H1, T_H2, and T_H17 cells, respectively.
- *Natural killer (NK) cells*—a type of ILC that kills target cells expressing few or no human leukocyte antigen (HLA) class I molecules, such as malignantly transformed cells and virally infected cells. NK cells express receptors that inhibit killer cell function when self-MHC class I is present. Innate NK cells mirror the functions of CD8 cytotoxic T cells of the adaptive immune system.
- *NK T cells*—innate-like lymphocytes that use an invariant T-cell receptor (TCR)-α chain combined with a limited set of TCR-β chains and coexpress receptors commonly found on NK cells. NK T cells recognize lipid antigens of bacterial, viral, fungal, and protozoal infectious agents.
- *Pathogen-associated molecular patterns (PAMPs)*—invariant molecular structures expressed by large groups of microorganisms that are recognized by host cellular PRRs in the mediation of innate immunity.
- *Pattern recognition receptors (PRR)*—germline-encoded receptors expressed by cells of the innate immune system that recognize PAMPs.
- *Polyreactive antibodies*—low-affinity antibodies produced by B cells that cross-react with multiple antigens and are available at the time of infection to bind and coat invading pathogens and harness innate responses to slow the infection until an adaptive high-affinity protective antibody response can be made.
- *T lymphocytes*—thymus-derived lymphocytes that mediate adaptive cellular immune responses including T helper, T regulatory, and cytotoxic T lymphocyte effector cell functions.
- *T-cell exhaustion*—state of T cells when the persistence of antigen disrupts memory T-cell function, resulting in defects in memory T-cell responses. Most frequently occurs in malignancies and in chronic viral infections such as HIV-1 and hepatitis C.
- *TCR for antigen*—complex of surface molecules that rearrange during postnatal T-cell development made up of clonotypic TCR-α and -β chains that are associated with the CD3 complex composed of invariant γ, δ, ε, ζ, and η chains. TCR-α and -β chains recognize peptide fragments of protein antigen physically bound in APC MHC class I or II molecules, leading to signaling via the CD3 complex to mediate effector functions.
- *T follicular helper T cells (Tfh)*—CD4 T cells regulated by bcl-6 in B-cell follicle germinal centers that produce IL-4 and IL-21 and drive B-cell differentiation and affinity maturation in peripheral lymphoid tissues such as lymph node and spleen.
- *T_H1 T cells*—CD4 helper T-cell subset regulated by transcription factor T-bet that produces interferon (IFN)-γ, IL-2, and TNF-β and participates in cell-mediated immunity.
- *T_H2 T cells*—CD4 helper T-cell subset regulated by transcription factors STAT6 and GATA3 that produces IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 and regulates antibody and eosinophil responses.
- *T regulatory cells (Treg)*—CD4 and CD8 T cells regulated by the transcription factor Foxp3 that play roles in modulating the immune system to prevent deleterious immune activation. Expression of Foxp3 is a defining Treg marker.
- *T_H9 T cells*—CD4 T cells regulated by the transcription factor PU.1 that secrete IL-9 and enhance inflammation in atopic disease and inflammatory bowel disease as well as mediate antitumor immunity.
- *T_H13 T cells*—T follicular helper cells (Tfh) regulated by the GATA3 transcription factor that produce IL-4, IL-5, and IL-13. T_H13 Tfh induce high-affinity IgE antibody responses that cause anaphylactic reactions to allergens.
- *T_H17 T cells*—CD4 T cells regulated by the transcription factor RORγt that secrete IL-17, IL-22, and IL-26 and play roles in autoimmune inflammatory disorders as well as defend against bacterial and fungal pathogens.
- *Tolerance*—B- and T-cell nonresponsiveness to antigens that results from encounter with foreign or self-antigens by B and T lymphocytes in the absence of expression of APC co-stimulatory molecules. Tolerance to antigens may be induced and maintained by multiple mechanisms either centrally (B-cell deletion in the thymus for T cells or bone marrow for B cells) or peripherally (by cell deletion or anergy at sites throughout the peripheral immune system).
- *Trained immunity*—the epigenetic, transcriptional, and functional reprogramming of innate immune cells to adapt to previous encounters with pathogens and respond to a second challenge in an altered manner.

INTRODUCTION

The human immune system has evolved over millions of years from both invertebrate and vertebrate organisms to develop sophisticated defense mechanisms that protect the host from microbes and their virulence factors. The normal immune system has three key properties: a highly diverse repertoire of antigen receptors that enables recognition of a nearly infinite range of pathogens; immune memory, to mount rapid recall immune responses; and immunologic tolerance, to avoid immune damage to normal self-tissues. From invertebrates, humans have inherited the *innate immune system*, an ancient defense system that uses germline-encoded proteins to recognize pathogens. Cells of the innate immune system, such as macrophages, DCs, and NK lymphocytes, recognize PAMPs that are highly conserved among many microbes and use a diverse set of PRR molecules. Important components of the recognition of microbes by the innate immune system include recognition by germline-encoded host molecules, recognition of key microbe virulence factors but not recognition of self-molecules, and nonrecognition of benign foreign molecules or microbes. Upon contact with pathogens, cells of the innate immune system may kill pathogens directly or, in concert with DCs, activate a series of events that both slow the infection and recruit the more recently evolved arm of the human immune system, the *adaptive immune system*. In addition, innate immune cells undergo epigenetic, transcriptional, and functional changes that allow adapted (either enhanced or reduced) innate cell responses to repeat encounters with pathogens, called *trained immunity*.

Adaptive immunity is found only in vertebrates and is based on the generation of antigen receptors on T and B lymphocytes by gene rearrangements, such that individual T or B cells express unique antigen receptors on their surface capable of specifically recognizing diverse antigens of infectious agents in the environment. Coupled with specific recognition mechanisms that maintain tolerance (nonreactivity) to self-antigens **(Chap. 350)**, T and B lymphocytes bring both *specificity* and *immune memory* to vertebrate host defenses.

This chapter describes the cellular components, key molecules **(Table 349-1)**, and mechanisms that make up the innate and adaptive immune systems and describes how adaptive immunity is recruited to the defense of the host by innate immune responses. An appreciation of the cellular and molecular bases of innate and adaptive immune responses is critical to understanding the pathogenesis of inflammatory, autoimmune, infectious, and immunodeficiency diseases, as well as a wide range of diseases associated with inflammation such as atherosclerotic cardiovascular disease and neurodegenerative diseases.

THE INNATE IMMUNE SYSTEM

All multicellular organisms, including humans, have developed the use of surface and intracellular germline-encoded molecules that recognize pathogens. Because of the myriad of human pathogens, host molecules of the human innate immune system sense "danger signals" and either recognize PAMPs, the common molecular structures shared by many pathogens, or recognize host cell molecules produced in response to infection such as heat shock proteins and fragments of the extracellular matrix. PAMPs must be conserved structures vital to pathogen virulence and survival, such as bacterial endotoxin, so that pathogens cannot mutate molecules of PAMPs to evade human innate immune responses. PRRs are host proteins of the innate immune system that recognize PAMPs as host danger signal molecules **(Tables 349-2 and 349-3)**. Thus, recognition of pathogen molecules by hematopoietic and

TABLE 349-1 Human Leukocyte Surface Antigens—The CD Classification of Leukocyte Differentiation Antigens

SURFACE ANTIGEN (OTHER NAMES)	FAMILY	MOLECULAR MASS, kDa	DISTRIBUTION	LIGAND(S)	FUNCTION
CD1a (T6, HTA-1)	Ig	49	CD, cortical thymocytes, Langerhans type of DCs	TCRγδ T cells, NK T cells	CD1 molecules present lipid antigens of intracellular bacteria such as *Mycobacterium leprae* and *M. tuberculosis* to TCRγδT cells or NK T cells
CD1b	Ig	45	CD, cortical thymocytes, Langerhans type of DCs	TCRγδ T cells, NK T cells	
CD1c	Ig	43	DC, cortical thymocytes, subset of B cells, Langerhans type of DCs	TCRγδ T cells, NK T cells	
CD1d	Ig	37	Cortical thymocytes, intestinal epithelium, Langerhans type of DCs	TCRγδ T cells, NK T cells	
CD2 (T12, LFA-2)	Ig	50	T, NK	CD58, CD48, CD59, CD15	Alternative T-cell activation, T-cell anergy, T-cell cytokine production, T- or NK-mediated cytolysis, T-cell apoptosis, cell adhesion
CD3 (T3, Leu-4)	Ig	γ:25–28, δ:21–28, ε:20–25, η:21–22, ζ:16	T, NK T	Associates with the TCR	T-cell activation and function; ζ is the signal transduction component of the CD3 complex
CD4 (T4, Leu-3)	Ig	55	T, myeloid	MHC-II, HIV gp120, IL-16, SABP	T-cell selection, T-cell activation, signal transduction with p56/*ck*, primary receptor for HIV-1
CD7 (3A1, Leu-9)	Ig	40	T, NK	K-12 (CD7L)	T- and NK-cell signal transduction and regulation of IFN-γ, TNF-α production
CD8 (T8, Leu-2)	Ig	34	T, subset of NK	MHC-I	T-cell selection, T-cell activation, signal transduction with p56/*ck*
CD14 (LPS-receptor)	LRG	53–55	M, G (weak), not by myeloid progenitors	Endotoxin (lipopolysaccharide), lipoteichoic acid, PI	TLR4 mediates with LPS and other PAMP activation of innate immunity
CD16a (FcγRIIIa)	Ig	50–80	NK, macrophages, neutrophils	Fc portion of IgG	Mediates phagocytosis and ADCC
CD19 B4	Ig	95	B (except plasma cells), FDC	Not known	Associates with CD21 and CD81 to form a complex involved in signal transduction in B-cell development, activation, and differentiation
CD20 (B1)	Unassigned	33–37	B (except plasma cells)	Not known	Cell signaling, may be important for B-cell activation and proliferation
CD21 (B2, CR2, EBV-R, C3dR)	RCA	145	Mature B, FDC, subset of thymocytes	C3d, C3dg, iC3b, CD23, EBV	Associates with CD19 and CD81 to form a complex involved in signal transduction in B-cell development, activation, and differentiation; Epstein-Barr virus receptor
CD22 (BL-CAM)	Ig	130–140	Mature B	CDw75	Cell adhesion, signaling through association with p72*sky*, p53/56*lyn*, PI3 kinase, SHP1, fLCγ
CD23 (FcεRII, B6, Leu-20, BLAST-2)	C-type lectin	45	B, M, FDC	IgE, CD21, CD11b, CD11c	Regulates IgE synthesis, cytokine release by monocytes
CD28	Ig	44	T, plasma cells	CD80, CD86	Co-stimulatory for T-cell activation; involved in the decision between T-cell activation and anergy
CD32a (FcγRIIa)	Ig	40	NK, macrophages, neutrophils	Fc portion of IgG	Mediates phagocytosis and ADCC
CD40	TNFR	48–50	B, DC, EC, thymic epithelium, MP, cancers	CD154 (CD40L)	B-cell activation, proliferation, and differentiation; formation of GCs; isotype switching; rescue from apoptosis
CD45 (LCA, T200, B220)	PTP	180, 200, 210, 220	All leukocytes	Galectin-1, CD2, CD3, CD4	T and B activation, thymocyte development, signal transduction, apoptosis
CD45RA	PTP	210, 220	Subset T, medullary thymocytes, "naive" T	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing exon 4 (A), restricted to a subset of T cells
CD45RB	PTP	200, 210, 220	All leukocytes	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing exon 5 (B)
CD45RC	PTP	210, 220	Subset T, medullary thymocytes, "naive" T	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing exon 6 (C), restricted to a subset of T cells
CD45RO	PTP	180	Subset T, cortical thymocytes, "memory" T	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing no differentially spliced exons, restricted to a subset of T cells
CD64 (FcγRI)	Ig	45–55	Macrophages and monocytes	Fc portion of IgG	Mediates phagocytosis and ADCC
CD80 (B7-1, BB1)	Ig	60	Activated B and T, MP, DC	CD28, CD152 (CTLA-4)	Co-regulator of T-cell activation; signaling through CD28 stimulates and through CD152 inhibits T-cell activation
CD86 (B7-2, B70)	Ig	80	Subset B, DC, EC, activated T, thymic epithelium	CD28, CD152 (CTLA-4)	Co-regulator of T-cell activation; signaling through CD28 stimulates and through CD152 inhibits T-cell activation

(*Continued*)

TABLE 349-1 Human Leukocyte Surface Antigens—The CD Classification of Leukocyte Differentiation Antigens (Continued)

SURFACE ANTIGEN (OTHER NAMES)	FAMILY	MOLECULAR MASS, kDa	DISTRIBUTION	LIGAND(S)	FUNCTION
CD89 (FCαR)	Ig	55–100	Neutrophils, eosinophils, monocytes, and MP	Fc portion of IgG	Mediates phagocytosis and ADCC of IgA-coated pathogens
CD95 (APO-1, Fas)	TNFR	43	Activated T and B	Fas ligand	Mediates apoptosis
CD112 (nekton-2, PVRL2)	Ig	62	Epithelial cells, endothelial cells, other tissues	DNAM-1 (CD226), TIGIT	T-cell activation (DNAM-1), T-cell inhibition (TIGIT)
CD134 (OX40)	TNFR	48	Activated T	OX40L (CD252)	T-cell survival, cytokine stimulation
CD137 (4-1BB)	TNFR	19	Activated T, DCs, B, NK	CD137L (41BBL)	T-cell co-stimulation
CD155 (PVR)	Ig	50–65	DCs, NK, epithelial cells	TIGIT, CD96, DNAM-1	T-cell inhibition (TIGIT, CD96), T-cell activation (DNAM-1)
CD223 (LAG-3)	Ig	57	NK, B, activated T	MHC class II	T-cell inhibition
CD226 (DNAM-1)	Ig	65	NK, monocytes, T	CD112, CD155	T-cell activation (CD112), T-cell activation (CD155)
CD252 (OX40L)	TNFR	16–25	Antigen-presenting cells, endothelial cells	OX40	T-cell survival, cytokine stimulation
CD272 (BTLA)	Ig	16	Activated T	HVEM	T-cell inhibition
CD274 (PD-L1)	Ig	40	T, NK, myeloid, B, tumor cells	PD-1 (CD279)	Inhibit TCR activation
CD278 (ICOS)	Ig	55–60	Activated T	ICOSL	T-cell activation
CD357 (GTTR)	TNFR	41	Activated T, Tregs	GITRL	T-cell activation
CD152 (CTLA-4)	Ig	30–33	Activated T	CD80, CD86	Inhibits T-cell proliferation
CD154 (CD40L)	TNF	33	Activated CD4+ T, subset CD8+ T, NK, M, basophil	CD40	Co-stimulatory for T-cell activation, B-cell proliferation and differentiation
CD279 (PD-1)	Ig	50–55	B, T, Tfh	PD-L1 (CD274), PD-L2 (CD273)	Inhibits T-cell proliferation

Abbreviations: ADCC, antibody-dependent cell-mediated cytotoxicity; BTLA, band T lymphocyte attenuators; CTLA, cytotoxic T lymphocyte–associated protein; DC, dendritic cells; DNAM-1, DNAX accessory molecule-1; EBV, Epstein-Barr virus; EC, endothelial cells; ECM, extracellular matrix; FcγRIII, low-affinity IgG receptor isoform A; FDC, follicular dendritic cells; G, granulocytes; GC, germinal center; GITR, glucocorticoid-induced TNFR-related protein; GPI, glycosyl phosphatidylinositol; HTA, human thymocyte antigen; HVEM, herpesvirus entry mediator; ICOS, inducible T-cell co-stimulator; Ig, immunoglobulin; IgG, immunoglobulin G; LAG-3, lymphocyte-activation gene 3; LCA, leukocyte common antigen; LPS, lipopolysaccharide; MHC-I, major histocompatibility complex class I; MP, macrophages; Mr, relative molecular mass; NK, natural killer cells; P, platelets; PBT, peripheral blood T cells; PD-1, programmed cell death-1; PI, phosphatidylinositol; PI3K, phosphatidylinositol 3-kinase; PLC, phospholipase C; PTP, protein tyrosine phosphatase; PVR, polio virus receptor; PVRL2, polio virus receptor-related 2; RCA, regulators of complement activation; SABP, seminal actin binding protein; TCR, T-cell receptor; Tfh, T follicular helper cells; TIGIT, T cell immunoreceptor with Ig and ITIM domains; TNF, tumor necrosis factor; TNFR, tumor necrosis factor receptor.

Note: For an expanded list of cluster of differentiation (CD) human antigens, see Harrison's Online at *http://www.accessmedicine.com*; and for a full list of CD human antigens from the most recent Human Workshop on Leukocyte Differentiation Antigens (VII), D Mason, P Andre, A Bensussan, et al (eds): *Leucocyte Typing VII.* Oxford: Oxford University Press, 2002.

nonhematopoietic cell types leads to activation/production of the complement cascade, cytokines, and antimicrobial peptides as effector molecules. In addition, pathogen PAMPs as host danger signal molecules activate DCs to mature and to express molecules on the DC surface that optimize antigen presentation to respond to foreign antigens.

TABLE 349-2 Major Components of the Innate Immune System

Pattern recognition receptors (PRRs)	Toll-like receptors (TLRs), C-type lectin receptors (CLRs), retinoic acid–inducible gene (RIG)-1-like receptors (RLRs), and NOD-like receptors (NLRs)
Antimicrobial peptides	α-Defensins, β-defensins, cathelin, protegrin, granulysin, histatin, secretory leukoprotease inhibitor, and probiotics
Cells	Macrophages, dendritic cells, innate lymphoid cells (ILC1, ILC2, ILC3, NK cells, lymphoid tissue inducer [LTi] cells), mucosal-associated invariant T (MAIT) cells, NK-T cells, neutrophils, eosinophils, mast cells, basophils, and epithelial cells
Complement components	Classic and alternative complement pathway, and proteins that bind complement components
Cytokines	Autocrine, paracrine, endocrine cytokines that mediate host defense and inflammation, as well as recruit, direct, and regulate adaptive immune responses

Abbreviation: NK, natural killer.

PATTERN RECOGNITION

Major PRR families of proteins include transmembrane proteins, such as the Toll-like receptors (TLRs) and C-type lectin receptors (CLRs), and cytoplasmic proteins, such as the retinoic acid–inducible gene (RIG)-1-like receptors (RLRs) and NOD-like receptors (NLRs) (Table 349-3). A major group of PRR collagenous glycoproteins with C-type lectin domains are termed *collectins* and include the serum protein mannose-binding lectin (MBL). MBL and other collectins, as well as two other protein families—the pentraxins (such as C-reactive protein and serum amyloid P) and macrophage scavenger receptors—all have the property of opsonizing (coating) bacteria for phagocytosis by macrophages and can also activate the complement cascade to lyse bacteria. Integrins are cell-surface adhesion molecules that affect attachment between cells and the extracellular matrix and mediate signal transduction that reflects the chemical composition of the cell environment. For example, integrins signal after cells bind bacterial lipopolysaccharide (LPS) and activate phagocytic cells to ingest pathogens.

There are multiple connections between the innate and adaptive immune systems; these include (1) a plasma protein, LPS-binding protein, that binds and transfers LPS to the macrophage LPS receptor, CD14; (2) a human family of proteins called *Toll-like receptor proteins* (TLRs), some of which are associated with CD14, bind LPS, and signal epithelial cells, DCs, and macrophages to produce cytokines and upregulate cell-surface molecules that signal the initiation of adaptive immune responses (**Fig. 349-1**, Table 349-3; and (3) families of intracellular microbial sensors called NLRs and RLRs. Proteins in the Toll family can be expressed on macrophages, DCs, and

TABLE 349-3 Pattern Recognition Receptors (PRRs) and Their Ligands

PRRs	LOCALIZATION	LIGAND	ORIGIN OF THE LIGAND
TLR			
TLR1	Plasma membrane	Triacyl lipoprotein	Bacteria
TLR2	Plasma membrane	Lipoprotein	Bacteria, viruses, parasite, self
TLR3	Endolysosome	dsRNA	Virus
TLR4	Plasma membrane	LPS	Bacteria, viruses, self
TLR5	Plasma membrane	Flagellin	Bacteria
TLR6	Plasma membrane	Diacyl lipoprotein	Bacteria, viruses
TLR7 (human TLR8)	Endolysosome	ssRNA	Virus, bacteria, self
TLR9	Endolysosome	CpG-DNA	Virus, bacteria, protozoa, self
TLR10	Endolysosome	Unknown	Unknown
TLR11	Plasma membrane	Profilin-like molecule	Protozoa
RLR			
RIG-I	Cytoplasm	Short dsRNA, triphosphate dsRNA	RNA viruses, DNA virus
MDA5	Cytoplasm	Long dsRNA	RNA viruses (Picornaviridae)
LGP2	Cytoplasm	Unknown	RNA viruses
NLR			
NOD1	Cytoplasm	iE-DAP	Bacteria
NOD2	Cytoplasm	MDP	Bacteria
CLR			
Dectin-1	Plasma membrane	β^2-Glucan	Fungi
Dectin-2	Plasma membrane	β^2-Glucan	Fungi
MINCLE	Plasma membrane	SAP130	Self, fungi

Abbreviations: CLR, C-type lectin receptors; dsRNA, double-strand RNA; iE-DAP, D-glutamyl-meso-diaminopimelic acid moiety; LGP2, Laboratory of Genetics and Physiology 2 protein encoded by the gene *DHX58*; MDA5, melanoma differentiation-associated protein 5; MDP, MurNAc-L-Ala-D-isoGln, also known as muramyl dipeptide; MINCLE, macrophage-inducible C-type lectin; NLR, NOD-like receptor; NOD, NOTCH protein domain; RIG, retinoic acid–inducible gene; RLR, RIG-like receptors; SAP130, Sin-3 associated protein 130; TLR, Toll-like receptor.

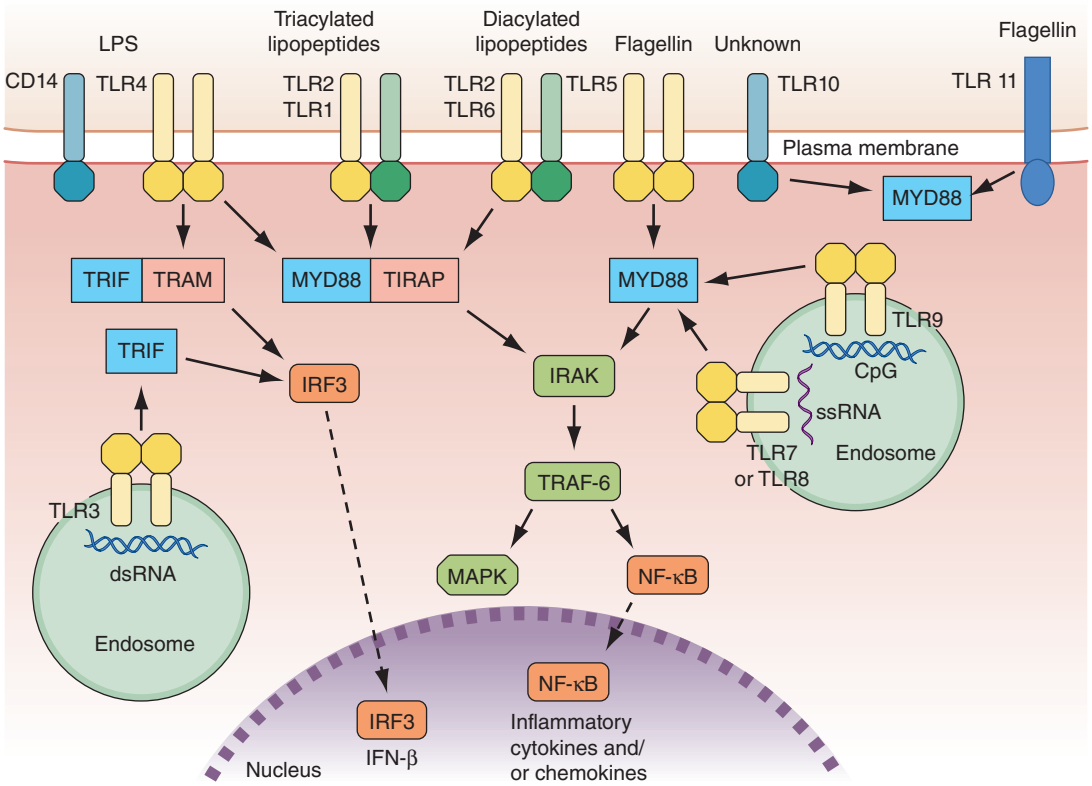

FIGURE 349-1 Overview of major TLR signaling pathways. All TLRs signal through MYD88, with the exception of TLR3. TLR4 and the TLR2 subfamily (TLR1, TLR2, TLR6) also engage TIRAP (Toll-interleukin 1 receptor domain-containing adapter protein). TLR3 signals through TRIF (Toll-interleukin 1 receptor domain-containing adapter-inducing interferon-β). TRIF is also used in conjunction with TRAM (TRIF-related adaptor molecule) in the TLR4-MYD88-independent pathway. *Dashed arrows* indicate translocation into the nucleus. dsRNA, double-strand RNA; IFN, interferon; IRF3, interferon regulatory factor 3; LPS, lipopolysaccharide; MAPK, mitogen-activated protein kinases; NF-κB, nuclear factor-κB; ssRNA, single-strand RNA; TLR, Toll-like receptor. *(Reproduced with permission from D Van Duin et al: Triggering TLR signaling in vaccination. Trends Immunol 27:49, 2006.)*

B cells as well as on a variety of non-hematopoietic cell types, including respiratory epithelial cells. Eleven TLRs have been identified in humans (Table 349-3). Upon ligation, TLRs activate a series of intracellular events that lead to the killing of bacteria- and viral-infected cells as well as to the recruitment and ultimate activation of antigen-specific T and B lymphocytes (Fig. 349-1). Importantly, signaling by massive amounts of LPS through TLR4 leads to the release of high levels of cytokines that mediate LPS-induced shock. Mutations in TLR4 proteins in mice protect from LPS shock, and TLR mutations in humans protect from LPS-induced inflammatory diseases such as LPS-induced asthma.

Two other families of cytoplasmic PRRs are the NLRs and the RLRs. These families, unlike the TLRs, are composed primarily of soluble intracellular proteins that scan host cell cytoplasm for intracellular pathogens (Tables 349-2 and 349-3).

The intracellular microbial sensors, NLRs, after triggering, form large cytoplasmic complexes termed *inflammasomes*, which are aggregates of molecules including NOD-like receptor pyrin (NLRP) proteins **(Table 349-4)**. Inflammasomes activate inflammatory caspases and IL-1β in the presence of nonbacterial danger signals (cell stress) and bacterial PAMPs. Mutations in inflammasome proteins can lead to chronic inflammation in a group of periodic febrile diseases called *autoinflammatory syndromes*. Polymorphisms in inflammasome components can either protect or enhance risk of infections or autoimmune/autoinflammatory diseases (Table 349-4). Inflammasomes are activated upon sensing of PAMPs. Crystallopathies are diseases caused by tissue crystal deposition such as monosodium urate that can activate the inflammasome and, in the case of urate deposition, can lead to gout with arthritis or renal disease.

EFFECTOR CELLS OF INNATE IMMUNITY

Cells of the innate immune system and their roles in the first line of host defense are listed in Table 349-5. Equally important as their roles in the mediation of innate immune responses are the roles that each cell type plays in recruiting T and B lymphocytes of the adaptive immune system to engage in specific pathogen responses.

Monocytes-Macrophages Monocytes arise from precursor cells within bone marrow **(Fig. 349-2)** and circulate with a half-life ranging from 1 to 3 days. Monocytes leave the peripheral circulation via capillaries and migration into a vast extravascular cellular pool. Tissue macrophages arise from monocytes that have migrated out of the circulation and by in situ proliferation of macrophage precursors in tissue. Common locations where tissue macrophages (and certain of their specialized forms) are found are lymph node, spleen, bone marrow, perivascular connective tissue, serous cavities such as the peritoneum, pleura, skin connective tissue, lung (alveolar macrophages), liver (Kupffer cells), bone (osteoclasts), central nervous system (microglia cells), and synovium (type A lining cells).

In general, monocytes-macrophages are on the first line of defense associated with innate immunity and ingest and destroy microorganisms through the release of toxic products such as hydrogen peroxide (H_2O_2) and nitric oxide (NO). Inflammatory mediators produced by macrophages attract additional effector cells such as neutrophils to the site of infection. Macrophage mediators include prostaglandins; leukotrienes; platelet activating factor; cytokines such as IL-1, TNF-α, IL-6, and IL-12; and chemokines **(Tables 349-6 and 349-7)**.

Although monocytes-macrophages were originally thought to be the major APCs of the immune system, it is now clear that cell types called *dendritic cells* are the most potent and effective APCs in the body (see below). Monocytes-macrophages mediate innate immune effector functions such as destruction of antibody-coated bacteria, tumor cells, or even normal hematopoietic cells in certain types of autoimmune cytopenias. Monocytes-macrophages ingest bacteria or are infected by viruses, and in doing so, they frequently undergo programmed cell death or *apoptosis*. Macrophages that are infected by intracellular infectious agents are recognized by DCs as infected and apoptotic cells and are phagocytosed by DCs. In this manner, DCs "cross-present" infectious agent antigens of macrophages to T cells. Activated macrophages can also mediate antigen-nonspecific lytic activity and eliminate cell types such as tumor cells in the absence of antibody. This activity is largely mediated by cytokines (i.e., TNF-α and IL-1). Monocytes-macrophages express lineage-specific molecules (e.g., the cell-surface LPS receptor, CD14) as well as surface receptors for a number of molecules, including the Fc region of IgG, activated complement components, and various cytokines (Table 349-6).

Dendritic Cells Human DCs contain several subsets, including myeloid DCs and plasmacytoid DCs. Myeloid DCs can differentiate into either macrophages-monocytes or tissue-specific DCs. In contrast to myeloid DCs, plasmacytoid DCs are inefficient APCs but are potent producers of type I IFN (e.g., IFN-α) in response to viral infections. The maturation of DCs is regulated through cell-to-cell contact and soluble factors, and DCs attract immune effectors through secretion of chemokines. When DCs come in contact with bacterial products, viral proteins, or host proteins released as danger signals from distressed host cells (Fig. 349-2), infectious agent molecules bind to various TLRs and activate DCs to release cytokines and chemokines that drive cells of the innate immune system to become activated to respond to invading organisms, and recruit T and B cells of the adaptive immune system to respond. Plasmacytoid DCs produce antiviral IFN-α that activates NK cell killing of pathogen-infected cells; IFN-α also activates T cells to mature into antipathogen cytotoxic (killer) T cells. Following contact with pathogens, both plasmacytoid and myeloid DCs produce chemokines that attract helper and cytotoxic T cells, B cells, polymorphonuclear cells, and naïve and memory T cells as well as regulatory T cells to ultimately dampen the immune response once the pathogen is controlled. TLR engagement on DCs upregulates MHC class II, B7-1 (CD80), and B7-2 (CD86), which enhance DC-specific antigen presentation and induce cytokine production. Thus, DCs are important bridges between early (innate) and later (adaptive) immunity. DCs also modulate and determine the types of immune responses induced by pathogens via the TLRs expressed on DCs (TLR7–9 on plasmacytoid DCs, TLR4 on monocytoid DCs) and via the TLR adapter proteins that are induced to associate with TLRs (Fig. 349-1, Table 349-1). In addition, other PRRs, such as C-type lectins, NLRs, and mannose receptors, upon ligation by pathogen products, activate cells of the adaptive immune system and, like TLR stimulation, by a variety of factors, determine the type and quality of the adaptive immune response that is triggered.

Innate Lymphoid Cells ILCs are comprised of ILC1, ILC2, ILC3, lymphoid tissue inducer (LTi), and NK cells. ILC1, ILC2, ILC3, and LTi are primarily tissue resident cells. ILCs develop from a common lymphoid precursor in the bone marrow and then differentiate into one of five ILC types—ILC1, ILC2, ILC3, LTi, or NK cells—based on their development **(Fig. 349-3*A*)** and function **(Fig. 349-3*B*)**. NK cells and ILC1s depend on T-bet transcription factor for their development and function and produce IFN-γ. NK cells are innate analogues to CD8 cytotoxic T cells in that they both mediate granzyme and perforin-based cytotoxic cell activity. ILC1s mirror CD4 T_H1 lymphocytes and react to intracellular pathogens such as viruses and to tumors. ILC2s are the analogues of T_H2 CD4 T cells and are dependent on GATA3 and RORα factors and produce type 2 cytokines, such as IL-5 and IL-13. ILC2s respond to extracellular parasites and allergens. ILC3s and LTi cells are dependent on transcription factor RORγ1 and produce IL-17. ILC3s are analogues of CD4 T_H17 lymphocytes and attack extracellular pathogens such as bacteria and fungi. LTi cells are critical for the formation of lymph nodes and Peyer's patches in gut during fetal development (Fig. 349-3*B*).

NK cells express surface receptors for the Fc portion of IgG (FcR) (CD16) and for NCAM-I (CD56), and many NK cells express T lineage markers, particularly CD2, CD7, and CD8, and proliferate in response to IL-2. NK cells arise in both bone marrow and thymic microenvironments. In addition to mediating cytotoxicity to foreign or malignant cells, NK cells also mediate ADCC. ADCC is the binding of an opsonized (antibody-coated) target cell to an Fc receptor-bearing effector cell via the Fc region of antibody, resulting in target cell lysis. NK cell cytotoxicity is the MHC-unrestricted, non-antibody-mediated

TABLE 349-4 Mutations in Innate Inflammasome Molecules Associated with Clinical Disease

Inherited Inflammasomopathies

MUTATED GENE	DISEASE	INHERITED PATTERN AND EFFECT	PHENOTYPE	PREDOMINANT EFFECTOR CELLS
NLRP1	NLRP1-associated autoinflammation with arthritis and dyskeratosis	Autosomal dominant GoF	Hyperkeratotic ulcerative skin lesions, fever, arthritis, ANA	Keratinocytes
NLRP3	Cryopyrin-associated periodic syndromes (CAPS)	Autosomal dominant GoF	Spectrum from cold-induced urticaria and fever to CNS inflammation and bone overgrowth	Monocytes, granulocytes (neutrophils), chondrocytes
NLRC4	Autoinflammatory infantile fever with enterocolitis (AIFEC)	Autosomal dominant GoF	Recurrent MAS, enterocolitis, cold-induced fever and urticaria, CNS inflammation	Monocytes/macrophages
MEFV	Familial Mediterranean fever (FMF)	Autosomal recessive LoF or gene-dosage-dependent autosomal dominant GoF	Fever, serositis, rash, SAA amyloidosis	Neutrophils, monocytes, serosal and synovial fibroblasts

Note: Mutated gene and respective syndrome name are reported for inflammasomopathies, as well as inheritance pattern and effect of mutations, clinical phenotype, and predominant disease effector cells. Inflammasome variants previously associated with infectious agents and/or diseases are briefly resumed from literature (*https://www.ncbi.nlm.nih.gov/pubmed*). Significantly associated polymorphisms were grouped according to the infectious agent/disease. Infectious agent or disease (in alphabetical order), gene name (gene), identification number of polymorphism (ID), resulting effect on inflammasome activation ("increased," "decreased," or "unknown"), cohort origin (cohort) and eventually specifications (severity, etc.), sample size (n), and type (case/control or cases only), association result ("risk" or "protection"), and respective reference are reported.

Abbreviations: ANA, antinuclear antibodies; CNS, central nervous system; GoF, gain-of-function; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; HS, Henoch-Schönlein; HSV, herpes simplex virus; HTLV, human T-lymphotropic virus; IBD, inflammatory bowel disease; JIA, juvenile idiopathic arthritis; LoF, loss-of-function; MAS, macrophage activation syndrome; PFAPA, periodic fever with aphthous stomatitis, pharyngitis, and cervical adenitis; SAA, serum amyloid A; SLE, systemic lupus erythematosus.

killing of target cells, which are usually malignant cell types, transplanted foreign cells, or virus-infected cells. Thus, NK cell cytotoxicity may play an important role in immune surveillance and destruction of malignant and virus-infected host cells. NK cell hyporesponsiveness is also observed in patients with *Chédiak-Higashi syndrome*, an autosomal recessive disease associated with fusion of cytoplasmic granules and defective degranulation of neutrophil lysosomes.

NK cells have a variety of surface receptors that have inhibitory or activating functions and belong to two structural families. These families include the immunoglobulin superfamily and the lectin-like type II transmembrane proteins. NK immunoglobulin superfamily receptors include the killer cell immunoglobulin-like activating or inhibitory receptors (KIRs), many of which have been shown to have HLA class I ligands. The KIRs are made up proteins with either two (KIR2D) or three (KIR3D) extracellular immunoglobulin domains (D). Moreover, their nomenclature designates their function as either inhibitory KIRs with a long (L) cytoplasmic tail and immunoreceptor tyrosine-based inhibitory motif (ITIM) (KIRDL) or activating KIRs with a short (S) cytoplasmic tail (KIRDS). NK cell inactivation by KIRs is a central mechanism to prevent damage to normal host cells. Genetic studies have demonstrated the association of KIRs with viral infection outcome and autoimmune disease **(Table 349-8)**.

In addition to the KIRs, a second set of immunoglobulin superfamily receptors includes the natural cytotoxicity receptors (NCRs), which

TABLE 349-5 Cells of the Innate Immune System and Their Major Roles in Triggering Adaptive Immunity

CELL TYPE	MAJOR ROLE IN INNATE IMMUNITY	MAJOR ROLE IN ADAPTIVE IMMUNITY
Macrophages	Phagocytose and kill bacteria; produce antimicrobial peptides; bind LPS; produce inflammatory cytokines	Produce IL-1 and TNF-α to upregulate lymphocyte adhesion molecules and chemokines to attract antigen-specific lymphocyte. Produce IL-12 to recruit T_H1 T helper cell responses; upregulate co-stimulatory and MHC molecules to facilitate T and B lymphocyte recognition and activation. Macrophages and dendritic cells, after LPS signaling, upregulate co-stimulatory molecules B7-1 (CD80) and B7-2 (CD86) that are required for activation of pathogen-specific T cells. There are also Toll-like proteins on B cells and dendritic cells that, after LPS ligation, induce CD80 and CD86 on these cells for T-cell antigen presentation.
Plasmacytoid dendritic cells (DCs) of lymphoid lineage	Produce large amounts of interferon-α (IFN-α), which has antitumor and antiviral activity, and are found in T-cell zones of lymphoid organs; they circulate in blood	IFN-α is a potent activator of macrophage and mature DCs to phagocytose invading pathogens and present pathogen antigens to T and B cells.
Myeloid DCs are of two types: interstitial and Langerhans-derived	Interstitial DCs are strong producers of IL-12 and IL-10 and are located in T-cell zones of lymphoid organs, circulate in blood, and are present in the interstices of the lung, heart, and kidney; Langerhans DCs are strong producers of IL-12; are located in T-cell zones of lymph nodes, skin epithelia, and the thymic medulla; and circulate in blood	Interstitial DCs are potent activators of macrophage and mature DCs to phagocytose invading pathogens and present pathogen antigens to T and B cells.
ILC1 cells	Weakly cytotoxic, dependent on T-bet transcription factor, first line of defense against viruses and bacteria	Produce IFN-γ to recruit CD4 T_H1 T cells
ILC2 cells	Mediate innate responses to parasites/helminths, repair damaged tissues by producing amphiregulin	Produce IL-4, IL-5, IL-13; recruit CD4 T_H2 T cells
ILC3 cells	Innate immune response to extracellular bacteria and gut microbiome	Produce IL-22, IL-17, GM-CSF, lymphotoxin; recruit CD4 T_H17 T cells
Lymphoid tissue inducer (LTi) cells	Critical for formation of secondary lymphoid tissue during embryogenesis	Produce lymphotoxin for lymph node and Peyer's patch development in which adaptive immune responses occur
Natural killer (NK) cells	Kill foreign and host cells that have low levels of MHC+ self-peptides. Express NK receptors that inhibit NK function in the presence of high expression of self-MHC.	Produce TNF-α and IFN-γ, which recruit T_H1 helper T-cell responses
NK-T cells	Lymphocytes with both T-cell and NK surface markers that recognize lipid antigens of intracellular bacteria such as *Mycobacterium tuberculosis* by CD1 molecules and kill host cells infected with intracellular bacteria	Produce IL-4 to recruit T_H2 helper T-cell responses, IgG1 and IgE production
Neutrophils	Phagocytose and kill bacteria, produce antimicrobial peptides	Produce nitric oxide synthase and nitric oxide, which inhibit apoptosis in lymphocytes and can prolong adaptive immune responses
Eosinophils	Kill invading parasites	Produce IL-5, which recruits Ig-specific antibody responses
Mast cells and basophils	Release TNF-α, IL-6, and IFN-γ in response to a variety of bacterial PAMPs	Produce IL-4, which recruits T_H2 helper T cell responses, and recruit IgG1- and IgE-specific antibody responses
Epithelial cells	Produce antimicrobial peptides; tissue-specific epithelia produce mediator of local innate immunity; e.g., lung epithelial cells produce surfactant proteins (proteins within the collectin family) that bind and promote clearance of lung-invading microbes	Produces TGF-β, which triggers IgA-specific antibody responses

Abbreviations: GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-4, IL-5, IL-6, IL-10, and IL-12, interleukin 4, 5, 6, 10, and 12, respectively; ILC, innate lymphoid cell; MHC, major histocompatibility complex: LPS, lipopolysaccharide; PAMP, pathogen-associated molecular patterns; TGF, transforming growth factor; T_H, helper T cell; TNF-α, tumor necrosis factor-alpha.

include NKp46, NKp30, and NKp44. These receptors help to mediate NK cell activation against target cells. The ligands to which NCRs bind on target cells have been recently recognized to be comprised of molecules of pathogens such as influenza, cytomegalovirus, and malaria as well as host molecules expressed on tumor cells.

NK cell signaling is, therefore, a highly coordinated series of inhibiting and activating signals that prevent NK cells from responding to uninfected, nonmalignant self-cells; however, they are activated to attack malignant and virally infected cells **(Fig. 349-4)**. Recent evidence suggests that NK cells, although not possessing rearranging immune recognition genes, may be able to mediate recall for NK cell responses to viruses and for immune responses such as contact hypersensitivity.

Some NK cells express CD3 and invariant TCR-α chains and are termed *NK T cells*. TCRs of NK T cells recognize lipid molecules of intracellular bacteria when presented in the context of CD1 molecules on APCs. Upon activation, NK T cells secrete effector cytokines such as IL-4 and IFN-γ. This mode of recognition of intracellular bacteria such as *Listeria monocytogenes* and *Mycobacterium tuberculosis* by NK T cells leads to induction of activation of DCs and is thought to be an important innate defense mechanism against these organisms.

The receptors for the Fc portion of IgG (FcγRs) are present on NK cells, B cells, macrophages, neutrophils, and mast cells and mediate interactions of IgG with antibody-coated target cells, such as virally infected cells. Antibody-NK interaction via antibody Fc and NK cell FcR links the adaptive and innate immune systems and regulates the mediation of IgG antibody effector functions such as ADCC. There are both activation and inhibitory FcγRs. Activation FcRs, such as FcγRI (CD64), FcγRIIa (CD32a), and FcγRIIIa (CD16a), are characterized by the presence of an immunoreceptor tyrosine-based activating motif (ITAM) sequence, whereas inhibitory FcRs, such as FcγRIIb (CD32b), contain an ITIM sequence. There is evidence that dysregulation in IgG-FcγR interactions plays roles in arthritis, multiple sclerosis, and systemic lupus erythematosus.

Neutrophils, Eosinophils, and Basophils Granulocytes are present in nearly all forms of inflammation and are amplifiers and

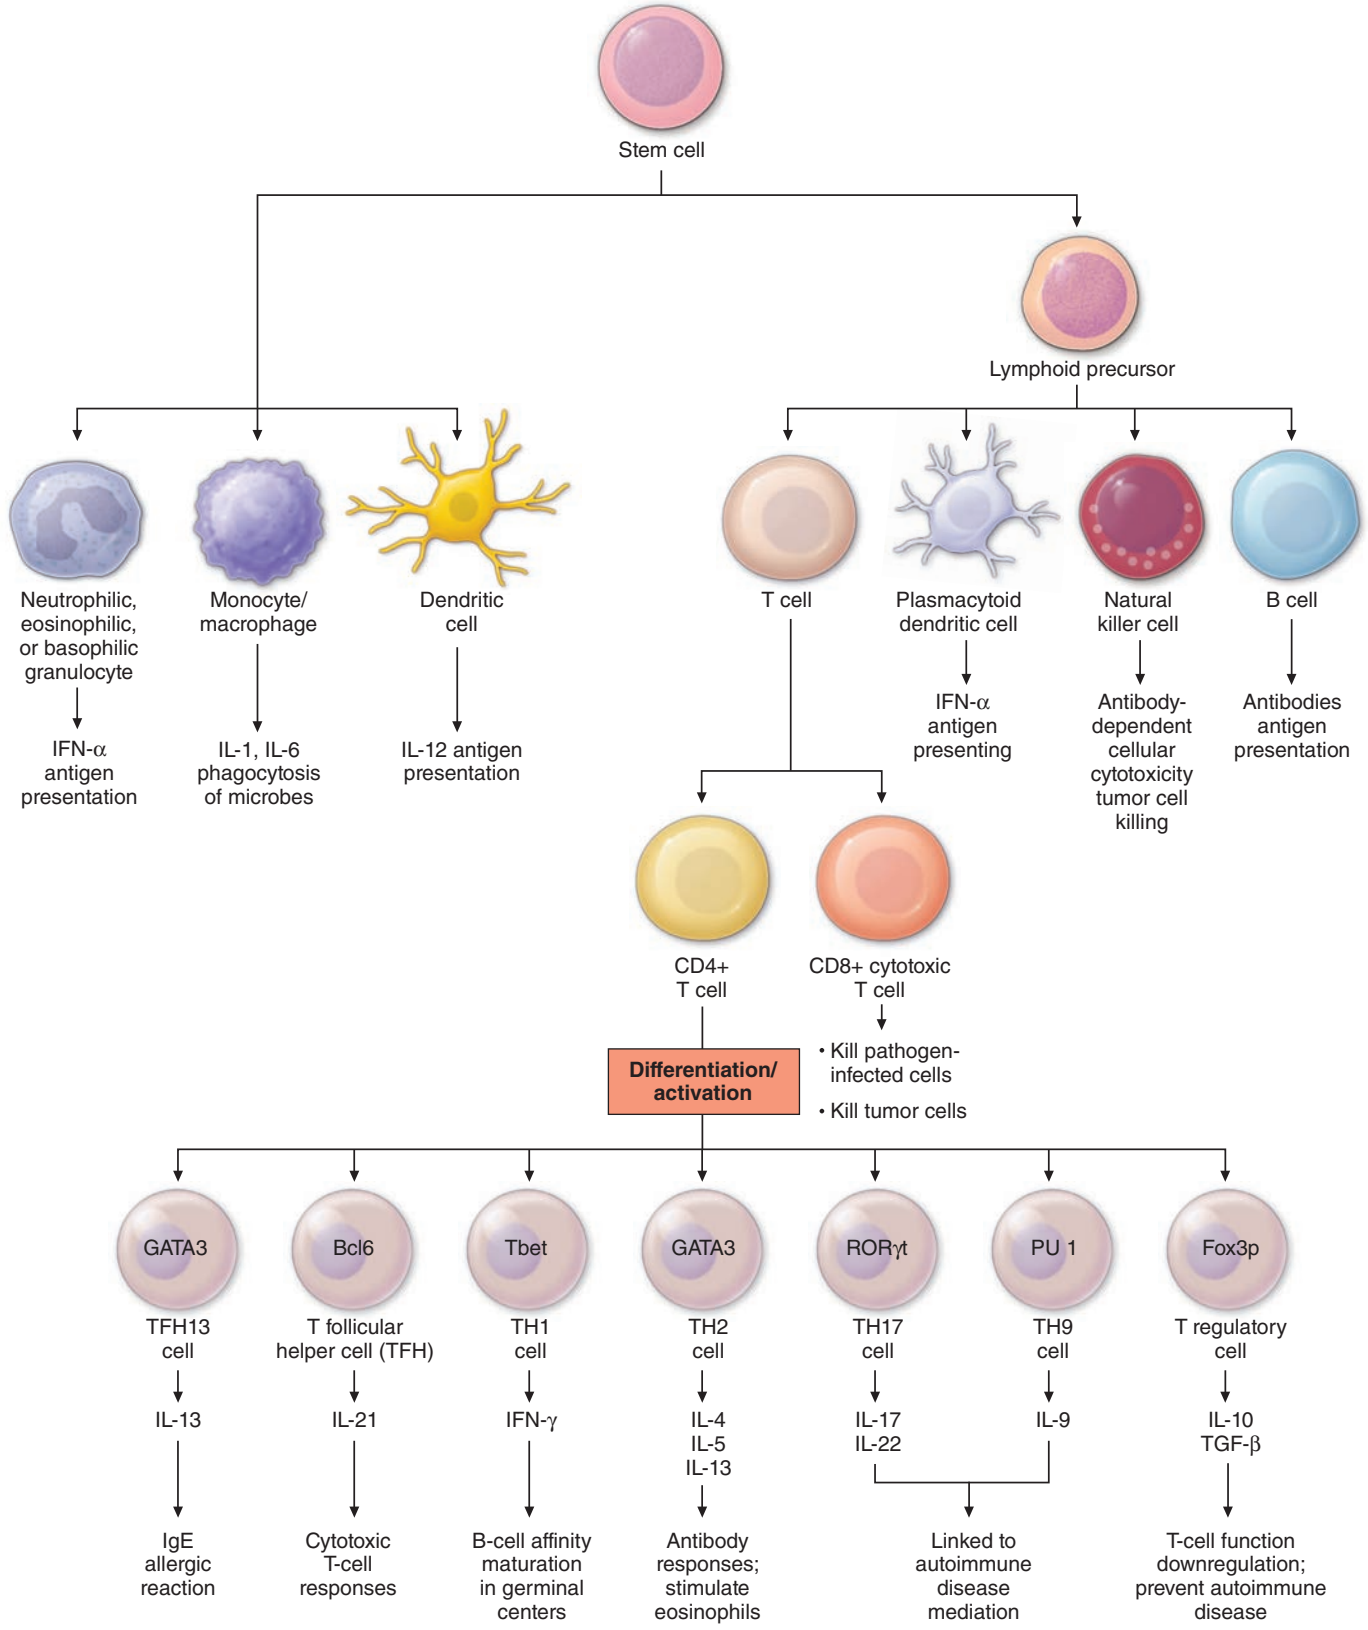

FIGURE 349-2 Model of immune effector cell development. Hematopoietic stem cells differentiate into T cells, antigen-presenting dendritic cells, natural killer cells, macrophages, granulocytes, or B cells. Foreign antigen is processed by dendritic cells, macrophages, and B cells, and peptide fragments of foreign antigen are presented to CD4+ and/or CD8+ T cells. CD8+ T-cell activation leads to induction of cytotoxic T lymphocyte (CTL) or killer T-cell generation, as well as induction of cytokine-producing CD8+ cytotoxic T cells. Granulocytes (neutrophils, eosinophils, or basophils) are effector cells of the innate immune system and mediate anti-infectious agent activity by cytokine production, infectious agent killing, or both. T_H1 CD4+ T cells play an important role in defense against intracellular microbes and help in the generation of CD8+ cytotoxic T cells. T_H2 CD4+ T cells producing interferon (IFN) γ or interleukin (IL) 4, IL-5, or IL-13 regulate Ig class switching and determine the type of antibody produced. T_H17 cells secrete IL-17 and IL-22, T_H9 cells secrete IL-9, and Tfh13 cells secrete IL-4, IL-5, and IL-13. T_H17 and T_H9 CD4 T cells are linked to mediation of autoimmune disease, and Tfh13 cells are linked to IgE-mediated anaphylaxis. CD4+ T regulatory cells produce IL-10 and transforming growth factor (TGF)-β and downregulate T- and B-cell responses once the microbe has been eliminated. Each of the types of CD4+ T cells are regulated by different transcription factors, and the key transcription factors are shown in the circles above each CD4+ T-cell type.

TABLE 349-6 Cytokines and Cytokine Receptors

CYTOKINE	RECEPTOR	CELL SOURCE	CELL TARGET	BIOLOGIC ACTIVITY
IL-1α, β	Type I IL-1r, type II IL-1r	Monocytes/macrophages, B cells, fibroblasts, most epithelial cells including thymic epithelium, endothelial cells	All cells	Upregulates adhesion molecule expression, neutrophil and macrophage emigration, mimics shock, fever, upregulates hepatic acute-phase protein production, facilitates hematopoiesis
IL-2	IL-2r α, β, common γ	T cells	T cells, B cells, NK cells, monocytes-macrophages	Promotes T-cell activation and proliferation, B-cell growth, NK-cell proliferation and activation, enhanced monocyte/macrophage cytolytic activity
IL-3	IL-3r, common β	T cells, NK cells, mast cells	Monocytes-macrophages, mast cells, eosinophils, bone marrow progenitors	Stimulates hematopoietic progenitors
IL-4	IL-4r α, common γ	T cells, mast cells, basophils	T cells, B cells, NK cells, monocytes-macrophages, neutrophils, eosinophils, endothelial cells, fibroblasts	Stimulates T_H2 helper T-cell differentiation and proliferation; stimulates B-cell Ig class switch to IgG1 and IgE anti-inflammatory action on T cells, monocytes; produced by T follicular helper cells in B-cell germinal centers that stimulate B-cell maturation.
IL-5	IL-5r α, common γ	T cells, mast cells, eosinophils	Eosinophils, basophils, murine B cells	Regulates eosinophil migration and activation
IL-6	IL-6r, gp130	Monocytes-macrophages, B cells, fibroblasts, most epithelium including thymic epithelium, endothelial cells	T cells, B cells, epithelial cells, hepatocytes, monocytes-macrophages	Induces acute-phase protein production, T- and B-cell differentiation and growth, myeloma cell growth, and osteoclast growth and activation
IL-7	IL-7r α, common γ	Bone marrow, thymic epithelial cells	T cells, B cells, bone marrow cells	Differentiates B-, T-, and NK-cell precursors, activates T and NK cells
IL-8	CXCR1, CXCR2	Monocytes-macrophages, T cells, neutrophils, fibroblasts, endothelial cells, epithelial cells	Neutrophils, T cells, monocytes-macrophages, endothelial cells, basophils	Induces neutrophil, monocyte, and T-cell migration, induces neutrophil adherence to endothelial cells and histamine release from basophils, and stimulates angiogenesis; suppresses proliferation of hepatic precursors
IL-9	IL-9r α, common γ	T cells	Bone marrow progenitors, B cells, T cells, mast cells	Induces mast cell proliferation and function, synergizes with IL-4 in IgG and IgE production and T-cell growth, activation, and differentiation
IL-10	IL-10r	Monocytes-macrophages, T cells, B cells, keratinocytes, mast cells	Monocytes-macrophages, T cells, B cells, NK cells, mast cells	Inhibits macrophage proinflammatory cytokine production, downregulates cytokine class II antigen and B7-1 and B7-2 expression, inhibits differentiation of T_H1 helper T cells, inhibits NK cell function, stimulates mast cell proliferation and function, B-cell activation, and differentiation
IL-11	IL-11r α, gp130	Bone marrow stromal cells	Megakaryocytes, B cells, hepatocytes	Induces megakaryocyte colony formation and maturation, enhances antibody responses, stimulates acute-phase protein production
IL-12 (35-kDa and 40-kDa subunits)	IL-12r	Activated macrophages, dendritic cells, neutrophils	T cells, NK cells	Induces T_H1 T helper cell formation and lymphokine-activated killer cell formation; increases CD8+ CTL cytolytic activity; ↓IL-17, ↑IFN-γ
IL-13	IL-13r/IL-4r α	T cells (T_H2)	Monocytes-macrophages, B cells, endothelial cells, keratinocytes	Upregulates VCAM-1 and C-C chemokine expression on endothelial cells and B-cell activation and differentiation, and inhibits macrophage proinflammatory cytokine production
IL-14	Unknown	T cells	Normal and malignant B cells	Induces B-cell proliferation, inhibits antibody secretion, and expands selected B-cell subgroups
IL-15	IL-15r α, common γ, IL2r β	Monocytes-macrophages, epithelial cells, fibroblasts	T cells, NK cells	Promotes T-cell activation and proliferation, angiogenesis, and NK cells
IL-16	CD4	Mast cells, eosinophils, CD8+ T cells, respiratory epithelium	CD4+ T cells, monocytes-macrophages, eosinophils	Promotes chemoattraction of CD4+ T cells, monocytes, and eosinophils; inhibits HIV-1 replication; inhibits T-cell activation through CD3/T-cell receptor
IL-17	IL-17r	CD4+ T cells	Fibroblasts, endothelium, epithelium, macrophages	Enhances cytokine/chemokine secretion; promotes delayed-type reactions
IL-18	IL-18r (IL-1R-related protein)	Keratinocytes, macrophages	T cells, B cells, NK cells	Upregulates IFN-γ production, enhances NK cell cytotoxicity
IL-21	IL-δγ chain/IL-21R	CD4 T cells	NK cells	Downregulates NK cell–activating molecules, NKG2D/DAP10; produced by T follicular helper cells in B-cell germinal centers that stimulate B-cell maturation.
IL-22	IL-22 R1/IL-10R2	DC, T cells	Epithelial cells	Innate responses against bacterial pathogens; promotes hepatocyte survival
IL-23	IL-12Rb1/IL23R	Macrophages, other cell types	T cells	Opposite effects of IL-12 (↑IL-17, ↑IFN-γ)
IL-24	IL-20R1/IL-20R2 IL-22R1/IL-20R2	Macrophages, T_H2 cells	Nonhematopoietic cells such as fibroblasts	Promotes wound healing

(*Continued*)

TABLE 349-6 Cytokines and Cytokine Receptors (Continued)

CYTOKINE	RECEPTOR	CELL SOURCE	CELL TARGET	BIOLOGIC ACTIVITY
IL-25 (also called IL-17E)	IL-17RB	CD4 T cells, mast cells	Fibroblasts, endothelium, epithelium, macrophages	Proinflammatory; induces cytokine production
IL-26	IL-20R1/IL-10R2	T_H1, T_H17 T cells, synovial cells	Epithelial cells	Proinflammatory; induces cytokine production
IL-27	gp130t wsx-1	Myeloid cells such as macrophages and DCs	T cells	Collaborates with other cytokines to activate T-cell differentiation
IL-28A (IFN-λ2)	IFN-λ receptor 1, IL-28Rα, IL-10Rβ	Myeloid lineage cells; epithelial cells	Epithelial cells	Enhanced clearance of viral infections
IL-28B (IFN-λ3)	IFN-λ receptor 1, IL-28Rα, IL-10Rβ	Myeloid lineage cells; epithelial cells	Epithelial cells	Enhanced clearance of viral infections
IL-29 (IFN-λ1)	IFN-λ receptor 1, IL-28Rα, IL-10Rβ	Myeloid lineage cells; epithelial cells	Epithelial cells	Enhanced clearance of viral infections
IL-30 (p28 of IL-27)	IL-27Rα; gp130+wsx-1	Activated macrophages and DCs; epithelial malignancies	Monocytes	Anti-inflammatory cytokines; upregulation of breast and prostate cancer metastasis
IL-31	IL-31RA/oncostatin MRβ	Eosinophils, CD4 T cells	Epithelial cells, monocytes	Pruritis, proinflammatory
IL-32 (NK4)	?	Monocytes, T cells, NK cells, epithelial cells	Monocytes, macrophages, bone marrow stroma	Angiogenesis, IL-2 production in bone marrow, proinflammatory
IL-33 (NF-HEV; IL-1 F11)	ST-2	Endothelial cells, epithelial cells, fibroblasts, mucosal epithelium	T cells, mast cells eosinophils, basophils, ILC2s	Alarmin cytokine, proinflammatory
IL-34 (C16of77)	CSF-1R, PTP-E, CD138	Neurons, Treg, myeloid cells		Anti-inflammatory myeloid cell proliferation
IL-35	IL-12Rβ2/IL-12Rβ2, gp130/gp130, IL-12Rb2/gp130	Tregs, Bregs	Macrophages, T cells	Prevents T_H1 and T_H17 proliferation; induced Treg/Breg proliferation/anti-inflammatory
IL-36α IL36β IL36γ IL36RA (IL-1 F5)	IL-36R	Keratocytes Mucosal epithelial cells Monocytes-macrophages Langerhans cells CD4 T cells	Epithelial cells, macrophages, DCs, T cells, B cells, plasma cells	T_H responses, proinflammatory
IL-38 IL-10 F10	IL-1R, IL-36R, IL-1RA PL1	Epithelial cells, B cells	Epithelial cells, macrophages, DCs, T cells, B cells, plasma cells	Blocks IL-36; anti-inflammatory
IL-39	?	Macrophages, DCs, B cells	Neutrophils	Proinflammatory
IL-40	?	B cells, bone marrow/stroma	B cells	Involved in IgA production, B-cell homeostasis and development
IFN-α	Type I interferon receptor	All cells	All cells	Promotes antiviral activity; stimulates T-cell, macrophage, and NK-cell activity; direct antitumor effects; upregulates MHC class I antigen expression; used therapeutically in viral and autoimmune conditions
IFN-β	Type I interferon receptor	All cells	All cells	Antiviral activity; stimulates T-cell, macrophage, and NK-cell activity; direct antitumor effects; upregulates MHC class I antigen expression; used therapeutically in viral and autoimmune conditions
IFN-γ	Type II interferon receptor	T cells, NK cells	All cells	Regulates macrophage and NK-cell activations; stimulates immunoglobulin secretion by B cells; induction of class II histocompatibility antigens; T_H1 T-cell differentiation
TNF-α	TNFrI, TNFrII	Monocytes-macrophages, mast cells, basophils, eosinophils, NK cells, B cells, T cells, keratinocytes, fibroblasts, thymic epithelial cells	All cells except erythrocytes	Fever, anorexia, shock, capillary leak syndrome, enhanced leukocyte cytotoxicity, enhanced NK-cell function, acute phase protein synthesis, proinflammatory cytokine induction
TNF-β	TNFrI, TNFrII	T cells, B cells	All cells except erythrocytes	Cell cytotoxicity, lymph node and spleen development
LT-β	LTβR	T cells	All cells except erythrocytes	Cell cytotoxicity, normal lymph node development
G-CSF	G-CSFr; gp130	Monocytes-macrophages, fibroblasts, endothelial cells, thymic epithelial cells, stromal cells	Myeloid cells, endothelial cells	Regulates myelopoiesis; enhances survival and function of neutrophils; clinical use in reversing neutropenia after cytotoxic chemotherapy
GM-CSF	GM-CSFr, common β	T cells, monocytes-macrophages, fibroblasts, endothelial cells, thymic epithelial cells	Monocytes-macrophages, neutrophils, eosinophils, fibroblasts, endothelial cells	Regulates myelopoiesis; enhances macrophage bactericidal and tumoricidal activity; mediator of dendritic cell maturation and function; upregulates NK-cell function; clinical use in reversing neutropenia after cytotoxic chemotherapy
M-CSF	M-CSFr (*c-fms* protooncogene)	Fibroblasts, endothelial cells, monocytes-macrophages, T cells, B cells, epithelial cells including thymic epithelium	Monocytes-macrophages	Regulates monocyte-macrophage production and function

(*Continued*)

TABLE 349-6 Cytokines and Cytokine Receptors (Continued)

CYTOKINE	RECEPTOR	CELL SOURCE	CELL TARGET	BIOLOGIC ACTIVITY
LIF	LIFr-α; gp130	Activated T cells, bone marrow stromal cells, thymic epithelium	Megakaryocytes, monocytes, hepatocytes, possibly lymphocyte subpopulations	Induces hepatic acute-phase protein production; stimulates macrophage differentiation; promotes growth of myeloma cells and hematopoietic progenitors; stimulates thrombopoiesis
OSM	OSMr; LIFr; gp130	Activated monocytes-macrophages and T cells, bone marrow stromal cells, some breast carcinoma cell lines, myeloma cells	Neurons, hepatocytes, monocytes-macrophages, adipocytes, alveolar epithelial cells, embryonic stem cells, melanocytes, endothelial cells, fibroblasts, myeloma cells	Induces hepatic acute-phase protein production; stimulates macrophage differentiation; promotes growth of myeloma cells and hematopoietic progenitors; stimulates thrombopoiesis; stimulates growth of Kaposi's sarcoma cells
SCF	SCFr (*c-kit* protooncogene)	Bone marrow stromal cells and fibroblasts	Embryonic stem cells, myeloid and lymphoid precursors, mast cells	Stimulates hematopoietic progenitor cell growth, mast cell growth; promotes embryonic stem cell migration
TGF-β (3 isoforms)	Type I, II, III TGF-β receptor	Most cell types	Most cell types	Downregulates T-cell, macrophage, and granulocyte responses; stimulates synthesis of matrix proteins; stimulates angiogenesis
Lymphotactin/ SCM-1	XCR1	NK cells, mast cells, double-negative thymocytes, activated CD8+ T cells	T cells, NK cells	Chemoattractant for lymphocytes; only known chemokine of C class
MCP-1	CCR2	Fibroblasts, smooth-muscle cells, activated PBMCs	Monocytes-macrophages, NK cells, memory T cells, basophils	Chemoattractant for monocytes, activated memory T cells, and NK cells; induces granule release from CD8+ T cells and NK cells; potent histamine-releasing factor for basophils; suppresses proliferation of hematopoietic precursors; regulates monocyte protease production
MCP-2	CCR1, CCR2	Fibroblasts, activated PBMCs	Monocytes-macrophages, T cells, eosinophils, basophils, NK cells	Chemoattractant for monocytes, memory and naïve T cells, eosinophils, ?NK cells; activates basophils and eosinophils; regulates monocyte protease production
MCP-3	CCR1, CCR2	Fibroblasts, activated PBMCs	Monocytes-macrophages, T cells, eosinophils, basophils, NK cells, dendritic cells	Chemoattractant for monocytes, memory and naïve T cells, dendritic cells, eosinophils, ?NK cells; activates basophils and eosinophils; regulates monocyte protease production
MCP-4	CCR2, CCR3	Lung, colon, small intestinal epithelial cells, activated endothelial cells	Monocytes-macrophages, T cells, eosinophils, basophils	Chemoattractant for monocytes, T cells, eosinophils, and basophils
Eotaxin	CCR3	Pulmonary epithelial cells, heart	Eosinophils, basophils	Potent chemoattractant for eosinophils and basophils; induces allergic airways disease; acts in concert with IL-5 to activate eosinophils; antibodies to eotaxin inhibit airway inflammation
TARC	CCR4	Thymus, dendritic cells, activated T cells	T cells, NK cells	Chemoattractant for T and NK cells
MDC	CCR4	Monocytes-macrophages, dendritic cells, thymus	Activated T cells	Chemoattractant for activated T cells; inhibits infection with T-cell tropic HIV-1
MIP-1α	CCR1, CCR5	Monocytes-macrophages, T cells	Monocytes-macrophages, T cells, dendritic cells, NK cells, eosinophils, basophils	Chemoattractant for monocytes, T cells, dendritic cells, and NK cells, and weak chemoattractant for eosinophils and basophils; activates NK-cell function; suppresses proliferation of hematopoietic precursors; necessary for myocarditis associated with coxsackievirus infection; inhibits infection with monocytotropic HIV-1
MIP-1β	CCR5	Monocytes-macrophages, T cells	Monocytes-macrophages, T cells, NK cells, dendritic cells	Chemoattractant for monocytes, T cells, and NK cells; activates NK-cell function; inhibits infection with monocytotropic HIV-1
RANTES	CCR1, CCR2, CCR5	Monocytes-macrophages, T cells, fibroblasts, eosinophils	Monocytes-macrophages, T cells, NK cells, dendritic cells, eosinophils, basophils	Chemoattractant for monocytes-macrophages, CD4+, CD45Ro+ T cells, CD8+ T cells, NK cells, eosinophils, and basophils; induces histamine release from basophils; inhibits infections with monocytotropic HIV-1
LARC/MIP-3α/ Exodus-1	CCR6	Dendritic cells, fetal liver cells, activated T cells	T cells, B cells	Chemoattractant for lymphocytes
ELC/MIP-3β	CCR7	Thymus, lymph node, appendix	Activated T cells and B cells	Chemoattractant for B and T cells; receptor upregulated on EBV-infected B cells and HSV-infected T cells
I-309/TCA-3	CCR8	Activated T cells	Monocytes-macrophages, T cells	Chemoattractant for monocytes; prevents glucocorticoid-induced apoptosis in some T-cell lines
SLC/TCA-4/ Exodus-2	CCR7	Thymic epithelial cells, lymph node, appendix, and spleen	T cells	Chemoattractant for T lymphocytes; inhibits hematopoiesis
DC-CK1/PARC	Unknown	Dendritic cells in secondary lymphoid tissues	Naïve T cells	May have a role in induction of immune responses

(*Continued*)

TABLE 349-6 Cytokines and Cytokine Receptors (Continued)

CYTOKINE	RECEPTOR	CELL SOURCE	CELL TARGET	BIOLOGIC ACTIVITY
TECK	CCR9	Dendritic cells, thymus, liver, small intestine	T cells, monocytes-macrophages, dendritic cells	Thymic dendritic cell–derived cytokine, possibly involved in T-cell development
GRO-α/MGSA	CXCR2	Activated granulocytes, monocyte-macrophages, and epithelial cells	Neutrophils, epithelial cells, ?endothelial cells	Neutrophil chemoattractant and activator; mitogenic for some melanoma cell lines; suppresses proliferation of hematopoietic precursors; angiogenic activity
GRO-β/MIP-2α	CXCR2	Activated granulocytes and monocyte-macrophages	Neutrophils and ?endothelial cells	Neutrophil chemoattractant and activator; angiogenic activity
NAP-2	CXCR2	Platelets	Neutrophils, basophils	Derived from platelet basic protein; neutrophil chemoattractant and activator
IP-10	CXCR3	Monocytes-macrophages, T cells, fibroblasts, endothelial cells, epithelial cells	Activated T cells, tumor-infiltrating lymphocytes, ?endothelial cells, ?NK cells	IFN-γ-inducible protein that is a chemoattractant for T cells; suppresses proliferation of hematopoietic precursors
MIG	CXCR3	Monocytes-macrophages, T cells, fibroblasts	Activated T cells, tumor-infiltrating lymphocytes	IFN-γ-inducible protein that is a chemoattractant for T cells; suppresses proliferation of hematopoietic precursors
SDF-1	CXCR4	Fibroblasts	T cells, dendritic cells, ?basophils, ?endothelial cells	Low-potency, high-efficacy T-cell chemoattractant; required for B lymphocyte development; prevents infection of CD4+, CXCR4+ cells by T-cell tropic HIV-1
Fractalkine	CX3CR1	Activated endothelial cells	NK cells, T cells, monocytes-macrophages	Cell-surface chemokine/mucin hybrid molecule that functions as a chemoattractant, leukocyte activator, and cell adhesion molecule
PF-4	Unknown	Platelets, megakaryocytes	Fibroblasts, endothelial cells	Chemoattractant for fibroblasts; suppresses proliferation of hematopoietic precursors; inhibits endothelial cell proliferation and angiogenesis

Abbreviations: B7-1, CD80; B7-2, CD86; Breg, regulatory B cells; CCR, CC-type chemokine receptor; CXCR, CXC-type chemokine receptor; DC, dendritic cell; DC-CK, dendritic cell chemokine; EBV, Epstein-Barr virus; ELC, EB11 ligand chemokine (MIP-1b); G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GRP, growth-related peptide; HSV, herpes simplex virus; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IP-10, IFN-γ-inducible protein-10; LARC, liver- and activation-regulated chemokine; LIF, leukemia inhibitory factor; MCP, monocyte chemotactic protein; M-CSF, macrophage colony-stimulating factor; MDC, macrophage-derived chemokine; MGSA, melanoma growth-stimulating activity; MHC, major histocompatibility complex; MIG, monokine induced by IFN-γ; MIP, macrophage inflammatory protein; NAP, neutrophil-activating protein; NK, natural killer; OSM, oncostatin M; PARC, pulmonary- and activation-regulated chemokine; PBMC, peripheral blood mononuclear cells; PF, platelet factor; RANTES, regulated on activation, normally T cell–expressed and –secreted; SCF, stem cell factor; SDF, stromal cell–derived factor; SLC, secondary lymphoid tissue chemokine; TARC, thymus- and activation-regulated chemokine; TCA, T-cell activation protein; TECK, thymus-expressed chemokine; TGF, transforming growth factor; T_H1 and T_H2, helper T cell subsets; TNF, tumor necrosis factor; Treg, regulatory T cells; VCAM, vascular cell adhesion molecule.

effectors of innate immune responses (Fig. 349-2). Unchecked accumulation and activation of granulocytes can lead to host tissue damage, as seen in neutrophil- and eosinophil-mediated *systemic necrotizing vasculitis*. Granulocytes are derived from stem cells in bone marrow. Each type of granulocyte (neutrophil, eosinophil, or basophil) is derived from a different subclass of progenitor cell that is stimulated to proliferate by colony-stimulating factors (Table 349-6). During terminal maturation of granulocytes, class-specific nuclear morphology and cytoplasmic granules appear that allow for histologic identification of granulocyte type.

Neutrophils express Fc receptor IIIa for IgG (CD16a) as well as receptors for activated complement components (C3b or CD35). Upon interaction of neutrophils with antibody-coated (opsonized) bacteria or immune complexes, azurophilic granules (containing myeloperoxidase, lysozyme, elastase, and other enzymes) and specific granules (containing lactoferrin, lysozyme, collagenase, and other enzymes) are released, and microbicidal superoxide radicals (O_2^-) are generated at the neutrophil surface. The generation of superoxide leads to inflammation by direct injury to tissue and by alteration of macromolecules such as collagen and DNA.

Eosinophils are potent cytotoxic effector cells for various parasitic organisms. In *Nippostrongylus brasiliensis* helminth infection, eosinophils are important cytotoxic effector cells for removal of these parasites. Key to regulation of eosinophil cytotoxicity to *N. brasiliensis* worms are antigen-specific T helper cells that produce IL-4, thus providing an example of regulation of innate immune responses by adaptive immunity antigen-specific T cells. Intracytoplasmic contents of eosinophils, such as major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin, are capable of directly damaging tissues and may be responsible in part for the organ system dysfunction in the *hypereosinophilic syndromes* **(Chap. 64)**. Because the eosinophil granule contains anti-inflammatory types of enzymes (histaminase, arylsulfatase, phospholipase D), eosinophils may homeostatically downregulate or terminate ongoing inflammatory responses.

Basophils and tissue mast cells are potent reservoirs of cytokines such as IL-4 and can respond to bacteria and viruses with antipathogen cytokine production through multiple TLRs expressed on their surface. Mast cells and basophils can also mediate immunity through the binding of antipathogen antibodies. This is a particularly important host defense mechanism against parasitic diseases. Basophils express high-affinity surface receptors for IgE (FcεRII) (CD23) and, upon cross-linking of basophil-bound IgE by antigen, can release histamine, eosinophil chemotactic factor of anaphylaxis, and neutral protease—all mediators of allergic immediate (anaphylaxis) hypersensitivity responses. In addition, basophils express surface receptors for activated complement components (C3a, C5a), through which mediator release can be directly affected. Thus, basophils, like most cells of the immune system, can be activated in the service of host defense against pathogens, or they can be activated for mediation release and cause pathogenic responses in allergic and inflammatory diseases. **For further discussion of tissue mast cells, see Chap. 354**.

The Complement System The complement system, an important soluble component of the innate immune system, is a series of plasma enzymes, regulatory proteins, and proteins that are activated in a cascading fashion, resulting in cell lysis. There are four pathways of the complement system: the classic activation pathway activated by antigen/antibody immune complexes, the MBL (a serum collectin) activation

TABLE 349-7 CC, CXC_1, CX_3, C_1, and XC Families of Chemokines and Chemokine Receptors

CHEMOKINE RECEPTOR	CHEMOKINE LIGANDS	CELL TYPES	DISEASE CONNECTION
CCR1	CCL3 (MIP-1α), CCL5 (RANTES), CCL7 (MCP-3), CCL14 (HCC1)	T cells, monocytes, eosinophils, basophils	Rheumatoid arthritis, multiple sclerosis
CCR2	CCL2 (MCP-1), CCL8 (MCP-2), CCL7 (MCP-3), CCL13 (MCP-4), CCL16 (HCC4)	Monocytes, dendritic cells (immature), memory T cells	Atherosclerosis, rheumatoid arthritis, multiple sclerosis, resistance to intracellular pathogens, type 2 diabetes mellitus
CCR3	CCL11 (eotaxin), CCL13 (eotaxin-2), CCL7 (MCP-3), CCL5 (RANTES), CCL8 (MCP-2), CCL13 (MCP-4)	Eosinophils, basophils, mast cells, T_H2, platelets	Allergic asthma and rhinitis
CCR4	CCL17 (TARC), CCL22 (MDC)	T cells (T_H2), dendritic cells (mature), basophils, macrophages, platelets	Parasitic infection, graft rejection, T-cell homing to skin
CCR5	CCL3 (MIP-1α), CCL4 (MIP-1α), CCL5 (RANTES), CCL11 (eotaxin), CCL14 (HCC1), CCL16 (HCC4)	T cells, monocytes	HIV-1 co-receptor (T cell–tropic strains), transplant rejection
CCR6	CCL20 (MIP-3α, LARC)	T cells (T regulatory and memory), B cells, dendritic cells	Mucosal humoral immunity, allergic asthma, intestinal T-cell homing
CCR7	CCL19 (ELC), CCL21 (SLC)	T cells, dendritic cells (mature)	Transport of T cells and dendritic cells to lymph nodes, antigen presentation, and cellular immunity
CCR8	CCL1 (1309)	T cells (T_H2), monocytes, dendritic cells	Dendritic cell migration to lymph node, type 2 cellular immunity, granuloma formation
CCR9	CCL25 (TECK)	T cells, IgA+ plasma cells	Homing of T cells and IgA+ plasma cells to the intestine, inflammatory bowel disease
CCR10	CCL27 (CTACK), CCL28 (MEC)	T cells	T-cell homing to intestine and skin
CXCR1	CXCL8 (interleukin-8), CXCL6 (GCP2)	Neutrophils, monocytes	Inflammatory lung disease, COPD
CXCR2	CXCL8, CXCL1 (GROα), CXCL2 (GROα), CXCL3 (GROα), CXCL5 (ENA-78), CXCL6	Neutrophils, monocytes, microvascular endothelial cells	Inflammatory lung disease, COPD, angiogenic for tumor growth
CXCR3-A	CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Type 1 helper cells, mast cells, mesangial cells	Inflammatory skin disease, multiple sclerosis, transplant rejection
CXCR3-B	CXCL4 (PF4), CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Microvascular endothelial cells, neoplastic cells	Angiostatic for tumor growth
CXCR4	CXCL12 (SDF-1)	Widely expressed	HIV-1 co-receptor (T cell–tropic), tumor metastases, hematopoiesis
CXCR5	CXCL13 (BCA-1)	B cells, follicular helper T cells	Formation of B-cell follicles
CXCR6	CXCL16 (SR-PSOX)	CD8+ T cells, natural killer cells, and memory CD4+ T cells	Inflammatory liver disease, atherosclerosis (CXCL16)
CX_3CR1	CX3CL1 (fractalkine)	Macrophages, endothelial cells, smooth-muscle cells	Atherosclerosis
XCR1	XCL1 (lymphotactin), XCL2	T cells, natural killer cells	Rheumatoid arthritis, IgA nephropathy, tumor response

Abbreviations: BCA-1, B-cell chemoattractant 1; COPD, chronic obstructive pulmonary disease; CTACK, cutaneous T cell–attracting chemokine; ELC, Epstein-Barr I1-ligand chemokine; ENA, epithelial cell–derived neutrophil-activating peptide; GCP, granulocyte chemotactic protein; GRO, growth-regulated oncogene; HCC, hemofiltrate chemokine; IP-10, interferon inducible 10; I-TAC, interferon-inducible T-cell alpha chemoattractant; LARC, liver- and activation-regulated chemokine; MCP, monocyte chemoattractant protein; MDC, macrophage-derived chemokine; MEC, mammary-enriched chemokine; MIG, monokine induced by interferon-γ; MIP, macrophage inflammatory protein; PF, platelet factor; SDF, stromal cell–derived factor; SLC, secondary lymphoid-tissue chemokine; SR-PSOX, scavenger receptor for phosphatidylserine-containing oxidized lipids; TARC, thymus- and activation-regulated chemokine; TECK, thymus-expressed chemokine; T_H2, type 2 helper T cells.

pathway activated by microbes with terminal mannose groups, the alternative activation pathway activated by microbes or tumor cells, and the terminal pathway that is common to the first three pathways and leads to the membrane attack complex that lyses cells **(Fig. 349-5)**. The series of enzymes of the complement system are serine proteases.

Activation of the classic complement pathway via immune complex binding to C1q links the innate and adaptive immune systems via specific antibody in the immune complex. The alternative complement activation pathway is antibody-independent and is activated by binding of C3 directly to pathogens and "altered self" such as tumor cells. In the renal glomerular inflammatory disease *IgA nephropathy*, IgA activates the alternative complement pathway and causes glomerular damage and decreased renal function. Activation of the classic complement pathway via C1, C4, and C2 and activation of the alternative pathway via factor D, C3, and factor B both lead to cleavage and activation of C3. C3 activation fragments, when bound to target surfaces such as bacteria and other foreign antigens, are critical for opsonization (coating by antibody and complement) in preparation for phagocytosis. The MBL pathway substitutes MBL-associated serine proteases (MASPs) 1 and 2 for C1q, C1r, and C1s to activate C4. The MBL activation pathway is activated by mannose on the surface of bacteria and viruses.

The three pathways of complement activation all converge on the final common terminal pathway. C3 cleavage by each pathway results in activation of C5, C6, C7, C8, and C9, resulting in the membrane attack complex that physically inserts into the membranes of target cells or bacteria and lyses them.

Thus, complement activation is a critical component of innate immunity for responding to microbial infection. The functional consequences of complement activation by the three initiating pathways and the terminal pathway are shown in Fig. 349-5. In general, the cleavage products of complement components facilitate microbe or damaged cell clearance (C1q, C4, C3), promote activation and enhancement of inflammation (anaphylatoxins, C3a, C5a), and promote microbe or opsonized cell lysis (membrane attack complex). Deficiencies of early complement components C1, C4, or C2 can be associated with autoimmune disorders or with encapsulated bacterial infections like *Streptococcus pneumoniae*. Deficiencies of late complement components (C5-C9) are associated with increased *Neisseria* infections.

CYTOKINES

Cytokines are soluble proteins produced by a wide variety of cell types (Tables 349-6 and 349-7). They are critical for both normal innate and adaptive immune responses, and their expression may be perturbed in most immune, inflammatory, and infectious disease states.

Cytokines are involved in the regulation of the growth, development, and activation of immune system cells and in the mediation of the inflammatory response. In general, cytokines are characterized by considerable redundancy; different cytokines have similar functions. In addition, many cytokines are pleiotropic in that they are capable of acting on many different cell types. This pleiotropism results from the expression on multiple cell types of receptors for the same cytokine (see below), leading to the formation of "cytokine networks." The action of cytokines may be (1) autocrine when the target cell is the same cell that secretes the cytokine, (2) *paracrine* when the target cell is nearby, and (3) *endocrine* when the cytokine is secreted into the circulation and acts distal to the source.

Cytokines have been named based on presumed targets or based on presumed functions. Those cytokines that are thought to primarily target leukocytes have been named IL-1, -2, -3, etc. Many cytokines that

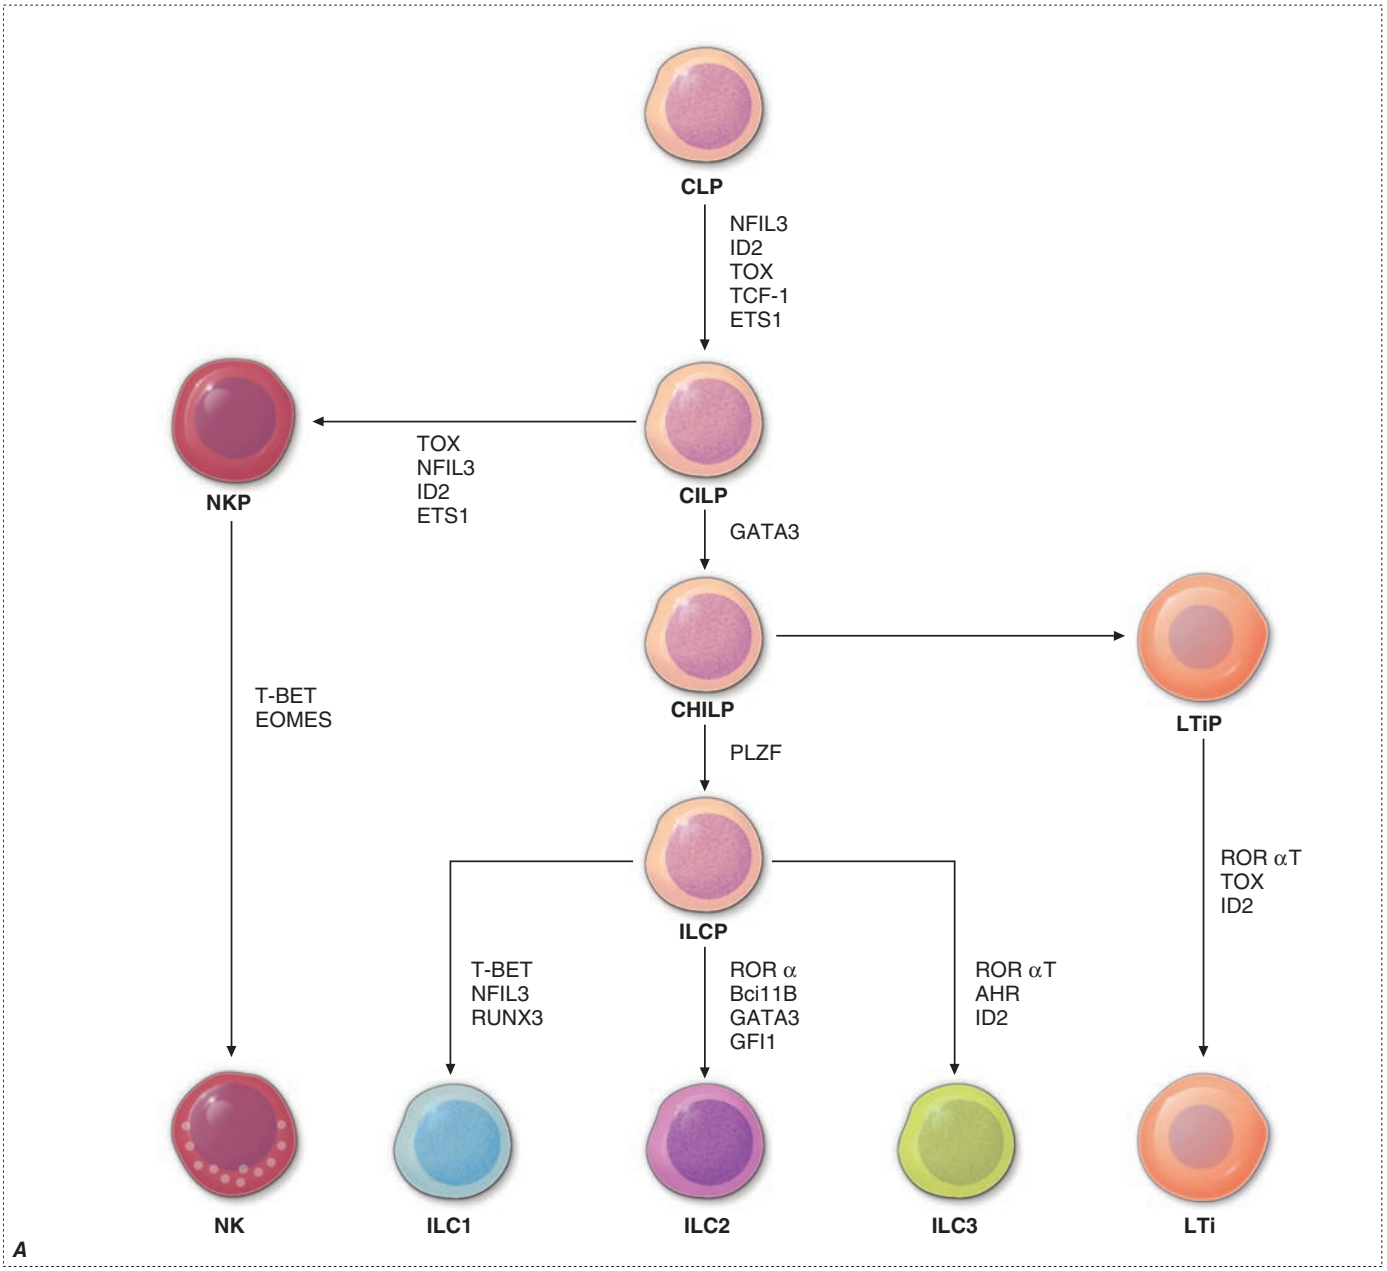

FIGURE 349-3 Development and function of innate lymphoid cells (ILCs). ***A.*** ILC development, mainly based on mouse ILC differentiation paths, is schematized. ILCs develop from common innate lymphoid progenitors (CILPs), which themselves differentiate from common lymphoid progenitors (CLPs). CILPs can differentiate into natural killer (NK) cell precursor (NKP) cells or into common helper innate lymphoid progenitors (CHILPs), which themselves give rise to lymphoid tissue inducer progenitors (LTiPs) and innate lymphoid cell precursors (ILCPs). LTiPs differentiate into lymphoid tissue inducers (LTis) and ILCPs into ILC1, ILC2, or ILC3. Each stage of differentiation is dependent on the expression of the indicated transcription factors: NFIL3 (nuclear factor IL-3 induced), Id2 (inhibitor of DNA binding 2), TOX (thymocyte selection-associated high mobility group box protein), TCF-1 (T-cell factor 1), ETS1 (avian erythroblastosis virus E26 homolog-1), GATA3 (GATA binding protein 3), PLZF (promyelocytic leukemia zinc finger), T-bet (T-box transcription factor), Eomes (eomesodermin), RUNX3 (runt-related transcription factor 3), RORα (RAR-related orphan receptor α), Bcl11b (B cell lymphoma/leukemia 11B), Gfi1 (growth factor independent 1), RORγt (RAR-related orphan receptor γt), and AHR (Aryl hydrocarbon receptor). It has been shown in humans that ILC1 subsets may originate from precursors other than ILCPs, but the identity of these precursors remains unknown at this time. ***B.*** Some of the most well-known immune functions of each ILC subset are shown: NK cells and ILC1s react to intracellular pathogens, such as viruses, and to tumors; ILC2s respond to large extracellular parasites and allergens; ILC3s combat extracellular microbes, such as bacteria and fungi; and Lutes are involved in the formation of secondary lymphoid structures. For each ILC subset, effector molecules that can be produced upon activation are indicated AREG, amphiregulin; RANK, receptor activation of nuclear factor κB; RANK-L, RANK-ligand. *(Reproduced with permission from E Vivier et al: Innate lymphoid cells: 10 years on. Cell 174:1054, 2018.)*

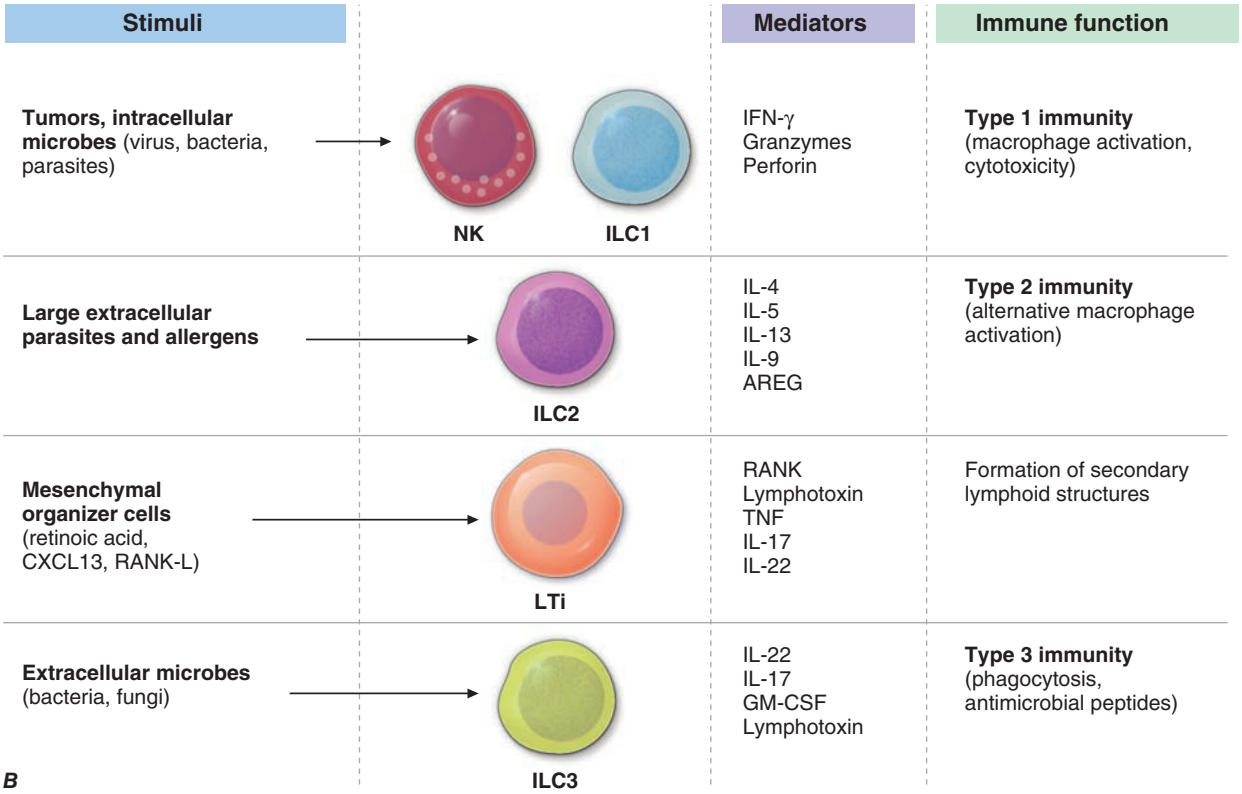

FIGURE 349-3 (Continued)

were originally described as having a certain function have retained those names (e.g., granulocyte colony-stimulating factor [G-CSF]). Cytokines belong in general to three major structural families: the hematopoietin family; the TNF, IL-1, platelet-derived growth factor (PDGF), and transforming growth factor (TGF) β families; and the CXC and C-C chemokine families. Chemokines are cytokines that regulate cell movement and trafficking; they act through G protein-coupled receptors and have a distinctive three-dimensional structure. IL-8 is the only chemokine that early on was named an IL (Table 349-6).

TABLE 349-8 Association of KIRS with Disease

DISEASE	KIR ASSOCIATION	OBSERVATION
Psoriatic arthritis	KIR2DS1/KIR2DS2; HLA-Cw group homozygosity	Susceptibility
Spondylarthritides	Increased KIR3DL2 expression	May contribute to disease pathology
	Interaction of HLA-B27 homodimers with KIR3DL1/KIR3DL2; independent of peptide	May contribute to disease pathogenesis
Ankylosing spondylitis	KIR3DL1/3DS1; HLA-B27 genotypes	Susceptibility
Rheumatoid vasculitis	KIR2DS2; HLA-Cw*03	Susceptibility
	Increased KIR2L2/2DS2 in patients with extraarticular manifestations	Clinical manifestations may have different genetic backgrounds with respect to KIR genotype
Rheumatoid arthritis	Decreased KIR2DS1/3DS1 in patients without bone erosions	Susceptibility
	KIR2DS4; HLA-Cw4	Susceptibility
Scleroderma	KIR2DS2+/KIR2DL2–	Susceptibility
Behçet's disease	Altered KIR3DL1 expression	Associated with severe eye disease
Psoriasis vulgaris	2DS1; HLA-Cw*06	Susceptibility
	2DS1; 2DL5; haplotype B	Susceptibility
IDDM	KIR2DS2; HLA-C1	Susceptibility
Type 1 diabetes	KIR2DS2; HLA-C1 and no HLA-C2, no HLA-Bw4	Increased disease progression
Preeclampsia	KIR2DL1 with fewer KIR2DS (mother); HLA-C2 (fetus)	Increased disease progression
AIDS	KIR3DS1; HLA-Bw4Ile80	Decreased disease progression
	KIR3DS1 homozygous; no HLA-Bw4Ile80	Increased disease progression
HCV infection	KIR2DL3 homozygous; HLA-C1 homozygous	Decreased disease progression
Cervical neoplasia (HPV induced)	KIR3DS1; HLA-C1 homozygous and no HLA-Bw4	Increased disease progression
Malignant melanoma	KIR2DL2 and/or KIR2DL3; HLA-C1	Increased disease progression

Abbreviations: HCV, hepatitis C virus; HLA, human leukocyte antigen; HPV, human papillomavirus; IDDM, insulin-dependent diabetes mellitus; KIR, killer cell immunoglobulin-like receptor.

In general, cytokines exert their effects by influencing gene activation that results in cellular activation, growth, differentiation, functional cell-surface molecule expression, and cellular effector function. In this regard, cytokines can have dramatic effects on the regulation of immune responses and the pathogenesis of a variety of diseases. Indeed, T cells have been categorized on the basis of the pattern of cytokines that they secrete, which results in either humoral immune response (T_H2) or cell-mediated immune response (T_H1). A third type of T helper cell is the T_H17 cell that contributes to host defense against extracellular bacteria and fungi, particularly at mucosal sites (Fig. 349-2).

Cytokine receptors can be grouped into five general families based on similarities in their extracellular amino acid sequences and conserved structural domains. The *immunoglobulin (Ig) superfamily* represents a large number of cell-surface and secreted proteins. The IL-1 receptors (type 1, type 2) are examples of cytokine receptors with extracellular Ig domains.

The hallmark of the *hematopoietic growth factor (type 1) receptor* family is that the extracellular regions of each receptor contain two conserved motifs. One motif, located at the N terminus, is rich in cysteine residues. The other motif is located at the C terminus proximal to the transmembrane region and comprises five amino acid residues, tryptophan-serine-X-tryptophan-serine (WSXWS). This family can be grouped on the basis of the number of receptor subunits they have and on the utilization of shared subunits. A number of cytokine receptors, i.e., IL-6, IL-11, IL-12, and leukemia inhibitory factor, are paired with gp130. There is also a common 150-kDa subunit shared by IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF) receptors. The gamma chain (γ_c) of the IL-2 receptor is common to the IL-2, IL-4, IL-7, IL-9, and IL-15 receptors. Thus, the specific cytokine receptor is responsible for ligand-specific binding, whereas the subunits such as gp130, the 150-kDa subunit, and γ_c are important in signal transduction. The γ_c gene is on the X chromosome, and mutations in the γ_c protein result in the *X-linked form of severe combined immune deficiency syndrome (X-SCID)* **(Chap. 351)**.

The members of the *interferon (type II) receptor* family include the receptors for IFN-γ and -β, which share a similar 210-amino-acid binding domain with conserved cysteine pairs at both the amino and carboxy termini. The members of the *TNF (type III) receptor family* share a common binding domain composed of repeated cysteine-rich regions. Members of this family include the p55 and p75 receptors for TNF (TNF-R1 and TNF-R2, respectively); CD40 antigen, which is an important B-cell surface marker involved in immunoglobulin isotype switching; fas/Apo-1, whose triggering induces apoptosis; CD27 and CD30, which are found on activated T cells and B cells; and nerve growth factor receptor.

The common motif for the *seven transmembrane helix family* was originally found in receptors linked to GTP-binding proteins. This family includes receptors for chemokines (Table 349-7), β-adrenergic receptors, and retinal rhodopsin. It is important to note that two members of the chemokine receptor family, CXC chemokine receptor type 4 (CXCR4) and β chemokine receptor type 5 (CCR5), have been found to serve as the two major co-receptors for binding and entry of HIV-1 into CD4-expressing host cells **(Chap. 202)**.

Significant advances have been made in defining the signaling pathways through which cytokines exert their intracellular effects. The Janus family of protein tyrosine kinases (JAK) is a critical element involved in signaling via the hematopoietin receptors. Four JAK kinases, JAK1, JAK2, JAK3, and Tyk2, preferentially bind different cytokine receptor subunits. Cytokine binding to its receptor brings the cytokine receptor subunits into apposition and allows a pair of JAKs to transphosphorylate and activate one another. The JAKs then phosphorylate the receptor on the tyrosine residues and allow

signaling molecules to bind to the receptor, whereby the signaling molecules become phosphorylated. Signaling molecules bind the receptor because they have domains (SH2, or src homology 2 domains) that can bind phosphorylated tyrosine residues. There are a number of these important signaling molecules that bind the receptor, such as the adapter molecule SHC, which can couple the receptor to the activation of the mitogen-activated protein kinase pathway. In addition, an important class of substrate of the JAKs is the signal transducers and activators of transcription (STAT) family of transcription factors. STATs have SH2 domains that enable them to bind to phosphorylated receptors, where they are then phosphorylated by the JAKs. It appears that different STATs have specificity for different receptor subunits. The STATs then dissociate from the receptor and translocate to the nucleus, bind to DNA motifs that they recognize, and regulate gene expression. The STATs preferentially bind DNA motifs that are slightly different from one another and thereby control transcription of specific genes. The importance of this pathway is particularly relevant to lymphoid development. Mutations of JAK3 itself also result in a disorder identical to X-SCID; however, because JAK3 is found on chromosome 19 and not on the X chromosome, JAK3 deficiency occurs in boys and girls **(Chap. 351)**.

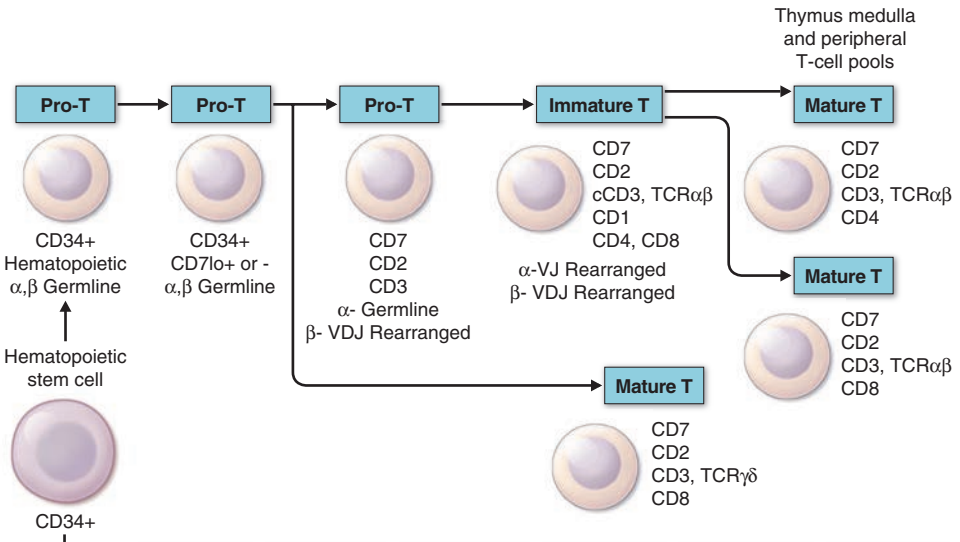
THE ADAPTIVE IMMUNE SYSTEM

Adaptive immunity is characterized by antigen-specific responses to a foreign antigen or pathogen. A key feature of adaptive immunity is that following the initial contact with antigen (*immunologic priming*), subsequent antigen exposure leads to more rapid and vigorous immune responses (*immunologic memory*). The adaptive immune system consists of dual limbs of cellular and humoral immunity. The principal effectors of cellular immunity are T lymphocytes, whereas the principal effectors of humoral immunity are B lymphocytes. Both B and T lymphocytes derive from a common stem cell **(Fig. 349-6)**.

The proportion and distribution of immunocompetent cells in various tissues reflect cell traffic, homing patterns, and functional capabilities. Bone marrow is the major site of maturation of B cells, monocytes-macrophages, DCs, and granulocytes and contains pluripotent stem cells that, under the influence of various colony-stimulating factors, can give rise to all hematopoietic cell types. T-cell precursors also arise from hematopoietic stem cells and home to the thymus for maturation. Mature T lymphocytes, B lymphocytes, monocytes, and DCs enter the circulation and home to peripheral lymphoid organs (lymph nodes, spleen) and mucosal surface-associated lymphoid tissue (gut, genitourinary, and respiratory tracts) as well as the skin and mucous membranes and await activation by foreign antigen.

T Cells The pool of effector T cells is established in the thymus early in life and is maintained throughout life both by new T-cell production in the thymus and by antigen-driven expansion of virgin peripheral T cells into "memory" T cells that reside in peripheral lymphoid organs. The thymus exports ~2% of the total number of thymocytes per day throughout life, with the total number of daily thymic emigrants decreasing by ~3% per year during the first four decades of life.

Mature T lymphocytes constitute 70–80% of normal peripheral blood lymphocytes (only 2% of the total-body lymphocytes are contained in peripheral blood), 90% of thoracic duct lymphocytes, 30–40% of lymph node cells, and 20–30% of spleen lymphoid cells. In lymph nodes, T cells occupy deep paracortical areas around B-cell germinal centers, and in the spleen, they are located in periarteriolar areas of white pulp **(Chap. 66)**. T cells are the primary effectors of cell-mediated immunity, with subsets of T cells maturing into CD8+ cytotoxic T cells capable of lysis of virus-infected or foreign cells (short-lived effector T cells) and CD4+ T cells capable of T-cell help for CD8+ T-cell and B-cell development. Two populations of long-lived memory T cells are triggered by infections: effector memory and central memory T cells. Effector memory T cells reside in nonlymphoid organs and respond rapidly to repeated pathogenic infections with cytokine production and cytotoxic functions to kill virus-infected



Heavy-chain genes	D-J rearranging	VDJ rearranging	VDJ rearranged	VDJ rearranged	VDJ rearranged	VDJ rearranged

FIGURE 349-6 Development stages of T and B cells. Elements of the developing T- and B-cell receptor for antigen are shown schematically. The classification into the various stages of B-cell development is primarily defined by rearrangement of the immunoglobulin (Ig) heavy (H) and light (L) chain genes and by the absence or presence of specific surface markers. The classification of stages of T-cell development is primarily defined by cell-surface marker protein expression (sCD3, surface CD3 expression; cCD3, cytoplasmic CD3 expression; TCR, T-cell receptor). For B-cell development, the pre-B-cell receptor is shown as a blue-orange B-cell receptor. *(From Janeway's Immunobioogy, 9th ed by Kenneth Murphy and Casey Weaver. Copyright © 2017 by Garland Science, Taylor & Francis Group, LLC. Used by permission of W. W. Norton & Company, Inc.)*

cells. Central memory T cells home to lymphoid organs where they replenish long- and short-lived and effector memory T cells as needed.

In general, CD4+ T cells are the primary regulatory cells of T and B lymphocyte and monocyte function by the production of cytokines and by direct cell contact (Fig. 349-2). In addition, T cells regulate erythroid cell maturation in bone marrow and, through cell contact (CD40 ligand), have an important role in activation of B cells and induction of Ig isotype switching. Considerable evidence now exists that colonization of the gut by commensal bacteria (the gut microbiome) is responsible for expansion of the peripheral CD4+ T-cell compartment in normal children and adults.

Human T cells express cell-surface proteins that mark stages of intrathymic T-cell maturation or identify specific functional subpopulations of mature T cells. Many of these molecules mediate or participate in important T-cell functions (Table 349-1, Fig. 349-6, **Chap. 350**).

The earliest identifiable T-cell precursors in bone marrow are CD34+ pro-T cells (i.e., cells in which TCR genes are neither rearranged nor expressed). In the thymus, CD34+ T-cell precursors begin cytoplasmic (c) synthesis of components of the CD3 complex of TCR-associated molecules (Fig. 349-6). Within T-cell precursors, TCR for antigen gene rearrangement yields two T-cell lineages, expressing either TCR-αβ chains or TCR-γδ chains. T cells expressing the TCR-αβ chains constitute the majority of peripheral T cells in blood, lymph node, and spleen and terminally differentiate into either CD4+ or CD8+ cells. Cells expressing TCR-γδ chains circulate as a minor population in blood; their functions, although not fully understood, have been postulated to be those of immune surveillance at epithelial surfaces and cellular defenses against mycobacterial organisms and other intracellular bacteria through recognition of bacterial lipids.

In the thymus, the recognition of self-peptides on thymic epithelial cells, thymic macrophages, and DCs plays an important role in shaping T-cell repertoire. As immature cortical thymocytes begin to express surface TCR for antigen, thymocytes with TCRs capable of interacting with self-peptides in the context of self-MHC antigens with low affinity are activated and survive (positive selection). Thymocytes with TCRs that are incapable of binding to self-MHC antigens or bind with high affinity die of attrition (no selection) or by apoptosis (negative selection). Thymocytes that are positively selected undergo maturation into CD4 or CD8 single positive T cells, and then migrate to the thymus medulla where they interact with self-peptide–self-MHC molecules, where they can again undergo selection. The purpose of negative and positive thymocyte selection is to eliminate potential pathogenic autoreactive T cells, and at the same time, select a repertoire of mature T cells capable of recognizing foreign antigens.

Mature TCRαβ thymocytes that are positively selected are functional MHC class II–restricted CD4+ T cells (Fig. 349-2), or they are CD8+ T cells destined to become CD8+ MHC class I–restricted cytotoxic T cells. *MHC class I* or *class II restriction* means that T cells recognize antigen peptide fragments only when they are presented in the antigen-recognition site of a class I or class II MHC molecule, respectively. After thymocyte maturation and selection, CD4 and CD8 thymocytes leave the thymus and migrate to the peripheral immune system. The thymus can continue to be a contributor to the peripheral immune system well into adult life, both normally and when the peripheral T-cell pool is damaged, such as occurs in AIDS and cancer chemotherapy.

MOLECULAR BASIS OF T-CELL RECOGNITION OF ANTIGEN The TCR for antigen is a complex of molecules consisting of an antigen-binding heterodimer of either αβ or γδ chains noncovalently linked with five CD3 subunits (γ, δ, ε, ζ, and η) **(Fig. 349-7)**. The CD3 ζ chains are either disulfide-linked homodimers (CD3-ζ_2) or disulfide-linked heterodimers composed of one ζ chain and one η chain. TCR-αβ or TCR-γδ molecules must be associated with CD3 molecules to be

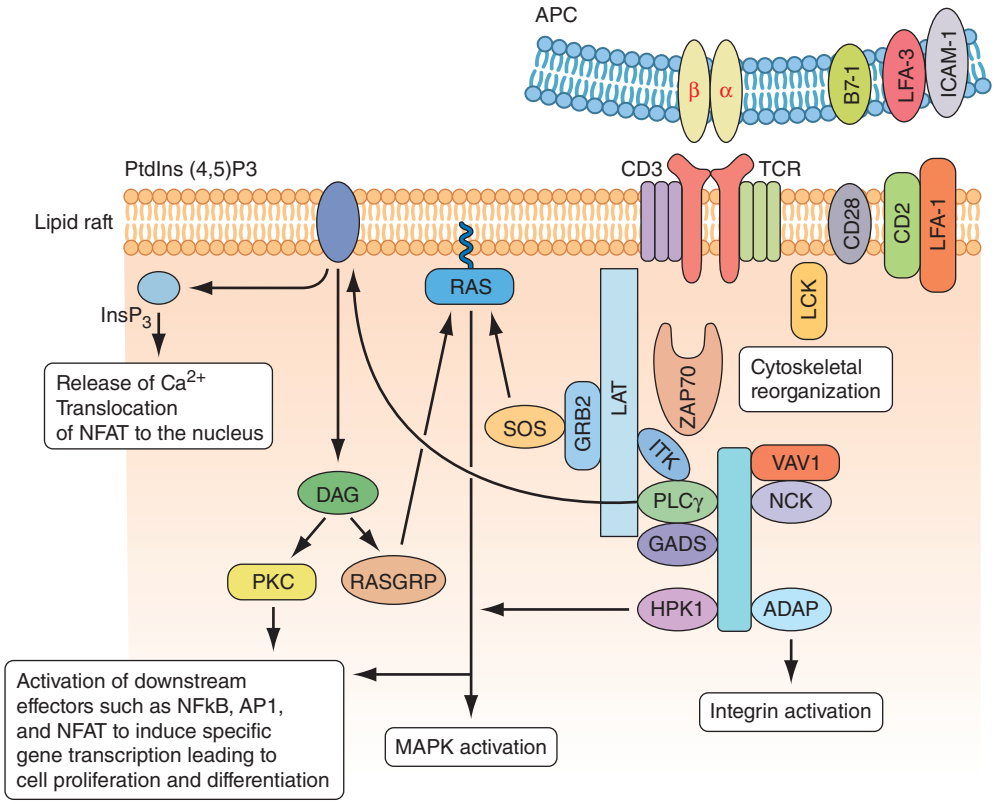

FIGURE 349-7 Signaling through the T-cell receptor. Activation signals are mediated via immunoreceptor tyrosine-based activation (ITAM) sequences in LAT and CD3 chains (*blue bars*) that bind to enzymes and transduce activation signals to the nucleus via the indicated intracellular activation pathways. Ligation of the T-cell receptor (TCR) by MHC complexed with antigen results in sequential activation of LCK and γ-chain-associated protein kinase of 70 kDa (ZAP70). ZAP70 phosphorylates several downstream targets, including LAT (linker for activation of T cells) and SLP76 (SCR homology 2 [SH2] domain-containing leukocyte protein of 76 kDa). SLP76 is recruited to membrane-bound LAT through its constitutive interaction with GADS (GRB2-related adaptor protein). Together, SLP76 and LAT nucleate a multimolecular signaling complex, which induces a host of downstream responses, including calcium flux, mitogen-activated protein kinase (MAPK) activation, integrin activation, and cytoskeletal reorganization. APC, antigen-presenting cell; NFAT, nuclear factor of activated T cells. *(Reproduced with permission from GA Koretzky, F Abtahian, MA Silverman. SLP76 and SLP65: complex regulation of signalling in lymphocytes and beyond. Nat Rev Immunol 6:67, 2006.)*

inserted into the T-cell surface membrane, TCR-α being paired with TCR-β and TCR-γ being paired with TCR-δ. Molecules of the CD3 complex mediate transduction of T-cell activation signals via TCRs, whereas TCR-α and -β or -γ and -δ molecules combine to form the TCR antigen-binding site.

The α, β, γ, and δ TCR for antigen molecules have amino acid sequence homology and structural similarities to immunoglobulin heavy and light chains and are members of the *immunoglobulin gene superfamily* of molecules. The genes encoding TCR molecules are encoded as clusters of gene segments that rearrange during T-cell maturation. This creates an efficient and compact mechanism for housing the diversity requirements of antigen receptor molecules. The TCR-α chain is on chromosome 14 and consists of a series of V (variable), J (joining), and C (constant) regions. The TCR-β chain is on chromosome 7 and consists of multiple V, D (diversity), J, and C TCR-β loci. The TCR-γ chain is on chromosome 7, and the TCR-δ chain is in the middle of the TCR-α locus on chromosome 14. Thus, molecules of the TCR for antigen have constant (framework) and variable regions, and the gene segments encoding the α, β, γ, and δ chains of these molecules are recombined and selected in the thymus, culminating in synthesis of the completed molecule. In both T- and B-cell precursors (see below), DNA rearrangements of antigen receptor genes involve the same enzymes, recombinase activating gene RAG1 and RAG2, both DNA-dependent protein kinases.

TCR diversity is created by the different V, D, and J segments that are possible for each receptor chain by the many permutations of V, D, and J segment combinations, by "N-region diversification" due to the addition of nucleotides at the junction of rearranged gene segments, and by the pairing of individual chains to form a TCR dimer. As T cells mature in the thymus, the repertoire of antigen-reactive T cells is modified by selection processes that eliminate many autoreactive T cells, enhance the proliferation of cells that function appropriately with self-MHC molecules and antigen, and allow T cells with nonproductive TCR rearrangements to die.

TCR-αβ cells do not recognize native protein or carbohydrate antigens. Instead, T cells recognize only short (~9–13 amino acids) peptide fragments derived from protein antigens taken up or produced in APCs. Foreign antigens may be taken up by endocytosis into acidified intracellular vesicles or by phagocytosis and degraded into small peptides that associate with MHC class II molecules (exogenous antigen-presentation pathway). Other foreign antigens arise endogenously in the cytosol (such as from replicating viruses) and are broken down into small peptides that associate with MHC class I molecules (endogenous antigen-presenting pathway). Thus, APCs proteolytically degrade foreign proteins and display peptide fragments embedded in the MHC class I or II antigen-recognition site on the MHC molecule surface, where foreign peptide fragments are available to bind to TCR-αβ or TCR-γδ chains of reactive T cells. CD4 molecules act as adhesives and, by direct binding to MHC class II (DR, DQ, or DP) molecules, stabilize the interaction of TCR with peptide antigen (Fig. 349-7). Similarly, CD8 molecules also act as adhesives to stabilize the TCR-antigen interaction by direct CD8 molecule binding to MHC class I (A, B, or C) molecules.

Antigens that arise in the cytosol and are processed via the endogenous antigen-presentation pathway are cleaved into small peptides by a complex of proteases called the *proteasome*. From the proteasome, antigen peptide fragments are transported from the cytosol into the lumen of the endoplasmic reticulum by a heterodimeric complex termed *transporters associated with antigen processing* or TAP proteins. There, MHC class I molecules in the endoplasmic reticulum membrane physically associate with processed cytosolic peptides. Following peptide association with class I molecules, peptide–class I complexes are exported to the Golgi apparatus, and then to the cell surface, for recognition by CD8+ T cells.

Antigens taken up from the extracellular space via endocytosis into intracellular acidified vesicles are degraded by vesicle proteases into peptide fragments. Intracellular vesicles containing MHC class II molecules fuse with peptide-containing vesicles, thus allowing peptide fragments to physically bind to MHC class II molecules. Peptide–MHC class II complexes are then transported to the cell surface for recognition by CD4+ T cells.

Whereas it is generally agreed that the TCR-αβ receptor recognizes peptide antigens in the context of MHC class I or class II molecules, lipids in the cell wall of intracellular bacteria such as *M. tuberculosis* can also be presented to a wide variety of T cells, including subsets of TCR-γδ T cells, and a subset of CD8+ TCR-αβ T cells. Importantly, bacterial lipid antigens are not presented in the context of MHC class I or II molecules, but rather are presented in the context of MHC-related CD1 molecules. Some γδ T cells that recognize lipid antigens via CD1 molecules have very restricted TCR usage, do not need antigen priming to respond to bacterial lipids, and may be a form of innate rather than acquired immunity to intracellular bacteria.

Just as foreign antigens are degraded and their peptide fragments presented in the context of MHC class I or class II molecules on APCs, endogenous self-proteins also are degraded, and self-peptide fragments are presented to T cells in the context of MHC class I or class II molecules on APCs. In peripheral lymphoid organs, there are T cells that are capable of recognizing self-protein fragments but normally are *anergic* or *tolerant*, i.e., nonresponsive to self-antigenic stimulation, due to lack of self-antigen upregulating APC *co-stimulatory molecules* such as B7-1 (CD80) and B7-2 (CD86) (see below and **Chap. 350**).

Once engagement of mature T-cell TCR by foreign peptide occurs in the context of self-MHC class I or class II molecules, binding of non-antigen-specific adhesion ligand pairs such as CD54-CD11/CD18 and CD58-CD2 stabilizes MHC peptide-TCR binding, and the expression of these adhesion molecules is upregulated (Fig. 349-6). Once antigen ligation of the TCR occurs, the T-cell membrane is partitioned into *lipid membrane microdomains*, or *lipid rafts*, that coalesce the key signaling molecules TCR/CD3 complex, CD28, CD2, LAT (linker for activation of T cells), intracellular activated (dephosphorylated) src family protein tyrosine kinases (PTKs), and the key CD3ζ-associated protein-70 (ZAP-70) PTK (Fig. 349-7). Importantly, during T-cell activation, the CD45 molecule, with protein tyrosine phosphatase activity, is partitioned away from the TCR complex to allow activating phosphorylation events to occur. The coalescence of signaling molecules of activated T lymphocytes in *microdomains* has suggested that T cell–APC interactions can be considered *immunologic synapses*, analogous in function to neuronal synapses.

After TCR-MHC binding is stabilized, activation signals are transmitted through the cell to the nucleus and lead to the expression of gene products important in mediating the wide diversity of T-cell functions such as the secretion of IL-2. The TCR does not have intrinsic signaling activity but is linked to a variety of signaling pathways via ITAMs expressed on the various CD3 chains that bind to proteins that mediate signal transduction. Each of the pathways results in the activation of particular transcription factors that control the expression of cytokine and cytokine receptor genes. Thus, antigen-MHC binding to the TCR induces the activation of the src family of PTKs, Fyn and Lck (Lck is associated with CD4 or CD8 co-stimulatory molecules); phosphorylation of CD3ζ chain; activation of the related tyrosine kinases ZAP-70 and Syk; and downstream activation of the calcium-dependent calcineurin pathway, the ras pathway, and the protein kinase C pathway. Each of these pathways leads to activation of specific families of transcription factors (including *NF-AT*, *fos* and *jun*, and *rel/NF-κB*) that form heteromultimers capable of inducing expression of IL-2, IL-2 receptor, IL-4, TNF-α, and other T-cell mediators.

In addition to the signals delivered to the T cell from the TCR complex and CD4 and CD8, molecules on the T cell, such as CD28 and inducible co-stimulator (ICOS), and molecules on DCs, such as B7-1 (CD80) and B7-2 (CD86), also deliver important co-stimulatory signals that upregulate T-cell cytokine production and are essential for T-cell activation. If signaling through CD28 or ICOS does not occur, or if CD28 is blocked, the T cell becomes anergic rather than activated (see "Immune Tolerance and Autoimmunity" below and **Chap. 350**). CTLA-4 (CD152) is similar to CD28 in its ability to bind CD80 and CD86. Unlike CD28, CTLA-4 transmits an inhibitory signal to T cells, acting as an off switch.

T-CELL EXHAUSTION IN VIRAL INFECTIONS AND CANCER In chronic viral infections such as HIV-1, hepatitis C virus, and hepatitis B virus and in chronic malignancies, the persistence of antigen disrupts memory

T-cell function, resulting in defects in memory T-cell responses. This has been defined as *T-cell exhaustion* and is associated with T-cell programmed cell death protein 1 (PD-1) (CD279) expression. Exhausted T cells have compromised proliferation and lose the ability to produce effector molecules, like IL-2, TNF-α, and IFN-γ. PD-1 downregulates T-cell responses and is associated with T-cell exhaustion and disease progression. For this reason, inhibition of T-cell PD-1 activity to enhance effector T-cell function is being explored as a target for immunotherapy in both viral infections and certain malignancies **(Chap. 350)**.

T-CELL SUPERANTIGENS Conventional antigens bind to MHC class I or II molecules in the groove of the αβ heterodimer and bind to T cells via the V regions of the TCR-α and -β chains. In contrast, superantigens bind directly to the lateral portion of the TCR-β chain and MHC class II β chain and stimulate T cells based solely on the Vβ gene segment used independent of the D, J, and Vα sequences present. *Superantigens* are protein molecules capable of activating up to 20% of the peripheral T-cell pool, whereas conventional antigens activate <1 in 10,000 T cells. T-cell superantigens include staphylococcal enterotoxins and other bacterial products. Superantigen stimulation of human peripheral T cells occurs in the clinical setting of *staphylococcal toxic shock syndrome*, leading to massive overproduction of T-cell cytokines that leads to hypotension and shock **(Chap. 147)**.

B CELLS Mature B cells constitute 5–10% of human peripheral blood lymphocytes, 20–30% of lymph node cells, 50% of splenic lymphocytes, and ~10% of bone marrow lymphocytes. B cells express on their surface intramembrane immunoglobulin (Ig) molecules that function as BCRs for antigen in a complex of Ig-associated α and β signaling molecules with properties similar to those described in T cells **(Fig. 349-8)**. Unlike T cells, which recognize only processed peptide fragments of conventional antigens embedded in the notches of MHC class I and class II antigens of APCs, B cells are capable of recognizing and proliferating to whole unprocessed native antigens via antigen binding to B-cell surface Ig (sIg) receptors. B cells also express surface receptors for the Fc region of IgG molecules (CD32) as well as receptors for activated complement components (C3d or CD21, C3b or CD35). The primary function of B cells is to produce antibodies. B cells also serve as APCs and are highly efficient at antigen processing. Their antigen-presenting function is enhanced by a variety of cytokines. Mature B cells are derived from bone marrow precursor cells that arise continuously throughout life (Fig. 349-6).

B lymphocyte development can be separated into antigen-independent and antigen-dependent phases. Antigen-independent B-cell development occurs in primary lymphoid organs and includes all stages of B-cell maturation up to the sIg+ mature B cell. Antigen-dependent B-cell maturation is driven by the interaction of antigen with the mature B-cell sIg, leading to memory B-cell induction, Ig class switching, and plasma cell formation. Antigen-dependent stages of B-cell maturation occur in secondary lymphoid organs, including lymph node, spleen, and gut Peyer's patches. In contrast to the T-cell repertoire that is generated intrathymically before contact with foreign antigen, the repertoire of B cells expressing diverse antigen-reactive sites is modified by further alteration of Ig genes after stimulation by antigen—a process called *somatic hypermutation*—that occurs in lymph node germinal centers.

During B-cell development, diversity of the antigen-binding variable region of Ig is generated by an ordered set of Ig gene rearrangements

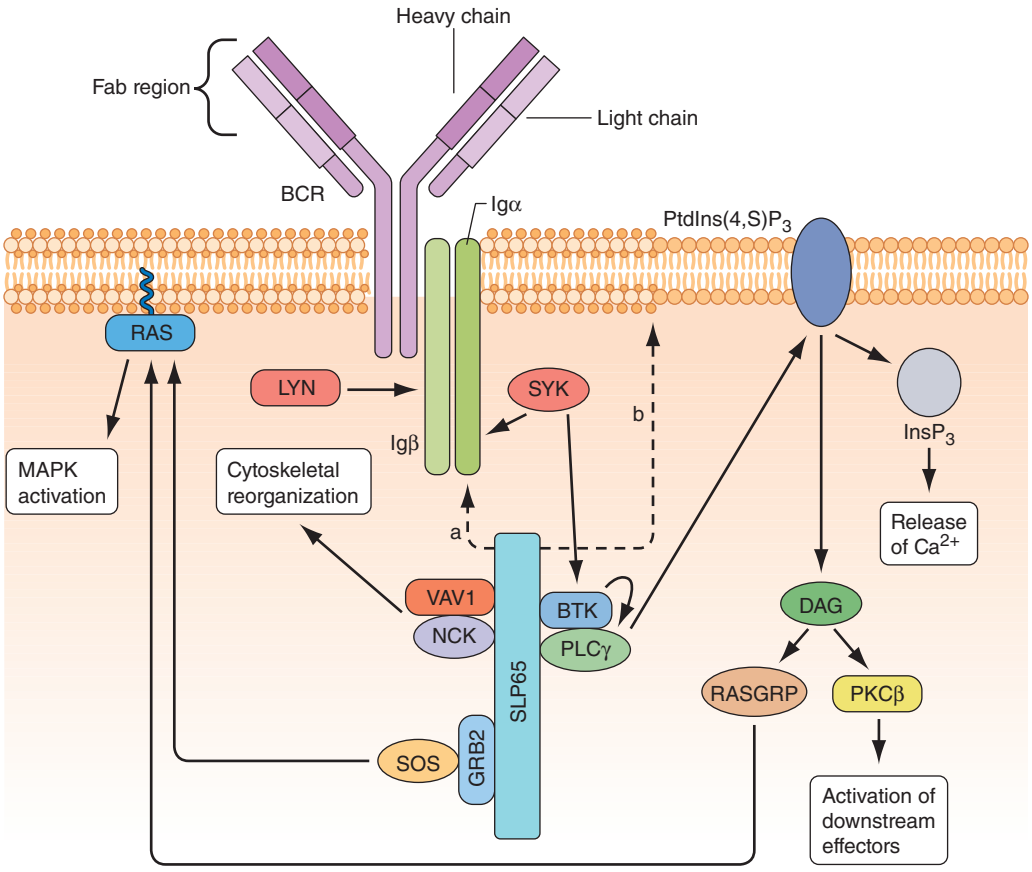

FIGURE 349-8 B-cell receptor (BCR) activation results in the sequential activation of protein tyrosine kinases, which results in the formation of a signaling complex and activation of downstream pathways as shown. Whereas SLP76 is recruited to the membrane through GADS and LAT, the mechanism of SLP65 recruitment is unclear. Studies have indicated two mechanisms: (a) direct binding by the SH2 domain of SLP65 to immunoglobulin (Ig) of the BCR complex or (b) membrane recruitment through a leucine zipper in the amino terminus of SLP65 and an unknown binding partner. ADAP, adhesion- and degranulation-promoting adaptor protein; AP1, activator protein 1; BTK, Bruton's tyrosine kinase; DAG, diacylglycerol; GRB2, growth factor receptor-bound protein 2; HPK1, hematopoietic progenitor kinase 1; $InsP_3$, inositol-1,4,5-trisphosphate; ITK, interleukin-2-inducible T-cell kinase; NCK, noncatalytic region of tyrosine kinase; NF-B, nuclear factor B; PKC, protein kinase C; PLC, phospholipase C; $PtdIns(4,5)P_2$, phosphatidylinositol-4,5-bisphosphate; RASGRP, RAS guanyl-releasing protein; SOS, son of sevenless homologue; SYK, spleen tyrosine kinase. *(Reproduced with permission from GA Koretzky, F Abtahian, MA Silverman. SLP76 and SLP65: complex regulation of signalling in lymphocytes and beyond. Nat Rev Immunol 6:67, 2006.)*

that are similar to the rearrangements undergone by TCR α, β, γ, and δ genes. For the heavy chain, there is first a rearrangement of D segments to J segments, followed by a second rearrangement between a V gene segment and the newly formed D-J sequence; the C segment is aligned to the V-D-J complex to yield a functional Ig heavy chain gene (V-D-J-C). During later stages, a functional κ or γ light chain gene is generated by rearrangement of a V segment to a J segment, ultimately yielding an intact Ig molecule composed of heavy and light chains.

The process of Ig gene rearrangement is regulated and results in a single antibody specificity produced by each B cell, with each Ig molecule comprising one type of heavy chain and one type of light chain. Although each B cell contains two copies of Ig light and heavy chain genes, only one gene of each type is productively rearranged and expressed in each B cell, a process termed *allelic exclusion*.

There are ~300 V_κ genes and 5 J_κ genes, resulting in the pairing of V_κ and J_κ genes to create >1500 different kappa light chain combinations. There are ~70 V_λ genes and 4 J_λ genes for >280 different lambda light chain combinations. The number of distinct light chains that can be generated is increased by somatic mutations within the V and J genes, thus creating large numbers of possible specificities from a limited amount of germline genetic information. As noted above, in heavy chain Ig gene rearrangement, the VH domain is created by the joining of three types of germline genes called V_H, D_H, and J_H, thus allowing for even greater diversity in the variable region of heavy chains than of light chains.

The most immature B-cell precursors (early pro-B cells) lack cytoplasmic Ig (cIg) and sIg (Fig. 349-6). The large pre-B cell is marked by the acquisition of the surface pre-BCR composed of μ heavy (H) chains and a pre-B light chain, termed *V pre-B*. V pre-B is a surrogate light chain receptor encoded by the non-rearranged V pre-B and the γ5 light chain locus (the pre-BCR). Pro- and pre-B cells are driven to proliferate and mature by signals from bone marrow stroma—in particular, IL-7. Light chain rearrangement occurs in the small pre-B-cell stage such that the full BCR is expressed at the immature B-cell stage. Immature B cells have rearranged Ig light chain genes and express sIgM. As immature B cells develop into mature B cells, sIgD is expressed as well as sIgM. At this point, B lineage development in bone marrow is complete, and B cells exit into the peripheral circulation and migrate to secondary lymphoid organs to encounter specific antigens.

Random rearrangements of Ig genes occasionally generate self-reactive antibodies, and mechanisms must be in place to correct these mistakes. One such mechanism is BCR editing, whereby autoreactive BCRs are mutated to not react with self-antigens. If receptor editing is unsuccessful in eliminating autoreactive B cells, then autoreactive B cells undergo negative selection in the bone marrow through induction of apoptosis after BCR engagement of self-antigen.

After leaving the bone marrow, B cells populate peripheral B-cell sites, such as lymph node and spleen, and await contact with foreign antigens that react with each B cell's clonotypic receptor. Antigen-driven B-cell activation occurs through the BCR, and a process known as *somatic hypermutation* takes place whereby point mutations in rearranged H- and L-genes give rise to mutant sIg molecules, some of which bind antigen better than the original sIg molecules. Somatic hypermutation, therefore, is a process whereby memory B cells in peripheral lymph organs have the best binding or the highest-affinity antibodies. This overall process of generating the best antibodies is called *affinity maturation of antibody*.

Lymphocytes that synthesize IgG, IgA, and IgE are derived from sIgM+, sIgD+ mature B cells. Ig class switching occurs in lymph node and other peripheral lymphoid tissue germinal centers. CD40 on B cells and CD40 ligand on T cells constitute a critical co-stimulatory receptor-ligand pair of immune-stimulatory molecules. Pairs of CD40+ B cells and CD40 ligand+ T cells bind and drive B-cell Ig class switching via T cell–produced cytokines such as IL-4 and TGF-β. IL-1, -2, -4, -5, and -6 synergize to drive mature B cells to proliferate and differentiate into Ig-secreting cells.

Humoral Mediators of Adaptive Immunity: Immunoglobulins

Immunoglobulins are the products of differentiated B cells and mediate the humoral arm of the immune response. The primary functions of antibodies are to bind specifically to antigen and bring about the inactivation or removal of the offending toxin, microbe, parasite, or other foreign substance from the body. The structural basis of Ig molecule function and Ig gene organization has provided insight into the role of antibodies in normal protective immunity, pathologic immune-mediated damage by immune complexes, and autoantibody formation against host determinants.

All immunoglobulins have the basic structure of two heavy and two light chains (Fig. 349-8). Immunoglobulin isotype (i.e., G, M, A, D, E) is determined by the type of Ig heavy chain present. IgG and IgA isotypes can be divided further into subclasses (G1, G2, G3, G4, and A1, A2) based on specific antigenic determinants on Ig heavy chains. The characteristics of human immunoglobulins are outlined in **Table 349-9**. The four chains are covalently linked by disulfide bonds. Each chain is made up of a V region and C regions (also called *domains*), themselves made up of units of ~110 amino acids. Light chains have one variable (V_L) and one constant (C_L) unit; heavy chains have one variable unit (V_H) and three or four constant (C_H) units, depending on isotype. As the name suggests, the constant, or C, regions of Ig molecules are made up of homologous sequences and share the same primary structure as all other Ig chains of the

TABLE 349-9 Physical, Chemical, and Biologic Properties of Human Immunoglobulins

PROPERTY	IgG	IgA	IgM	IgD	IgE
Usual molecular form	Monomer	Monomer, dimer	Pentamer, hexamer	Monomer	Monomer
Other chains	None	J chain, SC	J chain	None	None
Subclasses	G1, G2, G3, G4	A1, A2	None	None	None
Heavy chain allotypes	Gm (=30)	No A1, A2m (2)	None	None	None
Molecular mass, kDa	150	160, 400	950, 1150	175	190
Serum level in average adult, mg/mL	9.5–12.5	1.5–2.6	0.7–1.7	0.04	0.0003
Percentage of total serum Ig	75–85	7–15	5–10	0.3	0.019
Serum half-life, days	23	6	5	3	2.5
Synthesis rate, mg/kg per day	33	65	7	0.4	0.016
Antibody valence	2	2, 4	10, 12	2	2
Classical complement activation	+(G1, 2?, 3)	–	++	–	–
Alternate complement activation	+(G4)	+	–	+	–
Binding cells via Fc	Macrophages, neutrophils, large granular lymphocytes	Lymphocytes	Lymphocytes	None	Mast cells, basophils, B cells
Biologic properties	Placental transfer, secondary antibody for most antipathogen responses	Secretory immunoglobulin	Primary antibody responses	Marker for mature B cells	Allergy, antiparasite responses

same isotype and subclass. Constant regions are involved in biologic functions of Ig molecules. The C_H2 domain of IgG and the C_H4 units of IgM are involved with the binding of the C1q portion of C1 during complement activation. The C_H region at the carboxy-terminal end of the IgG molecule, the Fc region, binds to surface Fc receptors (CD16, CD32, CD64) of macrophages, DCs, NK cells, B cells, neutrophils, and eosinophils. The Fc of IgA binds to FcαR (CD89), and the Fc of IgE binds to FcεR (CD23).

Variable regions (V_L and V_H) constitute the antibody-binding (Fab) region of the molecule. Within the V_L and V_H regions are hypervariable regions (extreme sequence variability) that constitute the antigen-binding site unique to each Ig molecule. The idiotype is defined as the specific region of the Fab portion of the Ig molecule to which antigen binds. Antibodies against the idiotype portion of an antibody molecule are called *anti-idiotype antibodies*. The formation of such antibodies in vivo during a normal B-cell antibody response may generate a negative (or "off") signal to B cells to terminate antibody production.

IgG constitutes ~75–85% of total serum immunoglobulin. The four IgG subclasses are numbered in order of their level in serum, IgG1 being found in greatest amounts and IgG4 the least. IgG subclasses have clinical relevance in their varying ability to bind macrophage and neutrophil Fc receptors and to activate complement (Table 349-9). Moreover, selective deficiencies of certain IgG subclasses give rise to clinical syndromes in which the patient is inordinately susceptible to bacterial infections. IgG antibodies are frequently the predominant antibody made after rechallenge of the host with antigen (secondary antibody response).

IgM antibodies normally circulate as a 950-kDa pentamer with 160-kDa bivalent monomers joined by a molecule called the *J chain*, a 15-kDa nonimmunoglobulin molecule that also effects polymerization of IgA molecules. IgM is the first immunoglobulin to appear in the immune response (primary antibody response) and is the initial type of antibody made by neonates. Membrane IgM in the monomeric form also functions as a major antigen receptor on the surface of mature B cells (Table 349-9). IgM is an important component of immune complexes in autoimmune diseases. For example, IgM antibodies against IgG molecules (rheumatoid factors) are present in high titers in *rheumatoid arthritis*, other collagen diseases, and some infectious diseases (*subacute bacterial endocarditis*).

IgA constitutes only 7–15% of total serum immunoglobulin but is the predominant class of immunoglobulin in secretions. IgA in secretions (tears, saliva, nasal secretions, gastrointestinal tract fluid, and human milk) is in the form of secretory IgA (sIgA), a polymer consisting of two IgA monomers, a joining molecule, again termed the J chain, and a glycoprotein called the *secretory protein*. Of the two IgA subclasses, IgA1 is primarily found in serum, whereas IgA2 is more prevalent in secretions. IgA fixes complement via the alternative complement pathway and has potent antiviral activity in humans by prevention of virus binding to respiratory and gastrointestinal epithelial cells.

IgD is found in minute quantities in serum and, together with IgM, is a major receptor for antigen on the naïve B-cell surface. IgE, which is present in serum in very low concentrations, is the major class of immunoglobulin involved in arming mast cells and basophils by binding to these cells via the Fc region. Antigen cross-linking of IgE molecules on basophil and mast cell surfaces results in release of mediators of the immediate hypersensitivity (allergic) response (Table 349-9).

CELLULAR INTERACTIONS IN REGULATION OF NORMAL IMMUNE RESPONSES

The net result of activation of the humoral (B-cell) and cellular (T-cell) arms of the adaptive immune system by foreign antigen is the elimination of antigen directly by specific effector T cells or in concert with specific antibody.

The expression of adaptive immune cell function is the result of a complex series of immunoregulatory events that occur in phases. Both T and B lymphocytes mediate immune functions, and each of these cell types, when given appropriate signals, passes through stages, from activation and induction through proliferation, differentiation, and ultimately effector functions. The effector function expressed may be at the end point of a response, such as secretion of antibody by a differentiated plasma cell, or it might serve a regulatory function that modulates other functions, such as is seen with CD4+ and CD8+ T lymphocytes that modulate both differentiation of B cells and activation of CD8+ cytotoxic T cells.

CD4 helper T cells can be subdivided on the basis of cytokines produced (Fig. 349-2). Activated T_H1-type helper T cells secrete IL-2, IFN-γ, IL-3, TNF-α, GM-CSF, and TNF-β, whereas activated T_H2-type helper T cells secrete IL-3, -4, -5, -6, -10, and -13. T_H1 CD4+ T cells, through elaboration of IFN-γ, have a central role in mediating intracellular killing by a variety of pathogens. T_H1 CD4+ T cells also provide T-cell help for generation of cytotoxic T cells and some types of opsonizing antibody, and they generally respond to antigens that lead to delayed hypersensitivity types of immune responses for many intracellular viruses and bacteria (such as HIV-1 or *M. tuberculosis*). In contrast, T_H2 cells have a primary role in regulatory humoral immunity and isotype switching. T_H2 cells, through production of IL-4 and IL-10, have a regulatory role in limiting proinflammatory responses mediated by T_H1 cells (Fig. 349-2). In addition, T_H2 CD4+ T cells provide help to B cells for specific Ig production and respond to antigens that require high antibody levels for foreign antigen elimination (extracellular encapsulated bacteria such as *S. pneumoniae* and certain parasite infections). Additional subsets of the CD4 T_H cells have been described, one of which is termed T_H17, that secrete cytokines IL-17, -22, and -26. T_H17 cells have been shown to play a role in autoimmune inflammatory disorders in addition to defense against extracellular bacteria and fungi, particularly at mucosal surfaces. T_H9 cells are defined by their secretion of IL-9 and have been shown to play a role in atopic disease, inflammatory bowel disease, and antitumor immunity. Moreover, the Tfh subset of helper T cells is crucial for providing the necessary signals to B cells in germinal centers to undergo affinity maturation. A subset of Tfh cells called Tfh13 cells secrete IL-4, IL-5, and IL-13 in response to allergens and mediate anaphylaxis reactions (Fig. 349-2). In summary, the type of T-cell response generated in an immune response is determined by the microbe PAMPs presented to the DCs, the TLRs on the DCs that become activated, the types of DCs that are activated, and the cytokines that are produced (Table 349-6). Commonly, myeloid DCs produce IL-12 and activate T_H1 T-cell responses that result in IFN-γ and cytotoxic T-cell induction, and plasmacytoid DCs produce IFN-α and lead to T_H2 responses that result in IL-4 production and enhanced antibody responses.

As shown in Fig. 349-2, upon activation by DCs, T-cell subsets that produce IL-2, IL-3, IFN-γ, and/or IL-4, -5, -6, -10, and -13 are generated and exert positive and negative influences on effector T and B cells. For B cells, trophic effects are mediated by a variety of cytokines, particularly T cell–derived IL-3, -4, -5, and -6, that act at sequential stages of B-cell maturation, resulting in B-cell proliferation, differentiation, and ultimately antibody secretion. For cytotoxic T cells, trophic factors include inducer T-cell secretion of IL-2, IFN-γ, and IL-12.

Important types of immunomodulatory T cells that control immune responses are *CD4+ and CD8+ T regulatory cells*. These cells express the α chain of the IL-2 receptor (CD25), produce IL-10, and suppress both T- and B-cell responses. T regulatory cells (Tregs) are induced by immature DCs and play key roles in maintaining tolerance to self-antigens. Loss of Treg cells is the cause of organ-specific autoimmune disease in mice such as autoimmune thyroiditis, adrenalitis, and oophoritis (see "Immune Tolerance and Autoimmunity" below, **Chap. 350**). Tregs also play key roles in controlling the magnitude and duration of immune responses to microbes. Normally, after the initial immune response to a microbe has eliminated the invader, Tregs are activated to suppress the antimicrobe response and prevent host injury. Some microbes have adapted to induce Treg activation at the site of infection to promote parasite infection and survival. In *Leishmania* infection, the parasite induces Treg accumulation at skin infection sites that dampens anti-*Leishmania* T-cell responses and prevents parasite elimination. Although B cells recognize native antigen via B-cell surface Ig receptors, B cells require T-cell help to produce high-affinity antibody of multiple isotypes that are the most effective in eliminating foreign antigen. In B cell germinal centers, the CD4 T cells that promote B cell maturation and affinity maturation are termed T follicular

helper (Tfh) cells. T cell–B cell interactions that lead to high-affinity antibody production require (1) processing of native antigen by B cells and expression of peptide fragments on the B-cell surface for presentation to T_H cells, (2) the ligation of B cells by both the TCR complex and the CD40 ligand, (3) induction of the process termed *antibody isotype switching* in antigen-specific B-cell clones, and (4) induction of the process of affinity maturation of antibody in the germinal centers of B-cell follicles of lymph node and spleen.

Naïve B cells express cell-surface IgD and IgM, and initial contact of naïve B cells with antigen is via binding of native antigen to B-cell surface IgM. T-cell cytokines, released following T_H2 cell contact with B cells or by a "bystander" effect, induce changes in Ig gene conformation that promote recombination of Ig genes. These events then result in the switching of expression of heavy chain exons in a triggered B cell, leading to the secretion of IgG, IgA, or, in some cases, IgE antibody with the same V region antigen specificity as the original IgM antibody, for response to a wide variety of extracellular bacteria, protozoa, and helminths. CD40 ligand expression by activated T cells is critical for induction of B-cell antibody isotype switching and for B-cell responsiveness to cytokines. Patients with mutations in T-cell CD40 ligand have B cells that are unable to undergo isotype switching, resulting in lack of memory B-cell generation and the immunodeficiency syndrome of *X-linked hyper-IgM syndrome* **(Chaps. 350 and 351)**.

IMMUNE TOLERANCE AND AUTOIMMUNITY

Immune tolerance is defined as the absence of activation of pathogenic autoreactivity to self-antigens. *Autoimmune diseases* are syndromes caused by the activation of T or B cells or both, with no evidence of other causes such as infections or malignancies **(Chaps. 350 and 355)**. Immune tolerance and autoimmunity are present normally in health; when abnormal, they represent extremes from the normal state. For example, low levels of autoreactivity of T and B cells with self-antigens in the periphery are critical to T- and B-cell survival. Similarly, low levels of autoreactivity and thymocyte recognition of self-antigens in the thymus are the mechanisms whereby normal T cells are positively selected to survive and leave the thymus to respond to foreign microbes in the periphery and T cells highly reactive to self-antigens are negatively selected and die to prevent overly self-reactive T cells from migrating to the periphery (central tolerance). However, not all self-antigens are expressed in the thymus to delete highly self-reactive T cells, and there are mechanisms for induction of tolerance in peripheral T cells as well. Unlike the presentation of microbial antigens by mature DCs, the presentation of self-antigens by immature DCs neither activates nor matures the DCs to express high levels of co-stimulatory molecules such as B7-1 (CD80) or B7-2 (CD86). When peripheral T cells are stimulated by DCs expressing self-antigens in the context of HLA molecules, sufficient stimulation of T cells occurs to keep them alive, but otherwise, they remain anergic, or nonresponsive, until T cells contact a DC with high levels of co-stimulatory molecules expressing microbial antigens and become activated to respond to the microbe. If B cells have high self-reactive BCRs, they normally undergo either deletion in the bone marrow or receptor editing to express a less autoreactive receptor. Although many autoimmune diseases are characterized by abnormal or pathogenic autoantibody production **(Table 349-10)**, most autoimmune diseases are caused by a combination of excess T- and B-cell reactivity.

Multiple factors contribute to the genesis of autoimmune disease syndromes, including genetic susceptibility (e.g. HLAB27 with ankylosing spondylitis), environmental immune stimulants such as drugs (e.g., procainamide and phenytoin [Dilantin] with drug-induced systemic lupus erythematosus), infectious agent triggers (such as Epstein-Barr virus and autoantibody production against red blood cells and platelets), and loss of T regulatory cells (leading to thyroiditis, adrenalitis, and oophoritis).

Immunity at Mucosal Surfaces Mucosa covering the respiratory, digestive, and urogenital tracts; the eye conjunctiva; the inner ear; and the ducts of all exocrine glands contain cells of the innate and adaptive mucosal immune system that protect these surfaces against pathogens. In the healthy adult, mucosa-associated lymphoid tissue (MALT) contains 80% of all immune cells within the body and constitutes the largest mammalian lymphoid organ system.

MALT has three main functions: (1) to protect the mucous membranes from invasive pathogens; (2) to prevent uptake of foreign antigens from food, commensal organisms, and airborne pathogens and particulate matter; and (3) to prevent pathologic immune responses from foreign antigens if they do cross the mucosal barriers of the body.

MALT is a compartmentalized system of immune cells that functions independently from systemic immune organs. Whereas the systemic immune organs are essentially sterile under normal conditions and respond vigorously to pathogens, MALT immune cells are continuously bathed in foreign proteins and commensal bacteria, and they must select those pathogenic antigens that must be eliminated. MALT contains anatomically defined foci of immune cells in the intestine, tonsil, appendix, and peribronchial areas that are inductive sites for mucosal immune responses. From these sites, immune T and B cells migrate to effector sites in mucosal parenchyma and exocrine glands where mucosal immune cells eliminate pathogen-infected cells. In addition to mucosal immune responses, all mucosal sites have strong mechanical and chemical barriers and cleansing functions to repel pathogens.

Key components of MALT include specialized epithelial cells called "membrane" or "M" cells that take up antigens and deliver them to DCs or other APCs. Effector cells in MALT include B cells producing antipathogen neutralizing antibodies of secretory IgA as well as IgG isotype, T cells producing similar cytokines as in systemic immune system response, and T helper and cytotoxic T cells that respond to pathogen-infected cells.

Secretory IgA is produced in amounts of >50 mg/kg of body weight per 24 h and functions to inhibit bacterial adhesion, inhibit macromolecule absorption in the gut, neutralize viruses, and enhance antigen elimination in tissue through binding to IgA and receptor-mediated transport of immune complexes through epithelial cells.

Recent studies have demonstrated the importance of commensal gut and other mucosal bacteria to the health of the human immune system. Normal commensal flora induces anti-inflammatory events in the gut and protects epithelial cells from pathogens through TLRs and other PRR signaling. When the gut is depleted of normal commensal flora, the immune system becomes abnormal, with loss of T_H1 T-cell function. Restoration of the normal gut flora can reestablish the balance in T helper cell ratios characteristic of the normal immune system. Diet also has an impact on the gut microbiome. Altered microbiome composition has been etiologically related to obesity, insulin resistance, and diabetes. When the gut barrier is intact, either antigens do not transverse the gut epithelium or, when pathogens are present, a self-limited, protective MALT immune response eliminates the pathogen (Fig. 349-8). However, when the gut barrier breaks down, immune responses to commensal flora antigens can cause inflammatory bowel diseases such as *Crohn's disease* and, perhaps, *ulcerative colitis* **(Chap. 326)**. Uncontrolled MALT immune responses to food antigens, such as gluten, can cause *celiac disease* **(Chap. 326)**.

THE CELLULAR AND MOLECULAR CONTROL OF PROGRAMMED CELL DEATH

The process of apoptosis (programmed cell death) plays a crucial role in regulating normal immune responses to antigen. In general, a wide variety of stimuli trigger one of several apoptotic pathways to eliminate microbe-infected cells, eliminate cells with damaged DNA, or eliminate activated immune cells that are no longer needed **(Fig. 349-9)**. The largest known family of "death receptors" is the TNF receptor (TNF-R) family (TNF-R1, TNF-R2, Fas [CD95], death receptor 3 [DR3], death receptor 4 [DR4; TNF-related apoptosis-including ligand receptor 1, or TRAIL-R1], and death receptor 5 [DR5, TRAIL-R2]); their ligands are all in the TNF-α family. Binding of ligands to these death receptors leads to a signaling cascade that involves activation of the *caspase* family of molecules that leads to DNA cleavage and cell death. Two other pathways of programmed cell death involve nuclear *p53* in the elimination of cells with abnormal DNA and *mitochondrial cytochrome c* to induce cell death in damaged cells (Fig. 349-9). A number of human diseases have now been described that result from, or are

TABLE 349-10 Recombinant or Purified Autoantigens Recognized by Autoantibodies Associated with Human Autoimmune Disorders

AUTOANTIGEN	AUTOIMMUNE DISEASES
Cell- or Organ-Specific Autoimmunity	
Acetylcholine receptor	Myasthenia gravis
Actin	Chronic active hepatitis, primary biliary cirrhosis
Adenine nucleotide translator (ANT)	Dilated cardiomyopathy, myocarditis
β-Adrenoreceptor	Dilated cardiomyopathy
Aromatic L-amino acid decarboxylase	Autoimmune polyendocrine syndrome type 1 (APS-1)
Asialoglycoprotein receptor	Autoimmune hepatitis
Bactericidal/permeability-increasing protein (Bpi)	Cystic fibrosis vasculitides
Calcium-sensing receptor	Acquired hypoparathyroidism
Cholesterol side-chain cleavage enzyme (CYP11a)	Autoimmune polyglandular syndrome-1
Collagen type IV-α3-chain	Goodpasture's syndrome
Cytochrome P450 2D6 (CYP2D6)	Autoimmune hepatitis
Desmin	Crohn's disease, coronary artery disease
Desmoglein 1	Pemphigus foliaceus
Desmoglein 3	Pemphigus vulgaris
F-actin	Autoimmune hepatitis
GM gangliosides	Guillain-Barré syndrome
Glutamate decarboxylase (GAD65)	Type 1 diabetes, stiff-person syndrome
Glutamate receptor (GLUR)	Rasmussen encephalitis
H/K ATPase	Autoimmune gastritis
17-α-Hydroxylase (CYP17)	Autoimmune polyglandular syndrome-1
21-Hydroxylase (CYP21)	Addison's disease
IA-2 (ICA512)	Type 1 diabetes
Insulin	Type 1 diabetes, insulin hypoglycemic syndrome (Hirata's disease)
Insulin receptor	Type B insulin resistance, acanthosis, systemic lupus erythematosus
Intrinsic factor type 1	Pernicious anemia
Leukocyte function-associated antigen (LFA-1)	Treatment-resistant Lyme arthritis
Myelin-associated glycoprotein (MAG)	Polyneuropathy
Myelin-basic protein	Multiple sclerosis, demyelinating diseases
Myelin oligodendrocyte glycoprotein (MOG)	Multiple sclerosis
Myosin	Rheumatic fever
p-80-Collin	Atopic dermatitis
Pyruvate dehydrogenase complex-E2 (PDC-E2)	Primary biliary cirrhosis
Sodium iodide symporter (NIS)	Graves' disease, autoimmune hypothyroidism
SOX-10	Vitiligo
Thyroid and eye muscle shared protein	Thyroid-associated ophthalmopathy
Thyroglobulin	Autoimmune thyroiditis
Thyroid peroxidase	Autoimmune Hashimoto's thyroiditis
Thyrotropin receptor	Graves' disease
Tissue transglutaminase	Celiac disease
Transcription coactivator p75	Atopic dermatitis
Tryptophan hydroxylase	Autoimmune polyglandular syndrome-1
Tyrosinase	Vitiligo, metastatic melanoma
Tyrosine hydroxylase	Autoimmune polyglandular syndrome-1
Systemic Autoimmunity	
ACTH	ACTH deficiency
Aminoacyl-tRNA histidyl synthetase	Myositis, dermatomyositis
Aminoacyl-tRNA synthetase (several)	Polymyositis, dermatomyositis
Cardiolipin	Systemic lupus erythematosus, antiphospholipid syndrome
Carbonic anhydrase II	Systemic lupus erythematosus, Sjögren's syndrome, systemic sclerosis
Collagen (multiple types)	Rheumatoid arthritis, systemic lupus erythematosus, progressive systemic sclerosis
Centromere-associated proteins	Systemic sclerosis
DNA-dependent nucleoside-stimulated ATPase	Dermatomyositis
Fibrillarin	Scleroderma
Fibronectin	Systemic lupus erythematosus, rheumatoid arthritis, morphea
Glucose-6-phosphate isomerase	Rheumatoid arthritis
β2-Glycoprotein I (B2-GPI)	Primary antiphospholipid syndrome
Golgin (95, 97, 160, 180) Heat shock protein	Sjögren's syndrome, systemic lupus erythematosus, rheumatoid arthritis, various immune-related disorders
Hemidesmosomal protein 180	Bullous pemphigoid, herpes gestationis, cicatricial pemphigoid
Histone H2A-H2B-DNA	Systemic lupus erythematosus
IgE receptor	Chronic idiopathic urticaria
Keratin	Rheumatoid arthritis
Ku-DNA-protein kinase	Systemic lupus erythematosus
Ku-nucleoprotein La phosphoprotein (La 55-B)	Connective tissue syndrome Sjögren's syndrome
Myeloperoxidase	Necrotizing and crescentic glomerulonephritis, systemic vasculitis
Proteinase 3 (PR3)	Granulomatosis with polyangiitis (Wegener's), Churg-Strauss syndrome
RNA polymerase I–III (RNP)	Systemic sclerosis, systemic lupus erythematosus
Signal recognition protein (SRP54)	Polymyositis
Topoisomerase-1 (Scl-70)	Scleroderma, Raynaud's syndrome
Tublin	Chronic liver disease, visceral leishmaniasis
Vimentin	Systemic autoimmune disease
Plasma Protein and Cytokine Autoimmunity	
C1 inhibitor	Autoimmune C1 deficiency
C1q	Systemic lupus erythematosus, membrane proliferative glomerulonephritis
Cytokines (IL-1α, IL-1β, IL-6, TNF-α, IFN-γ IL17A, IL-17F, GM-CSF)	IL-1α, IL-1β: rheumatoid arthritis, systemic sclerosis, systemic lupus erythematosus; IL-6: bacterial infections; IFN-γ: bacterial infections, varicella-zoster virus reactivation; IL-17A, IL-17F: chronic mucocutaneous candidiasis; GM-CSF: pulmonary alveolar proteinosis, fungal infections
Factor II, factor V, factor VII, factor VIII, factor IX, factor X, factor XI, thrombin vWF	Prolonged coagulation time
Glycoprotein IIb/IIIg and Ib/IX	Autoimmune thrombocytopenia purpura
IgA	Immunodeficiency associated with systemic lupus erythematosus, pernicious anemia, thyroiditis, Sjögren's syndrome, and chronic active hepatitis
Oxidized LDL (OxLDL)	Atherosclerosis
Cancer and Paraneoplastic Autoimmunity	
Amphiphysin	Neuropathy, small-cell lung cancer
Cyclin B1	Hepatocellular carcinoma

(*Continued*)

TABLE 349-10 Recombinant or Purified Autoantigens Recognized by Autoantibodies Associated with Human Autoimmune Disorders (Continued)

AUTOANTIGEN	AUTOIMMUNE DISEASES
Cancer and Paraneoplastic Autoimmunity (continued)	
DNA topoisomerase II	Liver cancer
Desmoplakin	Paraneoplastic pemphigus
Gephyrin	Paraneoplastic stiff-person syndrome
Hu proteins	Paraneoplastic encephalomyelitis
Neuronal nicotinic acetylcholine receptor	Subacute autonomic neuropathy, cancer
p53	Cancer, systemic lupus erythematosus
p62 (IGF-II mRNA-binding protein)	Hepatocellular carcinoma (China)
Recoverin	Cancer-associated retinopathy
Ri protein	Paraneoplastic opsoclonus myoclonus ataxia
βIV spectrin	Lower motor neuron syndrome
Synaptotagmin	Lambert-Eaton myasthenic syndrome
Voltage-gated calcium channels	Lambert-Eaton myasthenic syndrome
Yo protein	Paraneoplastic cerebellar degeneration

associated with, mutated apoptosis genes. These include mutations in the Fas and Fas ligand genes in autoimmune and lymphoproliferation syndromes, and multiple associations of mutations in genes in the apoptotic pathway with malignant syndromes **(Chap. 350)**.

MECHANISMS OF IMMUNE-MEDIATED DAMAGE TO MICROBES OR HOST TISSUES

Several responses by the host innate and adaptive immune systems to foreign microbes culminate in rapid and efficient elimination of microbes. In these scenarios, the classic weapons of the adaptive immune system (T cells, B cells) interface with cells (macrophages, DCs, NK cells, neutrophils, eosinophils, basophils) and soluble products (microbial peptides, pentraxins, complement and coagulation systems) of the innate immune system **(Chaps. 64 and 352)**.

There are five general phases of host defenses: (1) migration of leukocytes to sites of antigen localization; (2) antigen-nonspecific recognition of pathogens by macrophages and other cells and systems of the innate immune system; (3) specific recognition of foreign

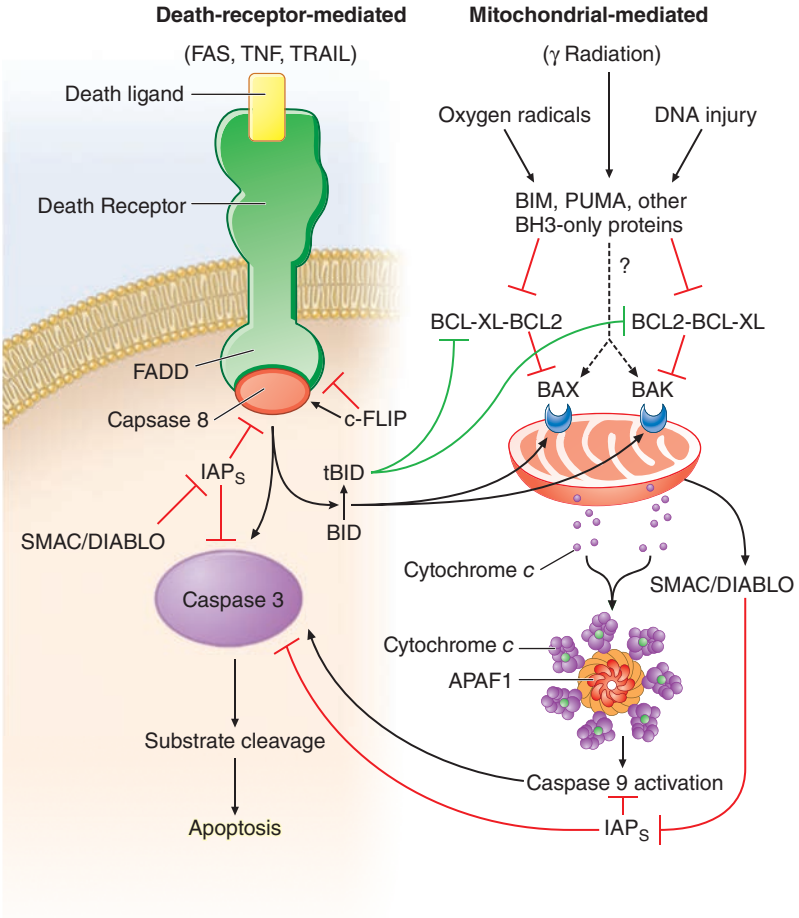

FIGURE 349-9 Pathways of cellular apoptosis. There are two major pathways of apoptosis: the death-receptor pathway, which is mediated by activation of death receptors, and the BCL2-regulated mitochondrial pathway, which is mediated by noxious stimuli that ultimately lead to mitochondrial injury. Ligation of death receptors recruits the adaptor protein FAS-associated death domain (FADD). FADD in turn recruits caspase 8, which ultimately activates caspase 3, the key "executioner" caspase. Cellular FLICE-inhibitory protein (c-FLIP) can either inhibit or potentiate binding of FADD and caspase 8, depending on its concentration. In the intrinsic pathway, proapoptotic BH3 proteins are activated by noxious stimuli, which interact with and inhibit antiapoptotic BCL2 or BCL-XL. Thus, BAX and BAK are free to induce mitochondrial permeabilization with release of cytochrome c, which ultimately results in the activation of caspase 9 through the apoptosome. Caspase 9 then activates caspase 3. SMAC/DIABLO is also released after mitochondrial permeabilization and acts to block the action of inhibitors of apoptosis protein (IAPs), which inhibit caspase activation. There is potential cross-talk between the two pathways, which is mediated by the truncated form of BID (tBID) that is produced by caspase 8–mediated BID cleavage; tBID acts to inhibit the BCL2-BCL-XL pathway and to activate BAX and BAK. There is debate (indicated by the *question mark*) as to whether proapoptotic BH3 molecules (e.g., BIM and PUMA) act directly on BAX and BAK to induce mitochondrial permeability or whether they act only on BCL2-BCL-XL. APAF1, apoptotic protease-activating factor 1; BH3, BCL homologue; TNF, tumor necrosis factor; TRAIL, TNF-related apoptosis-inducing ligand. *(From RS Hotchkiss et al: Cell death in disease: mechanisms and emerging therapeutic concepts. N Engl J Med 361:1570, 2009. Copyright © (2009) Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

antigens mediated by T and B lymphocytes; (4) amplification of the inflammatory response with recruitment of specific and nonspecific effector cells by complement components, cytokines, kinins, arachidonic acid metabolites, and mast cell–basophil products; and (5) macrophage, neutrophil, and lymphocyte participation in destruction of antigen with ultimate removal of antigen particles by phagocytosis (by macrophages or neutrophils) or by direct cytotoxic mechanisms (involving macrophages, neutrophils, DCs, and lymphocytes). Under normal circumstances, orderly progression of host defenses through these phases results in a well-controlled immune and inflammatory response that protects the host from the offending antigen. However, dysfunction of any of the host defense systems can damage host tissue and produce clinical disease. Furthermore, for certain pathogens or antigens, the normal immune response itself might contribute substantially to the tissue damage. For example, the immune and inflammatory response in the brain to certain pathogens such as *M. tuberculosis* may be responsible for much of the morbidity rate of this disease in that organ system **(Chap. 178)**. In addition, the morbidity rate associated with certain pneumonias such as that caused by *Pneumocystis jiroveci* may be associated more with inflammatory infiltrates than with the tissue-destructive effects of the microorganism itself **(Chap. 220)**.

Molecular Basis of Lymphocyte–Endothelial Cell Interactions The control of lymphocyte circulatory patterns between the bloodstream and peripheral lymphoid organs operates at the level of lymphocyte–endothelial cell interactions to control the specificity of lymphocyte subset entry into organs. Similarly, lymphocyte–endothelial cell interactions regulate the entry of lymphocytes into inflamed tissue. Adhesion molecule expression on lymphocytes and endothelial cells regulates the retention and subsequent egress of lymphocytes within tissue sites of antigenic stimulation, delaying cell exit from tissue and preventing reentry into the circulating lymphocyte pool **(Fig. 349-10)**. All types of lymphocyte migration begin with lymphocyte attachment to specialized regions of vessels, termed *high endothelial venules* (HEVs). An important concept is that adhesion molecules do not generally bind their ligand until a conformational change (ligand activation) occurs in the adhesion molecule that allows ligand binding. Induction of a conformation-dependent determinant on an adhesion molecule can be accomplished by cytokines or via ligation of other adhesion molecules on the cell.

The first stage of lymphocyte–endothelial cell interactions, *attachment and rolling*, occurs when lymphocytes leave the stream of flowing blood cells in a postcapillary venule and roll along venule endothelial

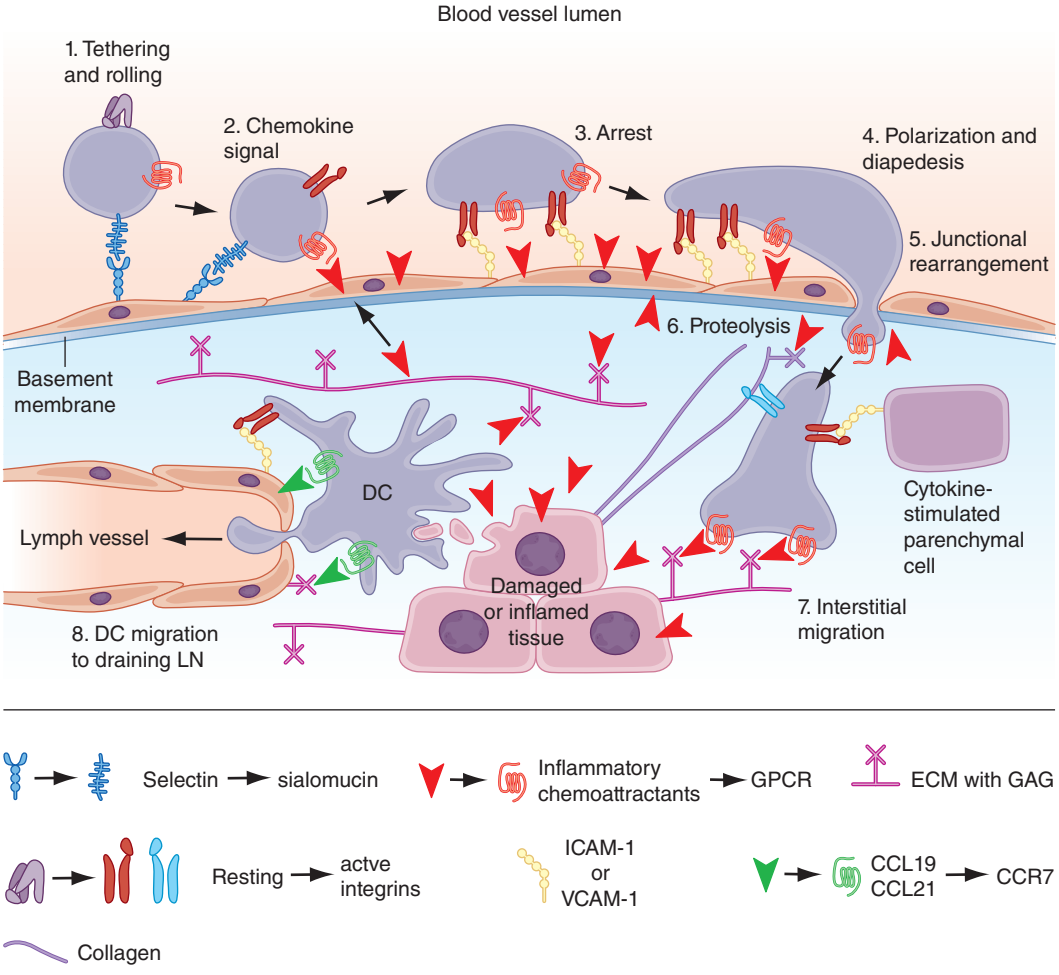

FIGURE 349-10 Key migration steps of immune cells at sites of inflammation. Inflammation due to tissue damage or infection induces the release of cytokines (not shown) and inflammatory chemoattractants (*red arrowheads*) from distressed stromal cells and "professional" sentinels, such as mast cells and macrophages (not shown). The inflammatory signals induce upregulation of endothelial selectins and immunoglobulin "superfamily" members, particularly ICAM-1 and/or VCAM-1. Chemoattractants, particularly chemokines, are produced by or translocated across venular endothelial cells (*red arrow*) and are displayed in the lumen to rolling leukocytes. Those leukocytes that express the appropriate set of trafficking molecules undergo a multistep adhesion cascade (steps 1–3) and then polarize and move by diapedesis across the venular wall (steps 4 and 5). Diapedesis involves transient disassembly of endothelial junctions and penetration through the underlying basement membrane (step 6). Once in the extravascular (interstitial) space, the migrating cell uses different integrins to gain "footholds" on collagen fibers and other ECM molecules, such as laminin and fibronectin, and on inflammation-induced ICAM-1 on the surface of parenchymal cells (step 7). The migrating cell receives guidance cues from distinct sets of chemoattractants, particularly chemokines, which may be immobilized on glycosaminoglycans (GAG) that "decorate" many ECM molecules and stromal cells. Inflammatory signals also induce tissue dendritic cells (DCs) to undergo maturation. Once DCs process material from damaged tissues and invading pathogens, they upregulate CCR7, which allows them to enter draining lymph vessels that express the CCR7 ligand CCL21 (and CCL19). In lymph nodes (LNs), these antigen-loaded mature DCs activate naïve T cells and expand pools of effector lymphocytes, which enter the blood and migrate back to the site of inflammation. T cells in tissue also use this CCR7-dependent route to migrate from peripheral sites to draining lymph nodes through afferent lymphatics. *(Reproduced with permission from AD Luster et al: Immune cell migration in inflammation: present and future therapeutic targets. Nat Immunol 6:1182, 2005.)*

cells (Fig. 349-10). Lymphocyte rolling is mediated by the L-selectin molecule (LECAM-1, LAM-1, CD62L) and slows cell transit time through venules, allowing time for activation of adherent cells.

The second stage of lymphocyte–endothelial cell interactions, *firm adhesion with activation-dependent stable arrest*, requires stimulation of lymphocytes by chemoattractants or by endothelial cell–derived cytokines. Cytokines thought to participate in adherent cell activation include members of the IL-8 family, platelet-activation factor, leukotriene B_4, and C5a. In addition, HEVs express chemokines, SLC (CCL21) and ELC (CCL19), which participate in this process. Following activation by chemoattractants, lymphocytes shed L-selectin from the cell surface and upregulate cell CD11b/18 (MAC-1) or CD11a/18 (LFA-1) molecules, resulting in firm attachment of lymphocytes to HEVs.

Lymphocyte homing to peripheral lymph nodes involves adhesion of L-selectin to glycoprotein HEV ligands collectively referred to as *peripheral node addressin* (*PNAd*), whereas homing of lymphocytes to intestine Peyer's patches primarily involves adhesion of the α4β7 integrin to mucosal addressin cell adhesion molecule-1 (MAdCAM-1) on the Peyer's patch HEVs. However, for migration to mucosal Peyer's patch lymphoid aggregates, naïve lymphocytes primarily use L-selectin, whereas memory lymphocytes use α4β7 integrin. α4β1 integrin (CD49d/CD29, VLA-4)–VCAM-1 interactions are important in the initial interaction of memory lymphocytes with HEVs of multiple organs in sites of inflammation **(Table 349-11)**.

The third stage of leukocyte emigration in HEVs is *sticking and arrest*. Sticking of the lymphocyte to endothelial cells and arrest at the site of sticking are mediated predominantly by ligation of a1β2 integrin LFA-1 to the integrin ligand ICAM-1 on HEVs. Whereas the first three stages of lymphocyte attachment to HEVs take only a few seconds, the fourth stage of lymphocyte emigration, *transendothelial migration*, takes ~10 min. Although the molecular mechanisms that control lymphocyte transendothelial migration are not fully characterized, the HEV CD44 molecule and molecules of the HEV glycocalyx (extracellular matrix) are thought to play important regulatory roles in this process (Fig. 349-10). Finally, expression of matrix metalloproteases capable of digesting the subendothelial basement membrane, rich in nonfibrillar collagen, appears to be required for the penetration of lymphoid cells into the extravascular sites.

Abnormal induction of HEV formation and use of the molecules discussed above have been implicated in the induction and maintenance of inflammation in a number of chronic inflammatory diseases. In animal models of type 1 diabetes mellitus, MAdCAM-1 and GlyCAM-1 have been shown to be highly expressed on HEVs in inflamed pancreatic islets, and treatment of these animals with inhibitors of L-selectin and a4 integrin function blocked the development of type 1 diabetes mellitus **(Chap. 403)**. A similar role for abnormal induction of the adhesion molecules of lymphocyte emigration has been suggested in *rheumatoid arthritis* **(Chap. 358)**, *Hashimoto's thyroiditis* **(Chap. 382)**, *Graves' disease* **(Chap. 382)**, *multiple sclerosis* **(Chap. 444)**, *Crohn's disease* **(Chap. 326)**, and *ulcerative colitis* **(Chap. 326)**.

Immune-Complex Formation Clearance of antigen by immune-complex formation between antigen, complement, and antibody is a highly effective mechanism of host defense. However, depending on the level of immune complexes formed and their physicochemical properties, immune complexes may or may not result in host and foreign cell damage. After antigen exposure, certain types of soluble antigen-antibody complexes freely circulate and, if not cleared

TABLE 349-11 Trafficking Molecules Involved in Inflammatory Disease Processes

		PROPOSED LEUKOCYTE RECEPTORS FOR ENDOTHELIAL TRAFFIC SIGNALS		
DISEASE	**KEY EFFECTOR CELL**	**L-SELECTIN, LIGAND**	**G PROTEIN-COUPLED RECEPTOR**	**INTEGRIN[a]**
Acute Inflammation				
Myocardial infarction	Neutrophil	PSGL-1	CXCR1, CXCR2, PAFR, BLT1	LFA-1, Mac-1
Stroke	Neutrophil	L-Selectin, PSGL-1	CXCR1, CXCR2, PAFR, BLT1	LFA-1, Mac-1
Ischemia-reperfusion	Neutrophil	PSGL-1	CXCR1, CXCR2, PAFR, BLT1	LFA-1, Mac-1
T_H1 Inflammation				
Atherosclerosis	Monocyte	PSGL-1	CCR1, CCR2, BLT1, CXCR2, CX3CR1	VLA-4
	T_H1	PSGL-1	CXCR3, CCR5	VLA-4
Multiple sclerosis	T_H1	PSGL-1 (?)	CXCR3, CXCR6	VLA-4, LFA-1
	Monocyte	PSGL-1 (?)	CCR2, CCR1	VLA-4, LFA-1
Rheumatoid arthritis	Monocyte	PSGL-1	CCR1, CCR2	VLA-1, VLA-2, VLA-4, LFA-1
	T_H1	PSGL-1	CXCR3, CXCR6	VLA-1, VLA-2, VLA-4, LFA-1
	Neutrophil	L-Selectin, PSGL-1	CXCR2, BLT1	LFA-1[b]
Psoriasis	Skin-homing T_H1	CLA	CCR4, CCR10, CXCR3	VLA-4[c], LFA-1
Crohn's disease	Gut-homing T_H1	PSGL-1	CCR9, CXCR3	α4, β7, LFA-1
Type 1 diabetes	T_H1	PSGL-1 (?)	CCR4, CCR5	VLA-4, LFA-1
	CD8	L-Selectin (?), PSGL-1 (?)	CXCR3	VLA-4, LFA-1
Allograft rejection	CD8	PSGL-1	CXCR3, CX3CR1, BLT1	VLA-4, LFA-1
	B cell	L-Selectin, PSGL-1	CXCR5, CXCR4	VLA-4, LFA-1
Hepatitis	CD8	PSGL-1	CXCR3, CCR5, CXCR6	VLA-4
Lupus	T_H1	None	CXCR6	VLA-4[d]
	Plasmacytoid DC	L-Selectin, CLA	CCR7, CXCR3, ChemR23	LFA-1, Mac-1
	B cell	CLA (?)	CXCR5, CXCR4	LFA-1
T_H2 Inflammation				
Asthma	T_H2	PSGL-1	CCR4, CCR8, BLT1	LFA-1
	Eosinophil	PSGL-1	CCR3, PAFR, BLT1	VLA-4, LFA-1
	Mast cells	PSGL-1	CCR2, CCR3, BLT1	VLA-4, LFA-1
Atopic dermatitis	Skin-homing T_H2	CLA	CCR4, CCR10	VLA-4, LFA-1

[a]Various β_1 integrins have been linked in different ways in basal lamina and interstitial migration of distinct cell types and inflammatory settings. [b]In some settings, Mac-1 has been linked to transmigration. [c]CD44 can act in concert with VLA-4 in particular models of leukocyte arrest. [d]T_H2 cells require VAP-1 to traffic to inflamed liver.

TABLE 349-12 Complement Deficiencies and Associated Diseases

COMPONENT	ASSOCIATED DISEASES
Classic Pathway	
Clq, Clr, Cls, C4	Immune-complex syndromes,[a] pyogenic infections
C2	Immune-complex syndromes,[a] few with pyogenic infections
C1 inhibitor	Rare immune-complex disease, few with pyogenic infections
C3 and Alternative Pathway C3	
C3	Immune-complex syndromes,[a] pyogenic infections
D	Pyogenic infections
Properdin	*Neisseria* infections
I	Pyogenic infections
H	Hemolytic-uremic syndrome
Membrane Attack Complex	
C5, C6, C7, C8	Recurrent *Neisseria* infections, immune-complex disease
C9	Rare *Neisseria* infections

[a]Immune-complex syndromes include systemic lupus erythematosus (SLE) and SLE-like syndromes, glomerulonephritis, and vasculitis syndromes.

Source: After JA Schifferli, DK Peters: Lancet 322:957, 1983. Copyright 1983.

by the reticuloendothelial system, can be deposited in blood vessel walls and in other tissues such as renal glomeruli and cause *vasculitis* or *glomerulonephritis* syndromes **(Chaps. 314 and 363)**. Deficiencies of early complement components are associated with inefficient clearance of immune complexes and immune complex–mediated tissue damage in autoimmune syndromes, whereas deficiencies of the later complement components are associated with susceptibility to recurrent *Neisseria* infections **(Table 349-12)**.

Immediate-Type Hypersensitivity Helper T cells that drive antiallergen IgE responses are usually T_H2-type inducer T cells that secrete IL-4, IL-5, IL-6, and IL-10. A subset of Tfh, Tfh13, cells have been identified that produce IL-4, IL-5, and IL-13, which play a key role in responses to allergens that induce IgE and mediate anaphylaxis. Mast cells and basophils have high-affinity receptors for the Fc portion of IgE (FcRI), and cell-bound antiallergen IgE effectively "arms" basophils and mast cells. Mediator release is triggered by antigen (allergen) interaction with Fc receptor-bound IgE, and the mediators released are responsible for the pathophysiologic changes of *allergic diseases*. Mediators released from mast cells and basophils can be divided into three broad functional types: (1) those that increase vascular permeability and contract smooth muscle (histamine, platelet-activating factor, SRS-A, BK-A), (2) those that are chemotactic for or activate other inflammatory cells (ECF-A, NCF, leukotriene B_4), and (3) those that modulate the release of other mediators (BK-A, platelet-activating factor) **(Chap. 352)**.

Cytotoxic Reactions of Antibody In this type of immunologic injury, complement-fixing (C1-binding) antibodies against normal or foreign cells or tissues (IgM, IgG1, IgG2, IgG3) bind complement via the classic pathway and initiate a sequence of events similar to that initiated by immune-complex deposition, resulting in cell lysis or tissue injury. Examples of antibody-mediated cytotoxic reactions include red cell lysis in *transfusion reactions*, *Goodpasture's syndrome* with anti–glomerular basement membrane antibody formation, and *pemphigus vulgaris* with anti-epidermal antibodies inducing blistering skin disease.

Delayed-Type Hypersensitivity Reactions Inflammatory reactions initiated by mononuclear leukocytes and not by antibody alone have been termed *delayed-type hypersensitivity reactions*. The term *delayed* has been used to contrast a secondary cellular response that appears 48–72 h after antigen exposure with an *immediate* hypersensitivity response generally seen within 12 h of antigen challenge and initiated by basophil mediator release or preformed antibody. For example, in an individual previously infected with *M. tuberculosis* organisms, intradermal placement of tuberculin purified protein derivative as a skin test challenge results in an indurated area of skin at 48–72 h, indicating previous exposure to tuberculosis.

The cellular events that result in classic delayed-type hypersensitivity responses are centered on T cells (predominantly, although not exclusively, IFN-γ, IL-2, and TNF-α-secreting T_H1-type helper T cells) and macrophages. Recently, NK cells have been suggested to play a major role in the form of delayed hypersensitivity that occurs following skin contact with immunogens. First, local immune and inflammatory responses at the site of foreign antigen upregulate endothelial cell adhesion molecule expression, promoting the accumulation of lymphocytes at the tissue site. In the scheme outlined in Fig. 349-2, antigen is processed by DCs and presented to small numbers of CD4+ T cells expressing a TCR specific for the antigen. IL-12 produced by APCs induces T cells to produce IFN-γ (T_H1 response). Macrophages frequently undergo epithelioid cell transformation and fuse to form multinucleated giant cells in response to IFN-γ. This type of mononuclear cell infiltrate is termed *granulomatous inflammation*. Examples of diseases in which delayed-type hypersensitivity plays a major role are fungal infections (*histoplasmosis*; **Chap. 212**), mycobacterial infections (*tuberculosis*, *leprosy*; **Chaps. 178 and 179**), chlamydial infections (*lymphogranuloma venereum*; **Chap. 189**), helminth infections (*schistosomiasis*; **Chap. 234**), reactions to toxins (*berylliosis*; **Chap. 289**), and hypersensitivity reactions to organic dusts (*hypersensitivity pneumonitis*; **Chap. 288**). In addition, delayed-type hypersensitivity responses play important roles in tissue damage in autoimmune diseases such as *rheumatoid arthritis*, *temporal arteritis*, and granulomatosis with polyangiitis (GPA) **(Chaps. 358 and 363)**.

Autophagy Autophagy is a process that involves a lysosomal degradation pathway mechanism of cells to dispose of intracellular debris and damaged organelles. Autophagy by cells of the innate immune system is used to control intracellular infectious agents such as *M. tuberculosis*, in part by initiation of phagosome maturation and enhancing MHC class II antigen presentation to CD4 T cells.

CLINICAL EVALUATION OF IMMUNE FUNCTION

Clinical assessment of immunity requires investigation of the four major components of the immune system that participate in host defense and in the pathogenesis of autoimmune diseases: (1) humoral immunity (B cells); (2) cell-mediated immunity (T cells, monocytes); (3) phagocytic cells of the reticuloendothelial system (macrophages), as well as polymorphonuclear leukocytes; and (4) complement. Clinical problems that require an evaluation of immunity include chronic infections, recurrent infections, unusual infecting agents, and certain autoimmune syndromes. The type of clinical syndrome under evaluation can provide information regarding possible immune defects **(Chap. 351)**. Defects in cellular immunity generally result in viral, mycobacterial, and fungal infections. An extreme example of deficiency in cellular immunity is AIDS **(Chap. 197)**. Antibody deficiencies result in recurrent bacterial infections, frequently with organisms such as *S. pneumoniae* and *Haemophilus influenzae* **(Chap. 351)**. Disorders of phagocyte function are frequently manifested by recurrent skin infections, often due to *Staphylococcus aureus* **(Chap. 64)**. Finally, deficiencies of early and late complement components are associated with autoimmune phenomena and recurrent *Neisseria* infections (Table 349-12). **For further discussion of useful initial screening tests of immune function, see Chap. 351**.

IMMUNOTHERAPY

Many therapies for autoimmune and inflammatory diseases involve the use of nonspecific immune-modulating or immunosuppressive agents such as glucocorticoids or cytotoxic drugs. The goal of development of new treatments for immune-mediated diseases is to design ways to specifically interrupt pathologic immune responses, leaving nonpathologic immune responses intact **(Chap. 350)**. Novel ways to interrupt pathologic immune responses that are under investigation include the use of anti-inflammatory cytokines or specific cytokine inhibitors as

anti-inflammatory agents, the use of monoclonal antibodies against T or B lymphocytes as therapeutic agents, the use of intravenous Ig for certain infections and immune complex–mediated diseases, the use of specific cytokines to reconstitute components of the immune system, and bone marrow transplantation to replace the pathogenic immune system with a more normal immune system **(Chaps. 64, 202, 350, and 351)**. CTLA-4 inhibitors such as ipilimumab and tremelimumab and anti-PD-1 antibodies such as nivolumab have been shown to reverse CD8 T-cell exhaustion in melanoma and other solid tumors and induce immune cell control of tumor growth **(Chap. 350)**. A new technique that engineers autologous T cells to express antibody receptors that target leukemic cells, termed *chimeric antigen receptor T cells* (CAR T cells), has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of certain types of leukemias and lymphomas **(Chap. 350)**.

Cell-based therapies have been studied for many years, including ex vivo activation of NK cells for reinfusion into patients with malignancies, and DC therapy of ex vivo priming of DCs for enhanced presentation of cancer antigens, with reinfusion of primed DCs into the patient. One such strategy for DC therapy has been approved by the FDA for treatment of advanced prostate cancer.

Cytokines and Cytokine Inhibitors Several TNF inhibitors are used as biological therapies in the treatment of rheumatoid arthritis; these include monoclonal antibodies, TNF-R Fc fusion proteins, and Fab fragments. Use of anti-TNF-α antibody therapies such as adalimumab, infliximab, and golimumab has resulted in clinical improvement in patients with these diseases and has opened the way for targeting TNF-α to treat other severe forms of autoimmune and/or inflammatory disease **(Chap. 350)**. Blockage of TNF-α has been effective in *rheumatoid arthritis*, *psoriasis*, *Crohn's disease*, and *ankylosing spondylitis*. Other cytokine inhibitors are recombinant soluble TNF-α receptor (R) fused to human Ig and anakinra (soluble *IL-1 receptor antagonist*, or IL-1ra). The treatment of autoinflammatory syndromes (Table 349-5) with recombinant IL-1 receptor antagonist can prevent symptoms in these syndromes, because the overproduction of IL-1β is a hallmark of these diseases.

TNF-αR-Fc fusion protein (etanercept) and IL-1ra act to inhibit the activity of pathogenic cytokines in rheumatoid arthritis, i.e., TNF-α and IL-1, respectively. Similarly, anti-IL-6, IFN-β, and IL-11 act to inhibit pathogenic proinflammatory cytokines. Anti-IL-6 (tocilizumab) inhibits IL-6 activity, whereas IFN-β and IL-11 decrease IL-1 and TNF-α production **(Chap. 350)**. Of particular note has been the successful use of IFN-γ in the treatment of the phagocytic cell defect in *chronic granulomatous disease* **(Chap. 64)**.

T_H17 CD4 T cells have been implicated in the pathogenesis of psoriasis, ulcerative colitis, and other autoimmune diseases. Monoclonal antibodies have now been developed that target cytokines (IL-12, IL-23) that induce T_H17 T-cell differentiation and are licensed by the FDA for treatment of psoriasis. Monoclonal antibodies that directly target IL-17 have also recently been licensed for psoriasis and psoriatic arthritis treatment. Monoclonal antibodies against cytokines and immunoregulatory molecules are now mainstays of cancer and autoimmune disease therapy **(Chap. 350)**.

Intravenous Immunoglobulin (IVIg) IVIg has been used successfully to block reticuloendothelial cell function and immune complex clearance in various immune cytopenias such as immune thrombocytopenia **(Chap. 115)**. In addition, IVIg is useful for prevention of tissue damage in certain inflammatory syndromes such as Kawasaki disease **(Chap. 363)** and as Ig replacement therapy for certain types of immunoglobulin deficiencies **(Chap. 351)**. In addition, controlled clinical trials support the use of IVIg in selected patients with graft-versus-host disease, multiple sclerosis, myasthenia gravis, Guillain-Barré syndrome, and chronic demyelinating polyneuropathy.

Stem Cell Transplantation Hematopoietic stem cell transplantation (SCT) is now being comprehensively studied to treat several autoimmune diseases including systemic lupus erythematosus, multiple sclerosis, and scleroderma. The goal of immune reconstitution in autoimmune disease syndromes is to replace a dysfunctional immune system with a normally reactive immune cell repertoire. Preliminary results in patients with scleroderma and lupus have showed encouraging results. Controlled clinical trials in these three diseases are now being launched in the United States and Europe to compare the toxicity and efficacy of conventional immunosuppression therapy with that of myeloablative autologous SCT. Recently, SCT was used in the setting of HIV-1 infection. HIV-1 infection of CD4+ T cells requires the presence of surface CD4 receptor and the chemokine receptor 5 (CCR5) co-receptor. Studies have demonstrated that patients who are homozygous for a 32-bp deletion in the CCR5 allele do not express CD4+ T-cell CCR5 and thus are resistant to HIV-1 infection with HIV-1 strains that use this co-receptor. Stem cells from a homozygous CCR5 delta32 donor were transplanted to an HIV-1-infected patient following standard conditioning for such transplants, and the patient has maintained long-term control of the virus without antiretrovirals. Thus, a number of recent insights into immune system function have spawned a new field of interventional immunotherapy and have enhanced the prospect for development of more specific and nontoxic therapies for immune and inflammatory diseases **(Chap. 350)**.

350 Mechanisms of Regulation and Dysregulation of the Immune System

Barton F. Haynes, Kelly A. Soderberg, Anthony S. Fauci

DEFINITIONS

Anergy—A reversible tolerance mechanism in which the T or B cell is in an unresponsive state following an antigen encounter but remains alive.

Chimeric antigen receptor T cells (CAR T)—Synthetic hybrid receptors created by recombinant techniques that combine an extracellular domain, usually derived from an antibody single-chain variable fragment (scFv), with intracellular signaling domains from activating co-stimulatory molecules (from endogenous T-cell receptors

[TCRs], CD28, or 4-1BB) that allow for retargeting of T cells to antigens on malignant cells.

Checkpoint inhibition therapy—A form of cancer immunotherapy whereby antibodies against T-cell or antigen-presenting cell regulators of immune cell inhibition are used to activate cytotoxic T cells to kill tumor cells.

Co-stimulation of T cells—A secondary signal that T cells require for activation following presentation of peptide antigen by major histocompatibility complex (MHC) molecules to TCRs on either CD4 or CD8 T cells. A prime mediator of co-stimulation is the T cell CD28 molecule binding to B7-1 (CD80, CD86) on antigen-presenting cells.

Cytokines—Soluble proteins that interact with specific cellular receptors that are involved in the regulation of the growth and activation of immune cells and mediate normal and pathologic inflammatory and immune responses.

Immune homeostasis—Balanced protective immunity that does not overreact to pathogens and harm the host, and immunity that is not deficient and does not predispose the host to harmful infections or malignancies.

Immunoediting—Process of immunity selecting clones of cancer cells with reduced immunogenicities resulting in tumor escape.

Natural killer cells—Lymphocytes with cytotoxic potential for host cells with non-self-antigens, such as cells infected with pathogens or tumor cells expressing tumor-specific neoantigens.

T-cell exhaustion—State of T cells when the persistence of antigen disrupts memory T-cell function, resulting in defects in memory T-cell responses. Most frequently occurs in malignancies and in chronic viral infections such as HIV-1 and hepatitis C.

T regulatory cells (Tregs)—CD4 and CD8 T cells regulated by the transcription factor FOXP3 that play roles in downmodulating B- and T-cell responses in peripheral lymphoid tissues to prevent deleterious immune activation that can lead to autoimmune diseases.

Tumor-infiltrating lymphocytes—Lymphocytes that infiltrate tumors that may be in the exhausted state and upon which checkpoint inhibition therapy works.

Tumor neoantigens—Molecules in malignant cells that develop mutations that create non-self-antigens that are recognized by host T cells as non-self and against which tumor-infiltrating CD4 and CD8 T cells respond to reject the tumor.

INTRODUCTION

Immune homeostasis is the maintenance of a balance between immunity that protects the host and dysregulated immunity that predisposes the host to harmful infections, autoimmunity, or malignancies. Overactivity of innate and adaptive immunity leads to autoimmunity and/or inflammatory diseases. Underactivity of immune responses can lead to both immune deficiency and autoimmunity. Disruption of immune homeostasis contributes either directly or indirectly to many forms of disease. Thus, a major goal of immunotherapy is to either maintain immune homeostasis or reestablish immune balance in diseases of immune dysregulation.

This is an important time in the study of the biology of the immune system. The development of high-throughput genome sequencing, full genome transcriptome analysis, proteomics, metabolomics, and the realization of the importance of the human microbiome to immune system homeostasis have provided remarkable opportunities for development of new treatments for immune-mediated and malignant diseases. The emerging concept is that the immune system itself can be manipulated to be used as a therapeutic intervention for cancer and also can be safely manipulated for control of autoimmune disease. Moreover, new data are emerging that immune dysregulation is involved in the pathogenesis of diseases not traditionally thought of as immune-related, such as neurodegenerative diseases and atherosclerotic cardiovascular disease, and that the normal process of aging is associated with inflammatory processes.

Thus, a new frontier of medicine is to understand basic regulatory mechanisms of the innate and adaptive immune system with the goal of learning specific rules of immune system regulation, such that eventually the immune system can be "tuned" to safely stay in the zone of immune homeostasis and, at the same time, effectively protect against emerging and reemerging infectious diseases or eliminate malignancies as they arise. Moreover, when inflammatory or autoimmune diseases arise, effective strategies of immune regulation can be developed to safely treat them.

Thus, this chapter builds on **Chap. 349, Introduction to the Immune System**, to discuss T- and B-cell immunoregulation, to highlight recent successes in translating basic immunologic research into treatments of various hematopoietic and solid tumors, and to discuss mechanisms of immune dysregulation in autoimmunity and aging.

MECHANISMS OF REGULATION OF T-CELL ACTIVATION

Key roles of T cells are to respond to and eliminate cells bearing foreign antigens and to ignore cells expressing self-antigens. To respond to foreign antigens, stimulating cells must deliver an activating co-stimulating signal in addition to TCR ligation. To avoid responding to cells bearing self-antigens, T cells must also maintain immune tolerance. Central T-cell tolerance is maintained by autoreactive T-cell deletion in the thymus, while peripheral tolerance is maintained by regulatory T cells (Treg), T-cell anergy, and peripheral clonal deletion (see section below, Mechanisms of Immune Dysregulation in Autoimmune Disease). Thus, T-cell activation is an integral component of the adaptive immune response to pathogens as well as to tumor neoantigens.

Two stimulatory signals are required for T-cell activation. One T-cell signal is delivered by antigen peptide presented in the context of MHC **(Chap. 349)**. However, in the absence of a co-stimulating signal, the T cell will not be activated by peptide MHC alone but rather will become anergic or unresponsive. A second co-stimulatory signal is needed for T-cell activation, resulting in cytoskeletal remodeling, production of cytokines, and cell survival and differentiation. In addition to the TCR/CD3 complex **(Chap. 349)**, T cells express a complex array of co-stimulatory as well as inhibitory molecules that bind to their respective receptors on the surface of antigen-presenting cells (APCs) and orchestrate both initiation and control of T-cell activation to maintain immune homeostasis **(Fig. 350-1, and see Chap. 349, Table 349-1)**. Of these, CD28, cytotoxic T lymphocyte antigen 4 (CTLA-4), and programmed cell death protein 1 (PD-1) and their ligands were among the first to be recognized to be central to control of T-cell activation.

The CD28 molecule is a member of the immunoglobulin (Ig) superfamily and is the original member of a subfamily of co-stimulatory or inhibitory molecules on the surface of T cells that includes CTLA-4, inducible T-cell costimulator (ICOS), PD-1, T-cell immunoreceptor with Ig and ITIM domains (TIGIT), and B- and T-cell attenuator (BTLA) (Fig. 350-1). CD28 stimulates intracellular signaling through AKT and PI3 kinase, resulting in induction of NF-κB, AP-1, and NFAT, which are all critical for T-cell activation and differentiation **(Chap. 349, Fig. 349-7)**. CTLA-4 and PD-1 are CD28 subfamily members that control T-cell activation by inhibiting the stimulating activity of CD28 and other T-cell co-stimulatory molecules.

CTLA-4 is a key negative regulator of T-cell activation that downmodulates the T-cell response to antigen by interaction with its ligands, B7-1 and B7-2, to control unchecked T-cell proliferation. CTLA-4 is upregulated following TCR engagement with MHC/peptide, thus dampening TCR signaling by competing with CD28 binding to B7 ligands (B7-1 [CD80] and B7-2 [CD86]) on APCs by virtue of higher affinity of CTLA-4 for B7 ligands. In this manner, T cells respond to foreign antigen but are prevented from damaging host tissues due to overexuberant responses **(Fig. 350-2*A*)**. CTLA-4 thus mediates its dampening effect on T-cell activation by competing with T-cell CD28 binding to B7 receptors, as well as through the suppressive effect of CTLA-4+ Tregs. The human *CTLA4* gene is just one of several genes in which monogenetic mutations are associated with decreased Treg function and autoimmune syndromes **(Table 350-1)**.

PD-1 is also a major inhibitory molecule of T-cell activation by interaction with its ligands PD-L1 and PD-L2 on APCs (Fig. 350-1).

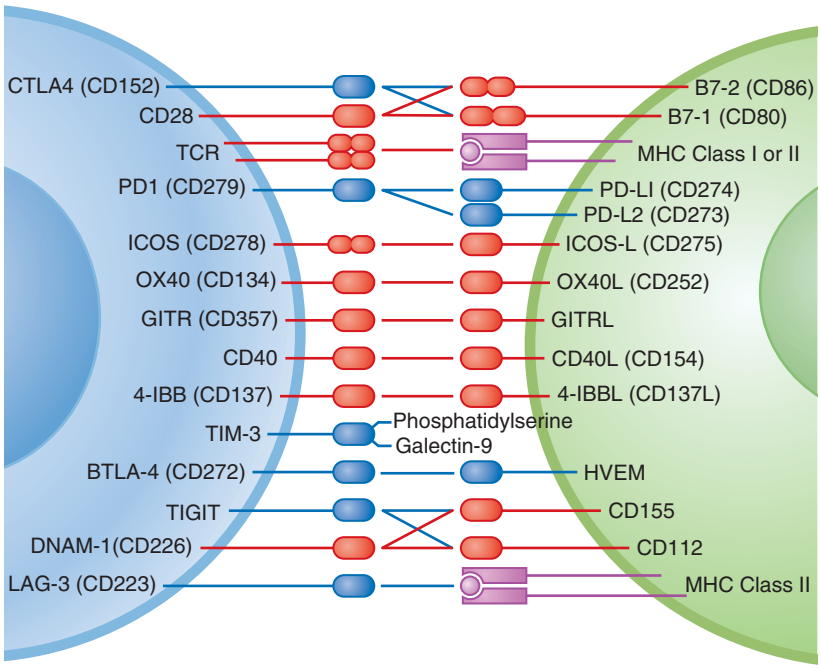

FIGURE 350-1 Regulatory stimulating or inhibiting molecules on T cells or antigen-presenting cells (APCs), tumor cells, or other cells.

While initially thought to be a cell death receptor, PD-1 is rapidly expressed upon activation of T and B cells and is also a marker of T follicular helper CD4+ T cells in B-cell germinal centers. PD-1 acts to dampen T-cell activation by dephosphorylation of CD28 via the Src homology region 2-containing protein tyrosine phosphatase 2 (SHP2).

Although a marker of immune cell activation, PD-1 is also a marker for exhausted T cells. T-cell exhaustion is an important mechanism of maintaining immune homeostasis and preventing host tissue T-cell damage, but also leads to immune dysfunction in the setting of chronic antigenic stimulation such as occurs in chronic viral diseases (HIV-1, hepatitis C) and in cancer. Chronic viral diseases and tumors lead to transcriptional and metabolic signatures that define the exhausted T-cell state. T-cell exhaustion has been a major roadblock to overcome for successful cancer immunotherapy.

CHECKPOINT INHIBITION THERAPY FOR CANCER

The field of immune checkpoint therapy has joined surgery, radiation, chemotherapy, and targeted therapy as a mainstay for cancer therapy. There are now an extensive number of therapeutic monoclonal antibodies approved by the U.S. Food and Drug Administration (FDA), initially starting with melanoma in 2011–2014 and now available for a wide range of malignancies including kidney, lung, liver, head and neck, and gastric tumors **(Table 350-2)**. Both CTLA-4 and PD-1 blockade have proved remarkably successful in treating a number of tumors, but only in a fraction of patients. Because each receptor ligand pair regulates distinct T-cell inhibitory pathways, combination therapy using anti-PD-1 and anti-CTLA-4 antibodies has been especially useful and has induced significant tumor regression in ~50% of melanoma patients. What is different in the use of checkpoint inhibitor antibodies is that the therapy is not targeted to the tumor per se, but rather is targeted to immunoregulatory molecules on host T cells. Moreover, therapy is not targeted to specific molecules on tumors, but rather is targeted to release exhausted tumor-infiltrating T cells (TILs) to be activated to kill tumor cells by removing immune regulatory inhibition.

CTLA-4 induces tumor rejection by a number of mechanisms. First, anti-CTLA-4 antibody mediates direct blockade of CTLA-4 competition with CD28 for B7-1 and B7-2 co-stimulatory ligands, thus allowing CD28-mediated T-cell activation **(Fig. 350-2*B*)**. Tumor cells do not express B7 molecules; thus, CTLA-4 blockade likely occurs in tumor-draining lymph nodes where exhausted T cells interact with APCs presenting tumor neoantigens to T cells. A second mechanism of CTLA-4 blockade–induced tumor rejection is depletion or reduction in suppressive effects of Tregs. Suppressive effect of Tregs include secretion of immunosuppressive cytokines such as transforming growth factor (TGF)-β or interleukin (IL) 10 or by direct inhibition of T-cell proliferation and/or cytolytic activity. A third potential mechanism of anti-CTLA-4 blockade is remodeling and broadening of the peripheral TCR repertoire for tumor antigens. Evidence suggests that the effects of anti-CTLA-4 antibody are restricted primarily to tumor neoantigen-specific CD8 T cells within the tumor microenvironment and not to T cells in lymph nodes or spleen.

PD-1 blockade by PD-1 antibody also induces tumor regression by reversing T-cell exhaustion, leading to enhanced T-cell killing

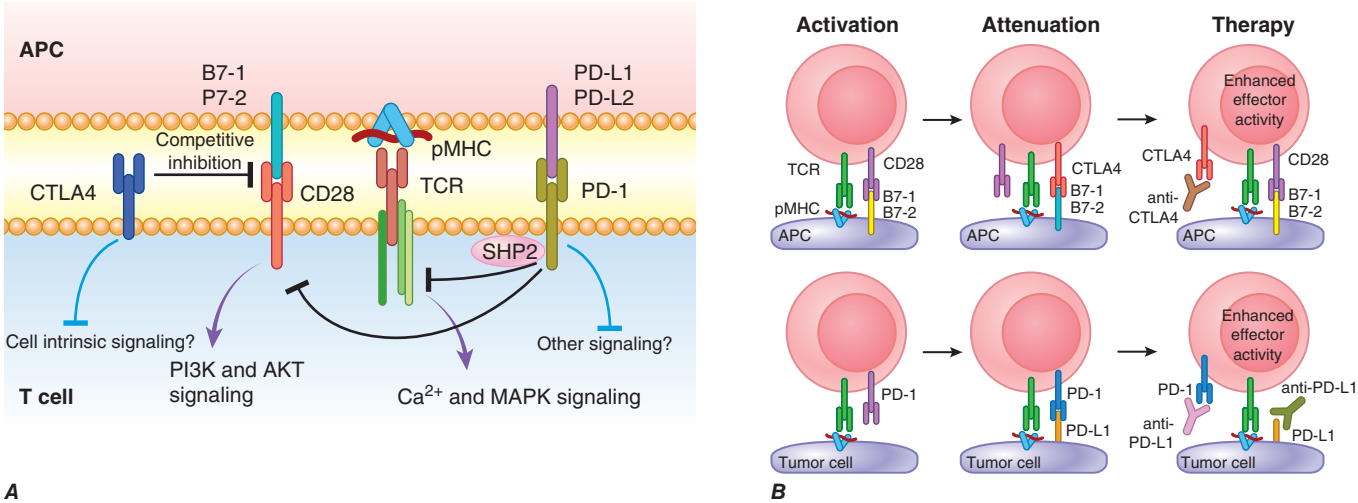

FIGURE 350-2 Molecular mechanisms of CTLA-4 and PD-1 attenuation of T-cell activation and schematic of the molecular mechanisms of action of CTLA-4 and PD-1 blockade. *A.* Schematic of the molecular interactions and downstream signaling induced by ligation of CTLA-4 and PD-1 by their respective ligands. The possibility of additional downstream cell-intrinsic signaling mechanisms is highlighted for both CTLA-4 and PD-1. ***B.*** The stepwise progression of T-cell activation, attenuation by normal regulatory mechanisms, and release of such negative regulation by therapeutic intervention using anti-CTLA-4 or anti-PD-1 antibodies is outlined. *(Reprinted from SC Wei et al: Fundamental mechanisms of immune checkpoint blockade therapy. Cancer Discov 8:1069, 2018, with permission from AACR.)*

TABLE 350-1 Monogenetic Mutations That Lead to Immune Dysregulation and Autoimmunity

MUTATIONS AND FUNCTIONAL DEFICITS	DISEASES OR SYNDROME
RAG1, RAG2; lymphopenia with recombinase deficiency	Severe combined immune deficiency (Omenn's syndrome) with autoreactive T cells
Fas, FasL, CASP10; apoptosis defects	Autoimmune lymphoproliferative disease
AIRE, deletion chromosome 22q11.2; decrease in central tolerance	**Ch. 22q11.2:** DiGeorge's syndrome with autoimmune T cells **AIRE:** autoimmunity, polyneuropathy, candidiasis, ectodermal dysplasia (APECED syndrome)
FOXP3, CD25, CTLA-4, LRBA; decrease in peripheral immune tolerance with decrease in Treg function	**FOXP3:** IPEX syndrome (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) **CD25:** enteropathy, dermatitis, autoimmunity, susceptibility to infections **CTLA-4:** associated with multiple autoimmune syndromes **LRBA:** infant with enteritis; hypogammaglobulinemia, autoimmune cytopenias
STAT-1, STAT-3; modulation of type 1 interferons	**STAT-1 deficiency:** decreased IFN-γ, susceptible to TB **STAT-1 gain of function:** chronic mucocutaneous candidiasis with autoimmune diseases **STAT-3 deficiency:** hyper-IgE syndrome (Job's syndrome) **STAT-3 gain of function:** lymphopenia, autoimmune cytopenias, diabetes, enteropathy
C1q, C1r/s, C2, C4; complement deficiencies	Systemic lupus erythematosus (SLE)
FcγRII, FcγRIII, C-reactive protein, complement receptor for C3bi (ITGAM or compliment receptor 3), COPA, tripeptidyl peptidase; lack of removal of cell debris	**FcγII, FcγIII, CRP, complement receptor for C3bi:** systemic lupus erythematosus **COPA:** autoimmune lung, renal, joint disease **Tripeptidyl peptidase II:** susceptibility to bacterial, viral, and fungal pathogens
Phosphoinositide-3-kinase delta (PI3Kδ), phospho-lipase Cγ2, protein kinase Cδ (PKCδ) deficiency, protein kinase Cδ (PKCδ) deficiency; hyperactivation of lymphocytes	**PI3Kδ:** lymphoproliferation, respiratory infections, hypogammaglobulinemia **Phospholipase Cγ2:** cold urticaria, antibody deficiency, autoimmunity **PKCδ:** early-onset SLE with decreased B-cell apoptosis, autoantibody-mediated renal disease and lymphoproliferation
Activation-induced cytidine deaminase (AID); class-impaired B-cell development	Hyper IgM syndrome type 2, low IgA, IgG, recurrent bacterial switch recombination; infections, autoimmune cytopenias, SLE

Abbreviations: APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; AIRE, autoimmune regulator; COPA, gene encodes the non-clathrin-coated vesicular coat protein, COP-alpha; CTLA-4, cytotoxic T lymphocyte associated protein-4; FcγR, Fcγ receptor; FOXP3, forkhead box P3; IFN, interferon; ITGAM, integrin alpha M; LRBA, lipopolysaccharide (LPS)-responsive and beige-like anchor protein; RAG, recombinase activating gene; STAT, signal transducer and activator of transcription; TB, tuberculosis; Treg, T regulatory cell.

Source: B Grimbacher et al: The crossroads of autoimmunity and immunodeficiency: Lessons from polygenic traits and monogenic defects. J Allergy Clin Immunol 137:3, 2016.

of tumor cells. Optimal PD-1 antibody-mediated checkpoint inhibition is seen when infiltrating CD8 T cells are present in the tumor microenvironment and reversal of the exhausted T-cell state can occur in situ. PD-1 blockade can also act by reversal of metabolic reprogramming of exhausted T cells, leading to enhanced cytolytic T-cell effector function. Antibodies to the primary PD-1 receptor, PD-L1, are also sufficient to induce reversal of T-cell exhaustion and induce tumor killing and are approved by the FDA for treatment of non-small-cell lung cancer (Table 350-2). PD-L1 is induced on tumor cells by T_H1 cytokines, which may explain anti-PD-L1 efficacy since T_H1 cytokines drive cytotoxic T-cell responses **(Chap. 349)**. Efficacy of anti-PD-L1 may also be due in part to mediation of antibody-dependent cellular cytotoxicity (ADCC) killing of tumor cells **(Chap. 349)**.

Tumor cells express neoantigens that are targets for T-cell recognition in the tumor microenvironment. Immune pressure within the tumor microenvironment can select for tumor cells that present few or mutated neoantigens and thus escape ongoing antitumor immunity. Moreover, a low number of tumor-infiltrating lymphocytes, tumor microenvironment production of immunosuppressive indoleamine 2,3-dioxygenase (IDO), and tumor infiltration with either myeloid-derived suppressor cells or Tregs can also limit checkpoint blockade therapy.

Other strategies for improving the immunoregulation of antitumor responses include combinations of anti-PD-1, anti-CTLA-4, or anti-PD-L1 antibodies with other checkpoint inhibitors (**see Chap. 349, Table 349-1,** and Fig. 350-1). For example, engagement of the ICOS pathway enhances the efficacy of CTLA-4 blockade in animal models of cancer immunotherapy. T-cell immunoglobulin and mucin-domain containing-3 (TIM-3), TIGIT, or lymphocyte-activation gene 3 (LAG-3) inhibition has been suggested to enhance checkpoint inhibition and augment CD8 tumor cell killing. A new transcription factor, thymocyte-selection-associated high mobility box (TOX), has been defined as a key controller of CD8 T-cell exhaustion. Thus, TOX inhibition could synergize with checkpoint inhibition therapy to reverse the T-cell exhaustion state. Finally, the combination of checkpoint inhibition with other cancer treatments including chemotherapy, radiation, tumor signaling pathway inhibitors, and epigenetic modulators is being tested.

Anti-PD-L1 antibodies also mediate antitumor effects by ADCC, which utilizes natural killer (NK) effector cells **(Chap. 349)**. Indeed, a number of checkpoint inhibitor molecules have been found to be expressed on NK cells including CTLA-4, PD-1, LAG-3, TIGIT, and TIM-3 (Fig. 350-1; **see also Chap. 349, Table 349-1**). A new field of work is to target NK cells with existing checkpoint inhibitors and with antibodies against an NK-specific inhibitory molecule, NKG2A, that are designed release NK cells to kill tumor cells. One such anti-NKG2A antibody, monalizumab, has entered human clinical trials. NK cells also express natural cytotoxicity-activating receptors including NKp30, NKp44, and NKp46 receptors **(Chap. 349)**. Engagement of natural cytotoxicity-activating receptors in concert with the NK FcγRIII (CD16) and antibody against a tumor antigen also can enhance NK cell targeting of tumor antigens and is in preclinical development.

CHIMERIC ANTIGEN RECEPTOR T CELLS

Chimeric antigen receptor (CAR) T cells are synthetic hybrid receptors created by recombinant techniques that combine an extracellular domain, usually derived from an antibody single-chain variable fragment (scFv), with intracellular signaling domains from activating co-stimulatory molecules (from endogenous TCRs, CD28, or 4-1BB) that allow for retargeting of T cells to antigens on malignant cells **(Fig. 350-3)**. A CAR T cell targeting the CD19 molecule on malignant B cells provided the first and most promising therapeutic results in the treatment of B-cell malignancies, with complete response rates of 70–90%. CAR T cells targeting the NY-ESO antigen on sarcoma cells have induced remissions in patients with synovial cell sarcoma. CAR T cells targeting B-cell maturation antigen (BCMA) on myeloma cells have also induced clinical responses. The CAR T-cell strategy is being developed for targeting solid tumors and modified as universal CAR T cells to overcome the need for MHC matching with T CAR recipients. One such strategy is to modify T cells to release cytokine, express co-stimulatory ligands, or secrete checkpoint-blocking single-chain variable fragment (scFvs). The next generation of CAR T cells are known as T cells redirected for universal cytokine-mediated killing (TRUCKs). Cytokine-secreting tumor-specific T cells could harness

TABLE 350-2 Summary of the Tumor Types for Which Immune Checkpoint Blockade Therapies Are Approved by the U.S. Food and Drug Administration (FDA)

TUMOR TYPE	THERAPEUTIC AGENT	TARGET	FDA APPROVAL YEAR
Melanoma	Ipilimumab	CTLA-4	2011
Melanoma	Nivolumab	PD-1	2014
Melanoma	Pembrolizumab	PD-1	2014
Non-small-cell lung cancer	Nivolumab	PD-1	2015
Non-small-cell lung cancer	Pembrolizumab	PD-1	2015
Melanoma (*BRAF* wild-type)	Ipilimumab + nivolumab	CTLA-4 + PD-1	2015
Melanoma (adjuvant)	Ipilimumab	CTLA-4	2015
Renal cell carcinoma	Nivolumab	PD-1	2015
Hodgkin's lymphoma	Nivolumab	PD-1	2016
Urothelial carcinoma	Atezolizumab	PD-L1	2016
Head and neck squamous cell carcinoma	Nivolumab	PD-1	2016
Head and neck squamous cell carcinoma	Pembrolizumab	PD-1	2016
Melanoma (any *BRAF* status)	Ipilimumab + nivolumab	CTLA-4 + PD-1	2016
Non-small-cell lung cancer	Atezolizumab	PD-L1	2016
Hodgkin's lymphoma	Pembrolizumab	PD-1	2017
Merkel cell carcinoma	Avelumab	PD-L1	2017
Urothelial carcinoma	Avelumab	PD-L1	2017
Urothelial carcinoma	Durvalumab	PD-L1	2017
Urothelial carcinoma	Nivolumab	PD-1	2017
Urothelial carcinoma	Pembrolizumab	PD-1	2017
MSI-high or MMR-deficient solid tumors of any histology	Pembrolizumab	PD-1	2017
MSI-high, MMR-deficient metastatic colorectal cancer	Nivolumab	PD-1	2017
Pediatric melanoma	Ipilimumab	CTLA-4	2017
Hepatocellular carcinoma	Nivolumab	PD-1	2017
Gastric and gastroesophageal carcinoma	Pembrolizumab	PD-1	2017
Non-small-cell lung cancer	Durvalumab	PD-L1	2018
Renal cell carcinoma	Ipilimumab + nivolumab	CTLA-4 + PD-1	2018

Note: A summary of the tumor indications, therapeutic agents, and year of FDA approval for immune checkpoint blockade therapies. FDA approval includes regular approval and accelerated approval granted as of May 2018. Ipilimumab is an anti-CTLA-4 antibody. Nivolumab and pembrolizumab are anti-PD-1 antibodies. Atezolizumab, avelumab, and durvalumab are anti-PD-L1 antibodies. Tumor type reflects the indications for which treatment has been approved. Only the first FDA approval granted for each broad tissue type or indication for each therapeutic agent is noted. In cases where multiple therapies received approval for the same tumor type in the same year, agents are listed alphabetically.

Abbreviations: BRAF, v-raf murine sarcoma viral oncogene, homolog B1; MMR, mismatch repair; MSI, microsatellite instability.

the adjuvant effect of recombinant cytokines by local delivery to the tumor to decrease cytokine side effects of excess inflammation, termed *cytokine release syndrome*, that can be seen with CAR T-cell therapy.

MECHANISMS OF IMMUNE DYSREGULATION IN AUTOIMMUNE DISEASE

Autoimmune diseases occur in ~5% of people and are caused by immune dysregulation from breakdowns in immune tolerance. A complex array of immune checkpoints are involved in the maintenance of immune homeostasis and, when mutated, can result in autoimmune syndromes (**Tables** 350-1 and **350-3**). Central tolerance for deletion of autoreactive T cells or modification of their TCRs occurs in the thymus, and for B cells with self-reactive B-cell receptors, central deletion occurs in bone marrow. Peripheral tolerance occurs in lymph nodes, spleen, and tissue-associated lymphoid tissue such as gastrointestinal tract Peyer's patches. The sites and modes of peripheral tolerance are varied and reflect the complex cellular and cytokine interactions that occur in mediation of T- and B-cell adaptive immunity **(Chap. 349)**. While B- and T-cell deletion can occur in the periphery, tolerance can also occur with cell inactivation termed *anergy*, a state of immune responsiveness following contact with antigen. T- and B-cell responses are also dampened in the periphery by Tregs producing TGF-β and IL-10. The result of immune dysregulation in autoimmune disease is the production of a myriad of antibodies against self-antigens (autoantibodies), many of which are pathogenic for the clinical manifestations of the autoimmune disease **(see Chap. 349, Table 349-10)**.

TABLE 350-3 Immune Tolerance Checkpoints in T- and B-Cell Immunity

CENTRAL TOLERANCE	PERIPHERAL TOLERANCE
THYMUS	**PERIPHERAL LYMPHOID TISSUES**
– TCR editing by V(D)J	– B and T cell anergy and inhibitory signaling (CTLA-4, PD-1 and other checkpoint molecules)
– Thymic negative selection	– TCR or BCR induction of BIM
– T cell anergy and inhibitory signaling	– T cell competition for IL-2, IL-7, IL-15 and peptide-MHC
– T regulatory cell differentiation	– B cell competition for survival cytokine BAFF
	– T cell growth dependence on CD28 ligands and other co-stimulatory molecules
	– Elimination of antigen-bearing dendritic cells by activated T cells producing perforin or FasL
	– Suppression of T and B cell responses by T regulatory cells and TGFβ, IL-10
	– T cell death by FasL
	– Regulation of T follicular helper cell differentiation and function
BONE MARROW	– B cell growth dependence on BCR ligands
– Immature B cell maturation arrest	– B cell growth dependence on TCR ligands
– BCR editing by V(D)J recombination	– B cell death by FasL on T cells
– Immature B cell deletion	– BCR modulation of plasma cell differentiation
	– BCR-induced death of germinal center B cells
	– Germinal center B cell dependence on T follicular helper cells (CD40L, IL-21)

Abbreviations: BAFF, B cell activating factor; BCR, B cell receptor; BIM, Bcl-2-like protein 11; Fas; TGFβ = T cell growth factor beta; FasL = Fas ligand that binds to the death receptor; MHC, major histocompatibility complex; TCR, T cell receptor; V(D)J, variable, diversity, joining regions of antibody V region.

Source: Adapted from CG Goodnow: Multistep pathogenesis of autoimmune disease. Cell 130:25, 2007.

Tregs are CD4 and CD8 T cells that downmodulate B- and T-cell responses in peripheral lymphoid tissues to prevent autoimmune diseases, and the transcriptional regulator FOXP3 is centrally involved in the establishment of the Treg phenotype. Mutations in genes that lead to loss of Tregs or their function result in autoimmune and inflammatory syndromes (Table 350-1). Mutations in FOXP3 lead to an X-linked syndrome characterized by immune dysregulation, polyendocrinopathy, and enteropathy (IPEX). Similarly, mutations in the CD25 (IL-2 receptor α) molecule expressed on Tregs lead to enteropathy, dermatitis, other manifestations of autoimmunity, and susceptibility to infections. Mutations in the checkpoint inhibitor T-cell molecule CTLA-4—also expressed on Tregs—leads to loss of Treg function and results in multiple autoimmune syndromes in humans depending on the CTLA-4 mutation. In mice, knockout of the *ctla4* gene leads to massive uncontrolled lymphoproliferation and early death. Finally, mutations in the lipopolysaccharide (lipopolysaccharide-responsive and beige-like anchor [LRBA]) protein cause a syndrome in infants characterized by enteritis, hypogammaglobulinemia, and autoimmune cytopenias.

Chronic viral infections can perturb Treg number and function. In HIV-1 infection, chronic antigenic stimulation leads to shifts in the B-cell repertoire toward an autoimmune permissive state, with increased numbers of autoreactive B cells and decreased CD4+ Tregs leading to serum autoantibodies or clinical manifestations of autoimmune disease in ~50% of untreated HIV-1-infected individuals.

In addition to checkpoint inhibition for cancer immunotherapy, monoclonal antibodies can be used for immune modulation to correct dysregulated immunity in autoimmune diseases to restore normal levels of immunoregulatory tolerance control. Monoclonal therapies have been developed and successfully used for the treatment of autoimmune and inflammatory diseases **(Table 350-4)**. Some of the monoclonal antibodies such as anti-CD20 (rituximab) have also been used for the treatment of B-cell malignancies. CTLA-4-Fc has been developed to prevent CD28-induced T-cell activation, resulting in immune suppression for rheumatoid arthritis (RA) and transplantation. TNF-α has been shown to play a central role in RA pathogenesis, and anti-TNF-α antibodies have been successful in treatment of RA and are approved for other autoimmune syndromes including other forms of arthritis, inflammatory bowel disease, and psoriasis. Antibodies against α4 integrin block the migration of α4β7+ T cells to the gastrointestinal tract and are used to treat inflammatory bowel disease (IBD). The T_H17 cytokine IL-17 has been found to be overproduced in psoriasis, and monoclonal anti-IL-17 antibody therapy for psoriasis is now approved by the FDA **(Chap. 57)**.

Tregs are therapeutic candidates for restoring immune tolerance in autoimmune and autoinflammatory diseases, with the prospect of reducing or replacing immunosuppressive drugs. Like CAR T cells, Treg therapy involves expanding autologous Treg cells in vitro and reinfusing them into individuals with autoimmune or inflammatory diseases. To make Treg therapy more targeted for suppression of antigen-specific immune responses, CAR T technology is being used to redirect Tregs to pathogenic T and B cells. Treg cellular therapy is in human clinical trials for the treatment of graft-versus-host disease in the setting of transplantation and for prevention of progression of type 1 diabetes mellitus **(Chap. 404)**.

IMMUNE DYSREGULATION IN AGING

Aging of the immune system in humans is characterized by decline in both innate and adaptive immunity. Aging is also paradoxically associated with a state of chronic inflammation, termed "inflammaging," with an increased risk of autoimmune disease. Aging is associated with reduced NK cell function, reduced monocyte/macrophage immune cell expression of toll-like receptors, reduced chemotaxis and phagocytosis, and reduced MHC expression and signaling. Other phagocytic cells such as polymorphonuclear cells are similarly dysfunctional. Dendritic cells in aged individuals are present in reduced numbers with impaired antigen-presenting function and signaling. Adaptive immunity is similarly impaired with decreased antibody repertoire breadth, decrease in number of B cells, and decrease in B-cell responses to specific antigens. Similarly, T-cell responses to antigen are decreased, such as to seasonal influenza vaccination.

Aging is characterized by accumulation of senescent cells in many tissues that secrete inflammatory cytokines, chemokines, and other inflammatory mediators. The best example of the role of enhanced cytokine production in the "inflammaging" syndrome is in thymic atrophy, which is a major event contributing to age-associated immune system decline. During life, the thymus decreases in size and naïve T-cell output decreases; beginning with puberty, thymocytes progressively decrease in number, such that after ~50 years of age, ~90% of thymocytes have been replaced by adipocytes in the thymus perivascular space. Thymic adipocytes produce leukemia inhibitory factor, oncostatin M, IL-6, and stem cell factor (SCF). Administration of these cytokines to young mice induces thymic atrophy, demonstrating that these thymosuppressive cytokines actively induce thymocyte loss. Adipocytes in other sites also produce inflammatory cytokines, contributing to tissue senescence. Finally, respiratory failure due to SARS-CoV-1, Middle Eastern respiratory syndrome, or SARS-CoV-2 infection is associated with a cytokine release syndrome with IL-6 overproduction, which occurs most frequently in older individuals.

TABLE 350-4 Monoclonal Antibodies Approved for Clinical Use in Autoimmune Disease, Some of Which Are Also Used in Malignancies[a]

TARGET MOLECULE	FUNCTION	FDA-APPROVED mAbs, TRAPS, AND BISPECIFIC mAbs	AUTOIMMUNE/ INFLAMMATORY	MALIGNANCY	OTHER/COMMENTS
CD52	Marker of T and B lymphocyte subsets	Alemtuzumab (Lemtrada)	Multiple sclerosis	Chronic lymphocytic leukemia	Trade name changed from Campath-1H (cancer) to Lemtrada (multiple sclerosis) Humanized IgG1k
CD25	Alpha-chain of the IL-2 receptor	Basiliximab (Simulect)	Multiple sclerosis		Basiliximab: chimeric mouse/ human IgG1k
		Daclizumab (Zenapax)	Transplant rejection		Daclizumab: humanized IgG1
CD20	Participates in B-cell differentiation	Obinutuzumab (Gazyva) Ibritumomab tiuxetan (Zevalin)	Rheumatoid arthritis	B-cell malignancies	Obinutuzumab is the first approved glycoengineered IgG1 mAb with enhanced ADCC
		Tositumomab (Bexxar)[a] Ofatumumab (Arzerra) Rituximab (Rituxan)			Rituximab is chimeric mouse/ human IgG1k Ibritumomab tiuxetan and tositumomab are radio-conjugates that can be used when tumors stop responding to the anti-CD20 mAbs
					Ibritumomab and tositumomab are mouse IgG2a
CD80/CD86	Provide co-stimulatory signals necessary for T-cell activation and survival; ligand trap prevents activation of CD28 immune checkpoint resulting in immune suppression	Belatacept (Nulojix) Abatacept (Orencia) (both CTLA-4-Fc fusion proteins)	Rheumatoid arthritis Transplant rejection		
TNF-α	Inflammatory cytokine that drives multiple autoimmune diseases[a]	Adalimumab (Humira) Certolizumab pegol (Cimzia) Golimumab (Simponi) Infliximab (Remicade) Etanercept (Enbrel) There are more than 20 anti-TNF biosimilars in various stages of development. Already approved are infliximab biosimilars (Remsima, Inflectra, Flixabi), etanercept biosimilars (Erelzi, Benepali), and adalimumab biosimilars (Amjevita). This field will change very rapidly as many dossiers are now under regulatory scrutiny. Biosimilars are given a suffix, e.g., etanercept-szzs (Erelzi)	Crohn's disease, ulcerative colitis, RA, juvenile idiopathic arthritis, psoriatic arthritis, ankylosing spondylitis, plaque psoriasis, hidradenitis suppurativa, uveitis		Not all TNF blockers are approved for all indications Drugs in italics are biosimilars: adalimumab, infliximab, infliximab, *Inflectra*, *adalimumab-atto* are IgG1k mAbs; *certolizumab pegol* is a pegylated Fab fragment; etanercept is a soluble Fc:TNF receptor trap that binds TNF (there is one biosimilar). At least four biosimilar TNF blockers have been approved in the EU (two each for infliximab and etanercept)
VEGF	Cytokine that stimulates vasculogenesis and angiogenesis. Overproduced in some inflammatory disorders and tumors to induce increased blood supply.	Bevacizumab (Avastin) Ramucirumab (Cyramza) Aflibercept (Eylea/Zaltrap) Ranibizumab (Lucentis)	Age-related macular degeneration, macular edema, diabetic macular edema, diabetic retinopathy	Colorectal cancer, nonsquamous NSCLC, breast cancer, glioblastoma, renal cell carcinoma, gastric cancer or gastroesophageal junction adenocarcinoma	Bevacizumab and ramucirumab are IgG1 mAbs for cancer therapy (ramucirumab was derived from phage display); ranibizumab is a Fab fragment (single arm binder). It has a short half-life if administered intravenously, but it is stable when locally injected into the eye. Aflibercept is a ligand trap with optical (Eylea) and cancer (Zaltrap) applications.
IL-4 receptor alpha subunit	Receptor that mediates IL-4 and IL-13-induced inflammation	Dupilumab (Dupixent)	Atopic dermatitis (eczema), steroid-dependent asthma		
IgE	Binds to mast cells, basophils, and other cells that express Fc-epsilon receptor and induces release of inflammatory cytokines	Omalizumab (Xolair)	Asthma		IgG1k mAb also used off-label to treat IgE-related conditions (allergic rhinitis, drug allergies, other)

(*Continued*)

TABLE 350-4 Monoclonal Antibodies Approved for Clinical Use in Autoimmune Disease, Some of Which Are Also Used in Malignancies[a] (Continued)

TARGET MOLECULE	FUNCTION	FDA-APPROVED mAbs, TRAPS, AND BISPECIFIC mAbs	AUTOIMMUNE/ INFLAMMATORY	MALIGNANCY	OTHER/COMMENTS
Alpha-4 integrin	Alpha-4 integrin facilitates exit of inflammatory cells from blood into intestine or across the blood-brain barrier	Vedolizumab (Entyvio) Natalizumab (Tysabri)	Multiple sclerosis, Crohn's disease, and ulcerative colitis		IgG4 natalizumab therapy has been associated with PML caused by John Cunningham virus in immunocompromised patients. IgG1k vedolizumab may not be associated with PML.
Complement C5	Inhibits complement cascade	Eculizumab (Solaris)	Prevents destruction of red blood cells by activated complement (paroxysmal nocturnal hemoglobinuria)		IgG2/4 mAb; most expensive drug in the world ($409,500 annually)
P40 subunit of IL-12 and IL-23	Mutations in cryopyrin lead to overproduction of IL-1 and inflammatory disease; IL-1 also drives other inflammatory diseases	Canakinumab (Ilaris) Rilonacept (Arcalyst)[a]	Rare inflammatory syndromes, active juvenile arthritis, gouty arthritis		Canakinumab is an IgG1k mAb; rilonacept is an IL-1 trap designed from the IL-1R fused with human mAb Fc region.
IL-6	Overexpression of IL-6 is associated with multiple malignancies	Siltuximab (Sylvant)		Pseudo-malignancy: Castleman's disease (similar to lymphoma)	Murine/human chimeric IgG1κ
IL-6R (IL-6 receptor)	Current approvals based on role of IL-6 in promoting inflammatory autoimmune disease	Tocilizumab (Actemra)	Rheumatoid arthritis, polyarticular juvenile arthritis, juvenile idiopathic arthritis		Human/mouse chimeric mAb with initial approval for efficacy in RA after failure of TNF blocker
BAFF (tumor necrosis factor superfamily member 13b)	Role in proliferation and differentiation of B cells	Belimumab (Benlysta)	Systemic lupus erythematosus		IgG1-γ/λ
SLAMF7/ CD319	SLAMF7 triggers the activation and differentiation of a wide variety of immune cells (innate and adaptive immune response) perhaps primarily mediated by natural killer cells and myeloma cells	Elotuzumab (Empliciti)		Multiple myeloma	This IgG1k mAb is thought to activate SLAMF7 receptor and to have a secondary mechanism of mediating ADCC vs multiple myeloma cells
IL-5	Induces differentiation and survival of eosinophils	Reslizumab (Cinqair) Mepolizumab (Nucala)	Asthma		Both IgG1k mAbs
IL-17A	Inflammatory cytokine	Ixekizumab (Taltz) Secukinumab (Cosentyx)	Plaque psoriasis, ankylosing spondylitis		Ixekizumab is an IgG4; secukinumab is an IgG1k

[a]Approved for use in United States only.

Note: An actively updated summary of MAb approvals can be found at *www.antibodysociety.org*. mAbs can be murine, chimeric (human Fc region), humanized, or human; traps are derived from receptors and compete with natural receptor for binding target; bispecific mAbs are engineered to bind to two different targets simultaneously (usually to bring immune cell into contact with target cell, thereby triggering target cell killing). Antibody-drug conjugate (X): toxin or radioisotope attached to mAb to increase efficacy. Agents approved for use in the United States only are noted; others are approved in both United States and United Kingdom.

Abbreviations: ADCC, antibody-dependent cell-mediated cytotoxicity; BAFF, B-cell activating factor; CTLA-4, cytotoxic T-cell lymphocyte-associated protein-4; EU, European Union; Ig, immunoglobulin; FDA, U.S. Food and Drug Administration; IL, interleukin; mAb, monoclonal antibody; NSCLC, non-small-cell lung cancer; PML, progressive multifocal leukoencephalopathy; RA, rheumatoid arthritis; SLAMF7, signaling lymphocyte activation molecule family member 7; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

351 Primary Immune Deficiency Diseases

Alain Fischer

Immunity is intrinsic to life and an important tool in the fight for survival against pathogenic microorganisms. The human immune system can be divided into two major components: the innate immune system and the adaptive immune system **(Chap. 349)**. The innate immune system provides the rapid triggering of inflammatory responses based on the recognition (at the cell surface or within cells) of either molecules expressed by microorganisms or molecules that serve as "danger signals" released by cells under attack. These receptor/ligand interactions trigger signaling events that ultimately lead to inflammation. Virtually all cell lineages (not just immune cells) are involved in innate immune responses; however, myeloid cells (i.e., neutrophils and macrophages) play a major role because of their phagocytic capacity. The adaptive immune system operates by clonal recognition of antigens followed by a dramatic expansion of antigen-reactive cells and execution of an immune effector program. Most of the effector cells die off rapidly, whereas memory cells persist. Although both T and B lymphocytes recognize distinct chemical moieties and execute distinct adaptive immune responses, the latter is largely dependent on the former in generating long-lived humoral immunity. Adaptive responses utilize components of the innate immune system; for example, the antigen-presentation capabilities of dendritic cells help to determine the type of effector response. Not surprisingly, immune responses are controlled by a series of regulatory mechanisms.

Hundreds of gene products have been characterized as effectors or mediators of the immune system **(Chap. 349)**. Whenever the expression or function of one of these products is genetically impaired (provided the function is nonredundant), a primary immunodeficiency (PID) occurs.

PIDs are genetic diseases with primarily Mendelian inheritance. More than 450 conditions have now been described, and deleterious mutations in ~420 genes have been identified. The overall prevalence of PIDs has been estimated in various countries at 5–10 per 100,000 individuals; however, given the difficulty in diagnosing these rare and complex diseases, this figure is probably an underestimate. PIDs can involve all possible aspects of immune responses, from innate through adaptive, cell differentiation, and effector function and regulation. For the sake of clarity, PIDs should be classified according to (1) the arm of the immune system that is defective and (2) the mechanism of the defect (when known). **Table 351-1** classifies the most prevalent PIDs according to this manner of classification; however, one should bear in mind that the classification of PIDs sometimes involves arbitrary decisions because of overlap and, in some cases, lack of data.

The consequences of PIDs vary widely as a function of the molecules that are defective. This concept translates into multiple levels of vulnerability to infection by pathogenic and opportunistic microorganisms, ranging from extremely broad (as in severe combined immunodeficiency [SCID]) to narrowly restricted to a single microorganism (as in Mendelian susceptibility to mycobacterial disease [MSMD]). The locations of the sites of infection and the causal microorganisms involved will thus help physicians arrive at proper diagnoses. PIDs can also lead to immunopathologic responses such as allergy (as in Wiskott-Aldrich syndrome [WAS]), lymphoproliferation, and autoimmunity. A combination of recurrent infections, inflammation, and autoimmunity can be observed in a number of PIDs, thus creating obvious therapeutic challenges. Finally, some PIDs increase the risk of cancer, notably but not exclusively lymphocytic cancers, for example, lymphoma.

TABLE 351-1 Classification of Primary Immune Deficiency Diseases

Deficiencies of the Innate Immune System	
• Phagocytic cells:	
- Impaired production: severe congenital neutropenia (SCN)	
- Asplenia	
- Impaired adhesion: leukocyte adhesion deficiency (LAD)	
- Impaired killing: chronic granulomatous disease (CGD)	
• Innate immunity receptors and signal transduction:	
- Defects in Toll-like receptor signaling	
- Mendelian susceptibility to mycobacterial disease	
• Complement deficiencies:	
- Classical, alternative, and lectin pathways	
- Lytic phase	
Deficiencies of the Adaptive Immune System	
• T lymphocytes:	
- Impaired development	Severe combined immune deficiencies (SCIDs)
- Impaired survival, migration, function	DiGeorge's syndrome
	Combined immunodeficiencies
	Hyper-IgE syndrome (autosomal dominant)
	DOCK8 deficiency
	CD40 ligand deficiency
	Wiskott-Aldrich syndrome
	Ataxia-telangiectasia and other DNA repair deficiencies
• B lymphocytes:	
- Impaired development	XL and AR agammaglobulinemia
- Impaired function	Hyper-IgM syndrome
	Common variable immunodeficiency (CVID)
	IgA deficiency
Regulatory Defects	
• Innate immunity	Autoinflammatory syndromes (outside the scope of this chapter)
	Severe colitis
	Hemophagocytic lymphohistiocytosis (HLH)
• Adaptive immunity	Autoimmune lymphoproliferation syndrome (ALPS)
	Autoimmunity and inflammatory diseases (IPEX, APECED)

Abbreviations: APECED, autoimmune polyendocrinopathy candidiasis ectodermal dysplasia; AR, autosomal recessive; IPEX, immunodysregulation polyendocrinopathy enteropathy X-linked syndrome; XL, X-linked.

DIAGNOSIS OF PRIMARY IMMUNODEFICIENCIES

The most frequent symptom prompting the diagnosis of a PID is the presence of recurrent or unusually severe infections. As mentioned above, recurrent allergic or autoimmune manifestations may also alert the physician to a possible diagnosis of PID. In such cases, a detailed account of the subject's personal and family medical history should be obtained. It is of the utmost importance to gather as much medical information as possible on relatives and up to several generations of ancestors. In addition to the obvious focus on primary symptoms, the clinical examination should evaluate the size of lymphoid organs and, when appropriate, look for the characteristic signs of a number of complex syndromes that may be associated with a PID.

The performance of laboratory tests should be guided to some extent by the clinical findings. Infections of the respiratory tract (bronchi, sinuses) mostly suggest a defective antibody response. In general, invasive bacterial infections can result from complement deficiencies, signaling defects of innate immune responses, asplenia, or defective antibody responses. Viral infections, recurrent *Candida* infections, and opportunistic infections are generally suggestive of impaired T-cell immunity. Skin infections and deep-seated abscesses primarily reflect innate immune defects (such as chronic granulomatous disease); however, they may also appear in the autosomal dominant hyper-IgE syndrome. **Table 351-2** summarizes the laboratory tests that are most frequently used to diagnose a PID. More specific tests (notably genetic tests) are then used to make a definitive diagnosis. Genomic tools now allow us to more efficiently track genetic defects through usage of gene panel resequencing and/or whole exome/genome sequencing.

TABLE 351-2 Tests Most Frequently Used to Diagnose a Primary Immune Deficiency (PID)

TEST	INFORMATION	PID DISEASE
Blood cell counts and cell morphology	Neutrophil counts[a] Lymphocyte counts[a] Eosinophilia Howell-Jolly bodies	↓ Severe congenital neutropenia, ↑↑ LAD T-cell ID WAS, hyper-IgE syndrome Asplenia
Chest x-ray	Thymic shadow Costochondral junctions	SCID, DiGeorge's syndrome Adenosine deaminase deficiency
Bone x-ray	Metaphyseal ends	Cartilage hair hypoplasia
Immunoglobulin serum levels	IgG, IgA, IgM IgE	B-cell ID Hyper-IgE syndrome, WAS, T-cell ID
Lymphocyte phenotype	T, B lymphocyte counts	T-cell ID, agammaglobulinemia
Dihydrorhodamine fluorescence (DHR) assay Nitroblue tetrazolium (NBT) assay	Reactive oxygen species production by PMNs	Chronic granulomatous disease
CH50, AP50	Classic and alternative complement pathways	Complement deficiencies
Ultrasonography of the abdomen	Spleen size	Asplenia

[a]Normal counts vary with age. For example, the lymphocyte count is between 3000 and 9000/μL of blood below the age of 3 months and between 1500 and 2500/μL in adults.

Abbreviations: ID, immunodeficiency; LAD, leukocyte adhesion deficiency; PMNs, polymorphonuclear leukocytes; SCID, severe combined immunodeficiency; WAS, Wiskott-Aldrich syndrome.

The PIDs discussed below have been grouped together according to the affected cells and the mechanisms involved (Table 351-1, Fig. 351-1).

PRIMARY IMMUNODEFICIENCIES OF THE INNATE IMMUNE SYSTEM

PIDs of the innate immune system are relatively rare and account for ~10% of all PIDs.

SEVERE CONGENITAL NEUTROPENIA

Severe congenital neutropenia (SCN) consists of a group of inherited diseases that are characterized by severely impaired neutrophil counts (<500 polymorphonuclear leukocytes [PMN]/μL of blood). The condition is usually manifested from birth. SCN may also be cyclic (with a 3-week periodicity), and other neutropenia syndromes can also be intermittent. Although the most frequent inheritance pattern for SCN is autosomal dominant, autosomal recessive and X-linked recessive conditions also exist. Bacterial infections at the interface between the body and the external milieu (e.g., the orifices, wounds, and the respiratory tract) are common manifestations. Bacterial infections can rapidly progress through soft tissue and are followed by dissemination in the bloodstream. Severe visceral fungal infections can also ensue. The absence of pus is a hallmark of this condition.

Diagnosis of SCN requires examination of the bone marrow. Most SCNs are associated with a block in granulopoiesis at the promyelocytic stage (Fig. 351-1). SCN has multiple etiologies, and to date, mutations in 21 different genes have been identified. Most of these mutations result in isolated SCN, whereas others are syndromic (Chap. 64). The most frequent forms of SCN are caused by the premature cell death of granulocyte precursors, as observed in deficiencies of GFI1, HAX1, and elastase 2 (*ELANE*), with the latter accounting for 50% of SCN sufferers. Certain *ELANE* mutations cause cyclic neutropenia syndrome. A gain-of-function mutation in the *WASP* gene (see the

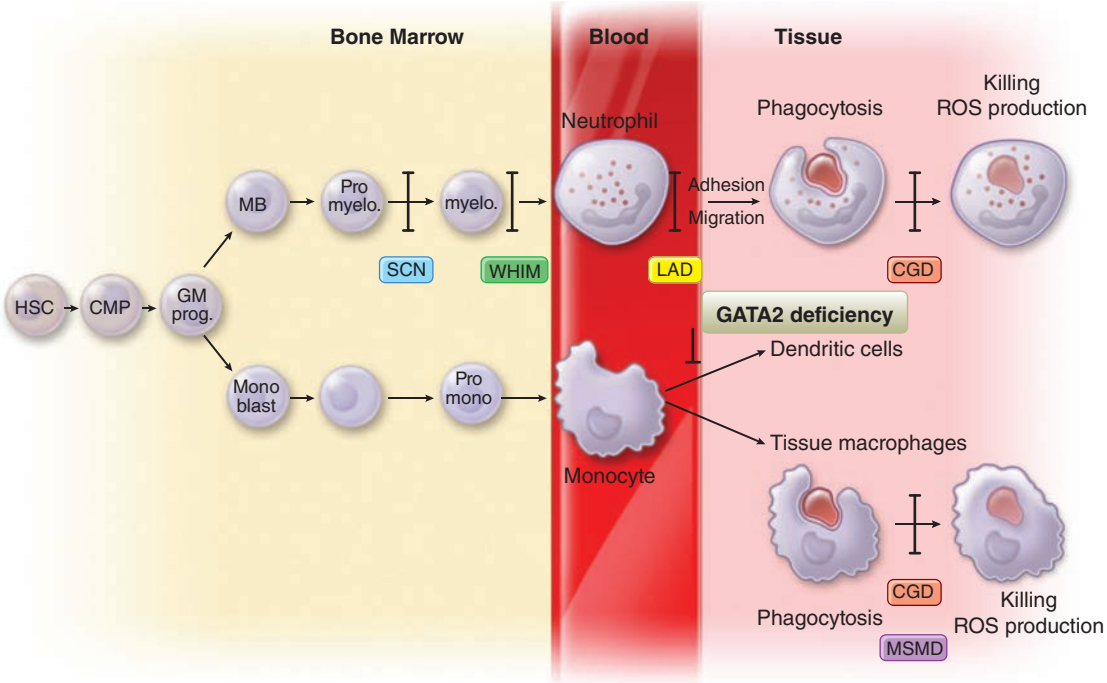

FIGURE 351-1 Differentiation of phagocytic cells and related primary immunodeficiencies (PIDs). Hematopoietic stem cells (HSCs) differentiate into common myeloid progenitors (CMPs) and then granulocyte-monocyte progenitors (GM prog.), which, in turn, differentiate into neutrophils (MB: myeloblasts; Promyelo: promyelocytes; myelo: myelocytes) or monocytes (monoblasts and promonocytes). Upon activation, neutrophils adhere to the vascular endothelium, transmigrate, and phagocytose the targets. Reactive oxygen species (ROS) are delivered to the microorganism-containing phagosomes. Macrophages in tissues kill using the same mechanism. Following activation by interferon γ (not shown here), macrophages can be armed to kill intracellular pathogens such as mycobacteria. For sake of simplicity, not all cell differentiation stages are shown. The abbreviations for PIDs are contained in boxes placed at corresponding stages of the pathway. CGD, chronic granulomatous diseases; GATA2, zinc finger transcription factor; LAD, leukocyte adhesion deficiencies; MSMD, Mendelian susceptibility to mycobacterial disease; SCN, severe congenital neutropenia; WHIM, warts, hypogammaglobulinemia, infections, and myelokathexis.

section "Wiskott-Aldrich Syndrome" below) causes X-linked SCN, which is also associated with monocytopenia.

As mentioned above, SCN exposes the patient to life-threatening, disseminated bacterial and fungal infections. Treatment requires careful hygiene measures, notably in infants. Later in life, special oral and dental care is essential, along with the prevention of bacterial infection by prophylactic administration of trimethoprim/sulfamethoxazole. Subcutaneous injection of the cytokine granulocyte colony-stimulating factor (G-CSF) usually improves neutrophil development and thus prevents infection in most SCN diseases. However, there are two caveats: (1) a few cases of SCN with *ELANE* mutation are refractory to G-CSF and may require curative treatment via allogeneic hematopoietic stem cell transplantation (HSCT); and (2) a subset of G-CSF-treated patients carrying *ELANE* mutations are at a greater risk of developing acute myelogenous leukemia associated (in most cases) with somatic gain-of-function mutations of the G-CSF receptor gene.

A few SCN conditions are associated with additional immune defects involving leukocyte migration as observed in the warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome (gain-of-function mutation of the chemokine *CXCR4*) or in moesin deficiency.

ASPLENIA

Primary failure of the development of a spleen is an extremely rare disease that can be either syndromic (in Ivemark syndrome) or isolated with an autosomal dominant expression; in the latter case, mutations in the ribosomal protein SA were recently found. Due to the absence of natural filtration of microbes in the blood, asplenia predisposes affected individuals to fulminant infections by encapsulated bacteria. Although most infections occur in the first years of life, cases may also arise in adulthood. The diagnosis is confirmed by abdominal ultrasonography and the detection of Howell-Jolly bodies in red blood cells. Effective prophylactic measures (twice-daily oral penicillin and appropriate vaccination programs) usually prevent fatal outcomes.

GATA2 DEFICIENCY

Recently, an immunodeficiency combining monocytopenia and dendritic and lymphoid (B and natural killer [NK]) cell deficiency (DCML), also called monocytopenia with nontuberculous mycobacterial infections (mono-MAC), has been described as a consequence of a dominant mutation in the gene *GATA2*, a transcription factor involved in hematopoiesis. This condition also predisposes to lymphedema, myelodysplasia, and acute myeloid leukemia. Infections (bacterial and viral) are life-threatening, thus indicating, together with the malignant risk, HSCT.

LEUKOCYTE ADHESION DEFICIENCY

Leukocyte adhesion deficiency (LAD) consists of three autosomal recessive conditions (LAD I, II, and III) **(Chap. 64)**. The most frequent condition (LAD I) is caused by mutations in the β2 integrin gene; following leukocyte activation, β2 integrins mediate adhesion to inflamed endothelium expressing cognate ligands. LAD III results from a defect in a regulatory protein (kindlin, also known as Fermt 3) involved in activating the ligand affinity of β2 integrins. The extremely rare LAD II condition is the end result of a defect in selectin-mediated leukocyte rolling that occurs prior to β2 integrin binding. There is a primary defect in fucose transporter such that oligosaccharide selectin ligands are missing in this syndromic condition.

Given that neutrophils are not able to reach infected tissues, LAD renders the individual susceptible to bacterial and fungal infections in a way that is similar to that of patients with SCN. LAD also causes impaired wound healing and delayed loss of the umbilical cord. A diagnosis can be suspected in cases of pus-free skin/tissue infections and massive hyperleukocytosis (>30,000/μL) in the blood (mostly granulocytes). Patients with LAD III also develop bleeding because the β2 integrin in platelets is not functional. Use of immunofluorescence and functional assays to detect β2 integrin can help form a diagnosis. Severe forms of LAD may require HSCT, although gene therapy is also now being considered. Neutrophil-specific granule deficiency (a very rare condition caused by a mutation in the gene for transcription factor C/EBPα) results in a condition that is clinically similar to LAD. Infrequent additional leukocyte motility defects have also been reported.

CHRONIC GRANULOMATOUS DISEASES

Chronic granulomatous diseases (CGDs) are characterized by impaired phagocytic killing of microorganisms by neutrophils and macrophages **(Chap. 64)**. The incidence is ~1 per 200,000 live births. About 70% of cases are associated with X-linked recessive inheritance versus autosomal inheritance in the remaining 30%. CGD causes deep-tissue bacterial and fungal abscesses in macrophage-rich organs such as the lymph nodes, liver, and lungs. Recurrent skin infections (such as folliculitis) are common and can prompt an early diagnosis of CGD. The infectious agents are typically catalase-positive bacteria (such as *Staphylococcus aureus* and *Serratia marcescens*) but also include *Burkholderia cepacia*, pathogenic mycobacteria (in certain regions of the world), and fungi (mainly filamentous molds, such as *Aspergillus*).

CGD is caused by defective production of reactive oxygen species (ROS) in the phagolysosome membrane following phagocytosis of microorganisms. It results from the lack of a component of NADPH oxidase (gp91phox or p22phox) or of the associated adapter/activating proteins (p47phox, p67phox, or p40phox) that mediate the transport of electrons into the phagolysosome for creating ROS by interaction with O_2. Under normal circumstances, these ROS either directly kill engulfed microorganisms or enable the rise in pH needed to activate the phagosomal proteases that contribute to microbial killing. Diagnosis of CGD is based on assays of ROS production in neutrophils and monocytes (Table 351-2). As its name suggests, CGD is also a granulomatous disease. Macrophage-rich granulomas can often arise in the liver, spleen, and other organs. These are sterile granulomas that cause disease by obstruction (bladder, pylorus, etc.) or protracted inflammation (colitis, restrictive lung disease).

The management of infections in patients with CGD can be a complex process. The treatment of bacterial infections is generally based on combination therapy with antibiotics that are able to penetrate into cells. The treatment of fungal infections requires aggressive, long-term use of antifungals. Inflammatory/granulomatous lesions are usually steroid-sensitive, but often become glucocorticoid-dependent; liver abscesses are best managed by administering antibiotics together with glucocorticoids.

The treatment of CGD mostly relies on preventing infections. It has been unambiguously demonstrated that prophylactic usage of trimethoprim/sulfamethoxazole is both well tolerated and highly effective in reducing the risk of bacterial infection. Daily administration of azole derivatives (notably itraconazole) also reduces the frequency of fungal complications. It has long been suggested that interferon γ administration is helpful, although medical experts continue to disagree over this controversial issue. Patients may do reasonably well for some time with prophylaxis and careful management. However, patients are at high risk lifelong of severe and persistent fungal infections and/or chronic inflammatory complications, leading to consideration of performing HSCT. Due to an increase in reported successes, HSCT is now an established curative approach for CGD; however, the risk-versus-benefit ratio must be carefully assessed on a case-by-case basis. Gene therapy approaches are also being evaluated.

MENDELIAN SUSCEPTIBILITY TO MYCOBACTERIAL DISEASE

This group of diseases is characterized by a defect in the interleukin-12 (IL-12)–interferon (IFN) γ axis (including IL-12p40, IL-12 receptor [R] β_1 and β_2, IFN-γ R_1 and R_2, TYK2, STAT1, IRF8, and ISG515 deficiencies), which ultimately leads to impaired IFN-γ-dependent macrophage activation. Both recessive and dominant inheritance modes have been observed. The hallmark of this PID is a specific and relatively narrow vulnerability to tuberculous and nontuberculous mycobacteria. The most severe phenotype (as observed in complete IFN-γ receptor deficiency) is characterized by disseminated infection that can be fatal even when aggressive and appropriate antimycobacterial therapy is applied. In addition to mycobacterial infections, MSMD

patients (and particularly those with an IL-12/IL-12R deficiency) are prone to developing *Salmonella* infections. Although MSMDs are very rare, they should be considered in any patient with persistent mycobacterial infection. Treatment with IFN-γ may efficiently bypass an IL-12/IL-12R deficiency. HSCT is a therapeutic option for the most severe cases.

TOLL-LIKE RECEPTOR (TLR) PATHWAY DEFICIENCIES

In a certain group of patients with early-onset, invasive *Streptococcus pneumoniae* infections or (less frequently) *Staphylococcus aureus* or other pyogenic infections, conventional screening for PIDs does not identify the cause of the defect in host defense. It has been established that these patients carry recessive mutations in genes that encode essential adaptor molecules (IRAK4 and MYD88) involved in the signaling pathways of the majority of known TLRs **(Chap. 349)**. Remarkably, susceptibility to infection appears to decrease after the first few years of life—perhaps an indication that adaptive immunity (once triggered by an initial microbial challenge) is then able to prevent recurrent infections.

Certain TLRs (TLR-3, -7, -8, and -9) are involved in the recognition of RNA and DNA and usually become engaged during viral infections. Very specific susceptibility to herpes simplex encephalitis has been described in patients with a deficiency in Unc93b (a molecule associated with TLR-3, -7, -8, and -9 required for correct subcellular localization), TLR-3, or associated signaling molecules TRIF, TBK1, and TRAF3, resulting in defective type I IFN production. The fact that no other TLR deficiencies have been found—despite extensive screening of patients with unexplained, recurrent infections—strongly suggests that these receptors are functionally redundant. Hypomorphic mutations in NEMO/IKK-γ (a member of the NF-κB complex, which is activated downstream of TLR receptors) lead to a complex, variable immunodeficiency and a number of associated features. Susceptibility to both invasive, pyogenic infections and mycobacteria may be observed in this particular setting.

Rare cases of predisposition to severe viral infections (influenza, live measles vaccine) have been found in patients with genetic defects in IFN type I receptor and signaling pathways.

COMPLEMENT DEFICIENCY

The complement system is composed of a complex cascade of plasma proteins **(Chap. 349)** that leads to the deposition of C3b fragments on the surface of particles and the formation of immune complexes that can culminate in the activation of a lytic complex at the bacterial surface. C3 cleavage can be mediated via three pathways: the classic, alternate, and lectin pathways. C3b coats particles as part of the opsonization process that facilitates phagocytosis following binding to cognate receptors. A deficiency in any component of the classic pathway (C1q, C1r, C1s, C4, and C2) can predispose an individual to bacterial infections that are tissue-invasive or that occur in the respiratory tract. Likewise, a C3 deficiency or a deficiency in factor I (a protein that regulates C3 consumption, thus leading to a C3 deficiency due to its absence) also results in the same type of vulnerability to infection. It has recently been reported that a very rare deficiency in ficolin-3 predisposes affected individuals to bacterial infections. Deficiencies in the alternative pathway (factors D and properdin) are associated with the occurrence of invasive *Neisseria* infections.

Lastly, deficiencies of any complement component involved in the lytic phase (C5, C6, C7, C8, and, to a lesser extent, C9) predispose affected individuals to systemic infection by *Neisseria*. This is explained by the critical role of complement in the lysis of the thick cell wall possessed by this class of bacteria.

Diagnosis of a complement deficiency relies primarily on testing the status of the classic and alternate pathway via functional assays, that is, the CH50 and AP50 tests, respectively. When either pathway is profoundly impaired, determination of the status of the relevant components in that pathway enables a precise diagnosis. Appropriate vaccinations and daily administration of oral penicillin are efficient means of preventing recurrent infections. It is noteworthy that several complement deficiencies (in the classic pathway and the lytic phase) may also predispose affected individuals to autoimmune diseases (notably systemic lupus erythematosus; **Chap. 356**).

PRIMARY IMMUNODEFICIENCIES OF THE ADAPTIVE IMMUNE SYSTEM

T LYMPHOCYTE DEFICIENCIES (TABLE 351-1, FIGS. 351-2 AND 351-3)

Given the central role of T lymphocytes in adaptive immune responses **(Chap. 349)**, PIDs involving T cells generally have severe pathologic consequences; this explains the poor overall prognosis and the need for early diagnosis and the early intervention with appropriate therapy. Several differentiation pathways of T-cell effectors have been described, one or all of which may be affected by a given PID (Fig. 351-2). Follicular helper CD4+ T cells in germinal centers are required for T-dependent antibody production, including the generation of

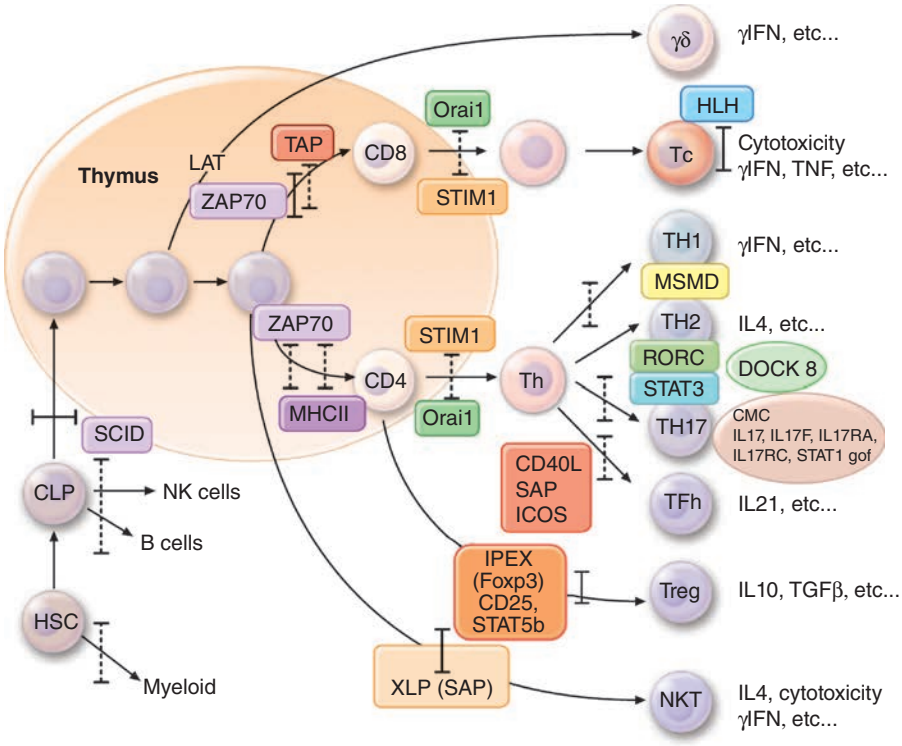

FIGURE 351-2 T-cell differentiation, effector pathways, and related primary immunodeficiencies (PIDs). Hematopoietic stem cells (HSCs) differentiate into common lymphoid progenitors (CLPs), which, in turn, give rise to the T-cell precursors that migrate to the thymus. The development of CD4+ and CD8+ T cells is shown. Known T-cell effector pathways are indicated, that is, γδ cells, cytotoxic T cells (Tc), T_H1, T_H2, T_H17, TFh (follicular helper) CD4 effector T cells, regulatory T cells (Treg), and natural killer T cells (NKTs); abbreviations for PIDs are contained in boxes. Vertical bars indicate a complete deficiency; broken bars a partial deficiency. DOCK8, autosomal recessive form of hyper-IgE syndrome; HLH, hematopoietic lymphohistiocytosis; IL17F, IL17RA, STAT1 (gof: gain of function), CMC (chronic mucocutaneous candidiasis), CD40L, ICOS, SAP deficiencies; IPEX, immunodysregulation polyendocrinopathy enteropathy X-linked syndrome; LAT, linker for activation of T cells; MHCII, major histocompatibility complex class II deficiency; MSMD, Mendelian susceptibility to mycobacterial disease; Orai1, STIM1 deficiencies; RORC, RAR related orphan receptor C; SCID, severe combined immunodeficiency; STAT3, autosomal dominant form of hyper-IgE syndrome; TAP, TAP1 and TAP2 deficiencies; XLP, X-linked proliferative syndromes; ZAP70, zeta-associated protein deficiency.

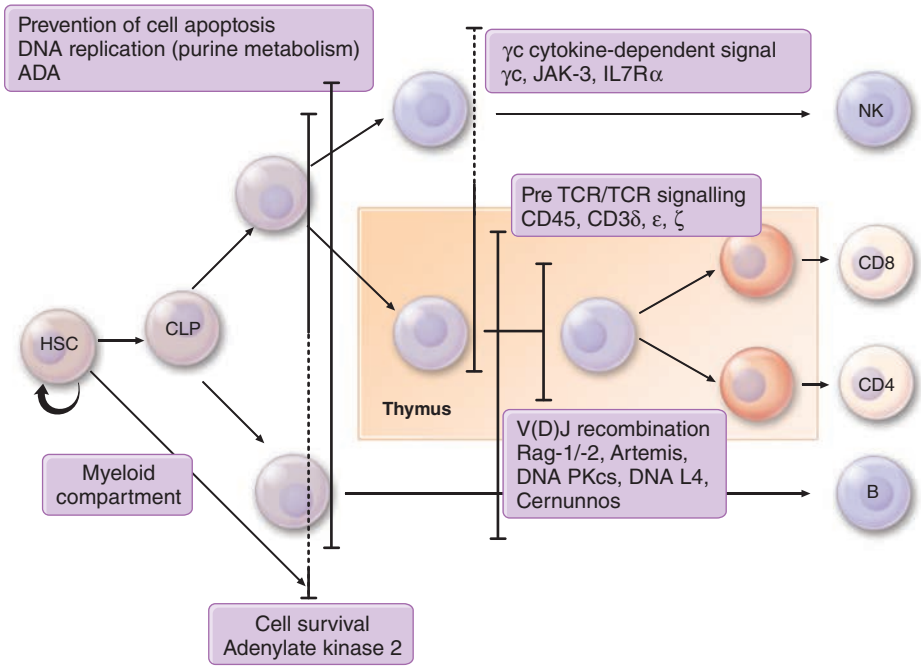

FIGURE 351-3 T-cell differentiation and severe combined immunodeficiencies (SCIDs). The vertical bars indicate the five mechanisms currently known to lead to SCID. The names of deficient proteins are indicated in the boxes adjacent to the vertical bars. A broken line means that deficiency is partial or involves only some of the indicated immunodeficiencies. ADA, adenosine deaminase deficiency; CLPs, common lymphoid progenitors; DNAL4, DNA ligase 4; HSCs, hematopoietic stem cells; NKs, natural killer cells; TCR, T-cell receptor.

Ig class-switched, high-affinity antibodies. CD4+ T_H1 cells provide cytokine-dependent (mostly IFN-γ-dependent) help to macrophages for intracellular killing of various microorganisms, including mycobacteria and *Salmonella*. CD4+ T_H2 cells produce IL-4, IL-5, and IL-13 and thus recruit and activate eosinophils and other cells required to fight helminth infections. CD4+ T_H17 cells produce IL-17 and IL-22 cytokines that recruit neutrophils to the skin and lungs to fight bacterial and fungal infections. Cytotoxic CD8+ T cells can kill infected cells, notably in the context of viral infections. In addition, certain T-cell deficiencies predispose affected individuals to *Pneumocystis jiroveci* lung infections early in life and to chronic gut/biliary duct/liver infections by *Cryptosporidium* and related genera later on in life. Lastly, naturally occurring or induced regulatory T cells are essential for controlling inflammation (notably reactivity to commensal bacteria in the gut) and autoimmunity. The role of other T-cell subsets with limited T-cell receptor (TCR) diversity (such as γδTCR T cells or natural killer T [NKT] cells) in PIDs is less well known; however, these subsets can be defective in certain PIDs, and this finding can sometimes contribute to the diagnosis (e.g., NKT-cell deficiency in X-linked proliferative syndrome [XLP]). T-cell deficiencies account for ~20% of all cases of PID.

Severe Combined Immunodeficiencies SCIDs constitute a group of rare PIDs characterized by a profound block in T-cell development and thus the complete absence of these cells. The developmental block is always the consequence of an intrinsic deficiency. The incidence of SCID is estimated to be 1 in 50,000 live births. Given the severity of the T-cell deficiency, clinical consequences occur early in life (usually within 3–6 months of birth). The most frequent clinical manifestations are recurrent oral candidiasis, failure to thrive, and protracted diarrhea and/or acute interstitial pneumonitis caused by *P. jiroveci* (although the latter can also be observed in the first year of life in children with B-cell deficiencies). Severe viral infections or invasive bacterial infections can also occur. Patients may also experience complications related to infections caused by live vaccines (notably bacille Calmette-Guérin [BCG]) that may lead not only to local and regional infection but also to disseminated infection manifested by fever, splenomegaly, and skin and lytic bone lesions. A scaly skin eruption can be observed in a context of maternal T-cell engraftment (see below).

A diagnosis of SCID can be suspected based on the patient's clinical history and, possibly, a family history of deaths in very young children (suggestive of either X-linked or recessive inheritance). Lymphocytopenia is strongly suggestive of SCID in >90% of cases (Table 351-2). The absence of a thymic shadow on a chest x-ray can also be suggestive of SCID. An accurate diagnosis relies on precise determination of the number of circulating T, B, and NK lymphocytes and their subsets. T-cell lymphopenia may be masked in some patients by the presence of maternal T cells (derived from maternal-fetal blood transfers) that cannot be eliminated. Although counts are usually low (<500/μL of blood), higher maternal T-cell counts may, under some circumstances, initially mask the presence of SCID. Thus, screening for maternal cells by using adequate genetic markers should be performed whenever necessary. Inheritance pattern analysis and lymphocyte phenotyping can discriminate between various forms of SCID and provide guidance in the choice of accurate molecular diagnostic tests (see below). To date, five distinct causative mechanisms for SCID (Fig. 351-3) have been identified. T-cell quantification of receptor excision circles (TREC) by using the Guthrie card is a reliable diagnostic test for newborn screening. It is now operational in the United States and several other countries worldwide. Its more widespread use will lead to the provision of therapy (see below) to uninfected patients resulting in a maximal chance of cure.

SEVERE COMBINED IMMUNODEFICIENCY CAUSED BY A CYTOKINE-SIGNALING DEFICIENCY The most frequent SCID phenotype (accounting for 30–40% of all cases) is the absence of both T and NK cells. This outcome results from a deficiency in either the common γ chain (γc) receptor that is shared by several cytokine receptors (the IL-2, -4, -7, -9, -15, and -21 receptors) or Jak-associated kinase (JAK) 3 that binds to the cytoplasmic portion of the γc chain receptor and induces signal transduction following cytokine binding. The former form of SCID (γc deficiency) has an X-linked inheritance mode, while the second is autosomal recessive. A lack of the IL-7Rα chain (which, together with γc, forms the IL-7 receptor) induces a selective T-cell deficiency.

PURINE METABOLISM DEFICIENCY Ten to 20% of SCID patients exhibit a deficiency in adenosine deaminase (ADA), an enzyme of purine metabolism that deaminates adenosine (ado) and deoxyadenosine (dAdo). An ADA deficiency results in the accumulation of ado and dAdo metabolites that induce premature cell death of lymphocyte progenitors. The condition results in the absence of B and NK lymphocytes as well as T cells. The clinical expression of complete ADA deficiency typically occurs very early in life. Since ADA is a ubiquitous enzyme, its deficiency can also cause bone dysplasia with abnormal costochondral junctions and metaphyses (found in 50% of cases) and neurologic defects. The very rare purine nucleoside phosphorylase (PNP) deficiency causes a profound although incomplete T-cell deficiency that is often associated with severe neurologic impairments.

DEFECTIVE REARRANGEMENTS OF T- AND B-CELL RECEPTORS A series of SCID conditions are characterized by a selective deficiency in T and B lymphocytes with autosomal recessive inheritance. These conditions account for 20–30% of SCID cases and result from mutations in genes encoding proteins that mediate the recombination of V(D)J gene elements in T- and B-cell antigen receptor genes (required for the

generation of diversity in antigen recognition). The main deficiencies involve RAG1, RAG2, DNA-dependent protein kinase, and Artemis. A less severe (albeit variable) immunologic phenotype can result from other deficiencies in the same pathway, that is, DNA ligase 4 and Cernunnos deficiencies. Given that these latter factors are involved in DNA repair, these deficiencies may also cause developmental defects.

DEFECTIVE (PRE-)T-CELL RECEPTOR SIGNALING IN THE THYMUS A selective T-cell defect can be caused by a series of rare deficiencies in molecules involved in signaling via the pre-TCR or the TCR. These include deficiencies in CD3 subunits associated with the (pre-)TCR (i.e., CD3δ, ε, and ζ) and CD45.

RETICULAR DYSGENESIS Reticular dysgenesis is an extremely rare form of SCID that causes T and NK deficiencies with severe neutropenia and sensorineural deafness. It results from an adenylate kinase 2 deficiency. RAC-2 gain of function can cause the same immunologic phenotype.

Patients with SCID require appropriate care with aggressive anti-infective therapies, immunoglobulin replacement, and (when necessary) parenteral nutrition support. In most cases, curative treatment relies on HSCT. Today, HSCT provides a very high curative potential for SCID patients who are otherwise in reasonably good condition. Gene therapy has been found to be successful for cases of X-linked SCID (γc deficiency) and SCID caused by an ADA deficiency. Lastly, a third option for the treatment of ADA deficiency consists of enzyme substitution with a pegylated enzyme.

Thymic Defects A profound T-cell defect can also result from faulty development of the thymus, as is most often observed in rare cases of DiGeorge's syndrome—a relatively common condition leading to a constellation of developmental defects. In ~1% of such cases, the thymus is completely absent, leading to virtually no mature T cells. However, expansion of oligoclonal T cells can occur and is associated with skin lesions. Diagnosis (using immunofluorescence in situ hybridization) is based on the identification of a hemizygous deletion in the long arm of chromosome 22. To recover the capability for T-cell differentiation, these cases require a thymic graft. CHARGE (*c*oloboma of the eye, *h*eart anomaly, choanal *a*tresia, *r*etardation, *g*enital, and *e*ar anomalies) syndrome (CHD7 deficiency) is a less frequent cause of impaired thymus development. Lastly, the very rare "nude" defect is characterized by the absence of both hair and the thymus.

Omenn Syndrome *Omenn syndrome* consists of a subset of T-cell deficiencies that present with a unique phenotype, including early-onset erythroderma, alopecia, hepatosplenomegaly, and failure to thrive. These patients usually display T-cell lymphocytosis, eosinophilia, and low B-cell counts. It has been found that the T cells of these patients exhibit a low TCR heterogeneity. This peculiar syndrome is the consequence of hypomorphic mutations in genes usually associated with SCID, that is, *RAG1*, *RAG2*, or (less frequently) *ARTEMIS* or *IL-7Rα*. The impaired homeostasis of differentiating T cells thus causes this immune system–associated disease. These patients are very fragile, requiring simultaneous anti-infective therapy, nutritional support, and immunosuppression. HSCT provides a curative approach.

Functional T-Cell Defects (Fig. 351-2) A subset of T-cell PIDs with autosomal inheritance is characterized by partially preserved T-cell differentiation but defective activation resulting in abnormal effector function. There are many causes of these defects, but all lead to susceptibility to viral and opportunistic infections, chronic diarrhea, and failure to thrive, with onset during childhood often associated with autoimmune manifestations. Careful phenotyping and in vitro functional assays are required to identify these diseases, the best characterized of which are the following.

ZETA-ASSOCIATED PROTEIN 70 (ZAP70) DEFICIENCY Zeta-associated protein 70 (ZAP70) is recruited to the TCR following antigen recognition. A ZAP70 deficiency leads typically to an almost complete absence of CD8+ T cells; CD4+ T cells are present but cannot be activated in vitro by TCR stimulation.

CALCIUM SIGNALING DEFECTS A small number of patients have been reported who exhibit a profound defect in in vitro T- and B-cell activation as a result of defective antigen receptor-mediated Ca^{2+} influx. This defect is caused by a mutation in the calcium channel gene (*ORAI1*) or its activator (*STIM-1*). It is noteworthy that these patients are also prone to autoimmune manifestations (blood cytopenias) and exhibit a nonprogressive muscle disease.

HUMAN LEUKOCYTE ANTIGEN (HLA) CLASS II DEFICIENCY Defective expression of HLA class II molecules is the hallmark of a group of four recessive genetic defects all of which affect molecules (RFX5, RFXAP, RFXANK, and CIITA) involved in the transactivation of the genes coding for HLA class II. As a result, low but variable CD4+ T-cell counts are observed in addition to defective antigen-specific T- and B-cell responses. These patients are particularly susceptible to herpesvirus, adenovirus, and enterovirus infections and chronic gut/liver *Cryptosporidium* infections.

HLA CLASS I DEFICIENCY Defective expression of molecules involved in antigen presentation by HLA class I molecules (i.e., TAP-1, TAP-2, and Tapasin) leads to reduced CD8+ T-cell counts, loss of HLA class I antigen expression, and a particular phenotype consisting of chronic obstructive pulmonary disease and severe vasculitis.

OTHER DEFECTS A variety of other T-cell PIDs have been described, some of which are associated with a precise molecular defect (e.g., IL-2-inducible T-cell kinase [ITK] deficiency; CD27, CD70, IL-21, and IL-21 receptor deficiencies; CARD11 deficiency; MALT1 deficiency; BCL10 deficiency; DOCK2 deficiency; RORC deficiency; RLTPR deficiency). These conditions are also characterized by profound vulnerability to infections, such as severe Epstein-Barr virus (EBV)–induced B-cell proliferation and autoimmune disorders. Milder phenotypes are associated with CD8 and CD3γ deficiencies. Combined immunodeficiency associated with anhidrotic ectodermic dysplasia is the consequence of defects in the NF-κB signaling pathway (X-linked IKKγ deficiency and gain-of-function IKb^{α}).

HSCT is indicated for most of these diseases, although the prognosis is worse than in SCID because many patients are chronically infected at the time of diagnosis. Fairly aggressive immunosuppression and myeloablation may be necessary to achieve engraftment of allogeneic stem cells.

T-Cell Primary Immunodeficiencies with DNA Repair Defects This is a group of PIDs characterized by a combination of T- and B-cell defects of variable intensity, together with a number of nonimmunologic features resulting from DNA fragility. The autosomal recessive disorder *ataxia-telangiectasia* (AT) is the most frequently encountered condition in this group. It has an incidence of 1:40,000 live births and causes B-cell defects (low IgA, IgG2 deficiency, and low antibody production), which often require immunoglobulin replacement. AT is associated with a progressive T-cell immunodeficiency. As the name suggests, the hallmark features of AT are telangiectasia and cerebellar ataxia. The latter manifestations may not be detectable before the age of 3–4 years, so that AT should be considered in young children with IgA deficiency and recurrent and problematic infections. Diagnosis is based on a cytogenetic analysis showing excessive chromosomal rearrangements (mostly affecting chromosomes 7 and 14) in lymphocytes. AT is caused by a mutation in the gene encoding the ATM protein—a kinase that plays an important role in the detection and repair of DNA lesions (or cell death if the lesions are too numerous) by triggering several different pathways. Overall, AT is a progressive disease that carries a very high risk of lymphoma, leukemia, and (during adulthood) carcinomas. A variant of AT ("AT-like disease") is caused by mutation in the *MRE11* gene.

Nijmegen breakage syndrome (NBS) is a less common condition that also results from chromosome instability (with the same cytogenetic abnormalities as in AT). NBS is characterized by a severe T- and B-cell combined immune deficiency with autosomal recessive inheritance. Individuals with NBS exhibit microcephaly and a bird-like face but have neither ataxia nor telangiectasia. The risk of malignancies is very high. NBS results from a deficiency in nibrin (NBSI, a protein associated with MRE11 and Rad50 that is involved in checking DNA lesions) caused by hypomorphic mutations.

Severe forms of *dyskeratosis congenita* (also known as Hoyeraal-Hreidarsson syndrome) combine a progressive immunodeficiency that can also include an absence of B and NK lymphocytes, progressive bone marrow failure, microcephaly, in utero growth retardation, and gastrointestinal disease. The disease can be X-linked or, more rarely, autosomal recessive. It is caused by the mutation of genes encoding telomere maintenance proteins, including dyskerin (DKC1).

Finally, *immunodeficiency with centromeric and facial anomalies* (ICF) is a complex syndrome of autosomal recessive inheritance that variably combines a mild T-cell immune deficiency with a more severe B-cell immune deficiency, coarse face, digestive disease, and mild mental retardation. A diagnostic feature is the detection by cytogenetic analysis of multiradial aspects in multiple chromosomes (most frequently 1, 9, and 16) corresponding to an abnormal DNA structure secondary to defective DNA methylation. It is the consequence of a deficiency in most cases in the DNA methyltransferase DNMT3B, ZBTB24, CDCA7, or HELLS.

T-Cell Primary Immunodeficiencies with Hyper-IgE Several T-cell PIDs are associated with elevated serum IgE levels (as in Omenn syndrome). A condition sometimes referred to as *autosomal recessive hyper-IgE syndrome* is notably characterized by recurrent bacterial infections in the skin and respiratory tract and severe skin and mucosal infections by pox viruses and human papillomaviruses, together with severe allergic manifestations. T and B lymphocyte counts are low. Mutations in the *DOCK8* gene have been found in many of these patients. This condition is an indication for HSCT.

A very rare, related condition with autosomal recessive inheritance that causes a similar susceptibility to infection with various microbes (see above), including mycobacteria, reportedly results from a deficiency in Tyk-2, a JAK family kinase involved in the signaling of many different cytokine receptors.

Autosomal Dominant Hyper-IgE Syndrome This unique condition, the *autosomal dominant hyper-IgE syndrome*, is usually diagnosed by the combination of recurrent skin and lung infections that can be complicated by pneumatoceles. Infections are caused by pyogenic bacteria and fungi. Several other manifestations characterize hyper-IgE syndrome, including facial dysmorphy, defective loss of primary teeth, hyperextensibility, scoliosis, and osteoporosis. Elevated serum IgE levels are typical of this syndrome. Defective T_H17 effector responses have been shown to account at least in part for the specific patterns of susceptibility to particular microbes. This condition is caused by a heterozygous (dominant) mutation in the gene encoding the transcription factor STAT3 that is required in a number of signaling pathways following binding of cytokine to cytokine receptors (such as that of IL-6 and the IL-6 receptor). It also results in partially defective antibody production because of defective IL-21 receptor signaling. Hence, immunoglobulin substitution can be considered as prophylaxis of bacterial infections.

Most recently, a recessive condition that mimics immunologic aspects of hyper-IgE syndrome has been ascribed to ZNF341 deficiency.

Cartilage Hair Hypoplasia The autosomal recessive *cartilage hair hypoplasia* (CHH) disease is characterized by short-limb dwarfism, metaphyseal dysostosis, and sparse hair, together with a combined T- and B-cell PID of extremely variable intensity (ranging from quasi-SCID to no clinically significant immune defects). The condition can predispose to erythroblastopenia, autoimmunity, and tumors. It is caused by mutations in the *RMRP* gene for a noncoding ribosome-associated RNA. Schimke immuno-osseous dysplasia is another autosomal recessive condition variably associating combined immunodeficiency, bone disease, and more importantly severe nephropathy.

CD40 Ligand and CD40 Deficiencies *Hyper-IgM syndrome* (HIGM) is a well-known PID that is usually classified as a B-cell immune deficiency (see Fig. 351-4 and below). It results from defective

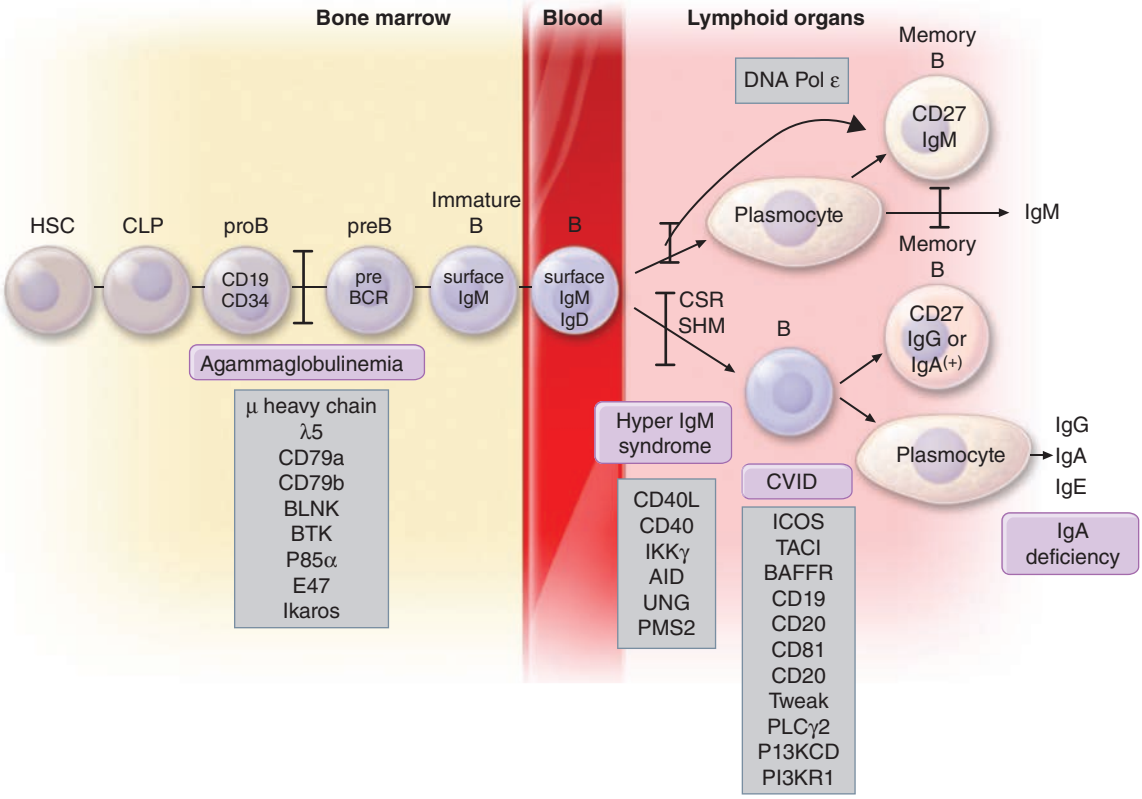

FIGURE 351-4 B-cell differentiation and related primary immunodeficiencies (PIDs). Hematopoietic stem cells (HSCs) differentiate into common lymphoid progenitors (CLPs), which give rise to pre-B cells. The B-cell differentiation pathway goes through the pre–B-cell stage (expression of the μ heavy chain and surrogate light chain), the immature B-cell stage (expression of surface IgM), and the mature B-cell stage (expression of surface IgM and IgD). The main phenotypic characteristics of these cells are indicated. In lymphoid organs, B cells can differentiate into plasma cells and produce IgM or undergo (in germinal centers) Ig class switch recombination (CSR) and somatic mutation of the variable region of V genes (SHM) that enable selection of high-affinity antibodies. These B cells produce antibodies of various isotypes and generate memory B cells. PIDs are indicated in the purple boxes. CVID, common variable immunodeficiency.

immunoglobulin class switch recombination (CSR) in germinal centers and leads to profound deficiency in production of IgG, IgA, and IgE (although IgM production is maintained). Approximately half of HIGM sufferers are also prone to opportunistic infections, for example, interstitial pneumonitis caused by *P. jiroveci* (in young children), protracted diarrhea and cholangitis caused by *Cryptosporidium*, and infection of the brain with *Toxoplasma gondii*.

In the majority of cases, this condition has an X-linked inheritance and is caused by a deficiency in CD40 ligand (L). CD40L induces signaling events in B cells that are necessary for both CSR and adequate activation of other CD40-expressing cells that are involved in innate immune responses against the above-mentioned microorganisms. More rarely, the condition is caused by a deficiency in CD40 itself. The poorer prognosis of CD40L and CD40 deficiencies (relative to most other HIGM conditions) implies that (1) thorough investigations have to be performed in all cases of HIGM and (2) potentially curative HSCT should be discussed on a case-by-case basis for this group of patients.

Wiskott-Aldrich Syndrome WAS is a complex, recessive, X-linked disease with an incidence of ~1 in 200,000 live births. It is caused by mutations in the *WASP* gene that affect not only T lymphocytes but also the other lymphocyte subsets, dendritic cells, and platelets. WAS is typically characterized by the following clinical manifestations: recurrent bacterial infections, eczema, and bleeding caused by thrombocytopenia. However, these manifestations are highly variable—mostly as a consequence of the many different *WASP* mutations that have been observed. Null mutations predispose affected individuals to invasive and bronchopulmonary infections, viral infections, severe eczema, and autoimmune manifestations. The latter include autoantibody-mediated blood cytopenia, glomerulonephritis, skin and visceral vasculitis (including brain vasculitis), erythema nodosum, and arthritis. Another possible consequence of WAS is lymphoma, which may be virally induced (e.g., by EBV or Kaposi's sarcoma–associated herpesvirus). Thrombocytopenia can be severe and compounded by the peripheral destruction of platelets associated with autoimmune disorders. Hypomorphic mutations usually lead to milder outcomes that are generally limited to thrombocytopenia. It is noteworthy that even patients with "isolated" X-linked thrombocytopenia can develop severe autoimmune disease or lymphoma later in life. The immunologic workup is not very informative; there can be a relative CD8+ T-cell deficiency, frequently accompanied by low serum IgM levels and decreased antigen-specific antibody responses. A typical feature is reduced-sized platelets on a blood smear. Diagnosis is based on intracellular immunofluorescence analysis of WAS protein (WASp) expression in blood cells. WASp regulates the actin cytoskeleton and thus plays an important role in many lymphocyte functions, including cell adhesion and migration and the formation of synapses between antigen-presenting and target cells. Predisposition to autoimmune disorders is in part related to defective regulatory T cells. The treatment of WAS should match the severity of disease expression. Prophylactic antibiotics, immunoglobulin G (IgG) supplementation, and careful topical treatment of eczema are indicated. Although splenectomy improves platelet count in a majority of cases, this intervention is associated with a significant risk of infection (both before and after HSCT). Allogeneic HSCT is curative, with good results overall. Gene therapy trials have been performed. A similar condition has been reported in a girl with a deficiency in the Wiskott-Aldrich interacting protein (WIP).

A few other complex PIDs are worth mentioning. *Sp110 deficiency* causes a T-cell PID with liver venoocclusive disease and hypogammaglobulinemia. *Chronic mucocutaneous candidiasis* (CMC) is a heterogeneous disease, considering the different inheritance patterns that have been observed. In some cases, chronic candidiasis is associated with late-onset bronchopulmonary infections, bronchiectasis, and brain aneurysms. Moderate forms of CMC are related to autoimmunity and AIRE deficiency (see below). In this setting, predisposition to *Candida* infection is associated with the detection of autoantibodies to T_H17 cytokines. Recently, deficiencies in IL-17A, IL-17F, and IL-17 receptor A and C and in the associated protein Act1, and above all, gain-of-function mutations in *STAT1* have been found to be associated with CMC. In all cases, CMC is related to defective T_H17 function. Innate immunodeficiency in CARD9 also predisposes to chronic invasive fungal infection.

B LYMPHOCYTE DEFICIENCIES (TABLE 351-1, FIG. 351-4)

Deficiencies that predominantly affect B lymphocytes are the most frequent PIDs and account for 60–70% of all cases. B lymphocytes make antibodies. Pentameric IgMs are found in the vascular compartment and are also secreted at mucosal surfaces. IgG antibodies diffuse freely into extravascular spaces, whereas IgA antibodies are produced and secreted predominantly from mucosa-associated lymphoid tissues. Although Ig isotypes have distinct effector functions, including Fc receptor–mediated and (indirectly) C_3 receptor–dependent phagocytosis of microorganisms, they share the ability to recognize and neutralize a given pathogen. Defective antibody production therefore allows the establishment of invasive, pyogenic bacterial infections as well as recurrent sinus and pulmonary infections (mostly caused by *S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and, less frequently, gram-negative bacteria). If left untreated, recurrent bronchial infections lead to bronchiectasis and, ultimately, cor pulmonale and death. Parasitic infections such as caused by *Giardia lamblia* and bacterial infections caused by *Helicobacter* and *Campylobacter* of the gut are also observed. A complete lack of antibody production (namely agammaglobulinemia) can also predispose affected individuals to severe, chronic, disseminated enteroviral infections causing meningoencephalitis, hepatitis, and a dermatomyositis-like disease.

Even with the most profound of B-cell deficiencies, infections rarely occur before the age of 6 months; this is because of transient protection provided by the transplacental passage of immunoglobulins during the last trimester of pregnancy. Conversely, a genetically nonimmunodeficient child born to a mother with hypogammaglobulinemia is, in the absence of maternal Ig substitution, usually prone to severe bacterial infections in utero and for several months after birth.

Diagnosis of B-cell PIDs relies on the determination of serum Ig levels (Table 351-2). Determination of antibody production following immunization with tetanus toxoid vaccine or nonconjugated pneumococcal polysaccharide antigens can also help diagnose more subtle deficiencies. Another useful test is B-cell phenotype determination in switched μ−δ− CD27+ and nonswitched memory B cells (μ+δ+ CD27+). In agammaglobulinemic patients, examination of bone marrow B-cell precursors (Fig. 351-4) can help obtain a precise diagnosis and guide the choice of genetic tests.

Agammaglobulinemia Agammaglobulinemia is characterized by a profound defect in B-cell development (<1% of the normal B-cell blood count). In most patients, very low residual Ig isotypes can be detected in the serum. In 85% of cases, agammaglobulinemia is caused by a mutation in the *BTK* gene that is located on the X chromosome. The *BTK* gene product is a kinase that participates in (pre) B-cell receptor signaling. When the kinase is defective, there is a block (albeit a leaky one) at the pre-B to B-cell stage (Fig. 351-4). Detection of *BTK* by intracellular immunofluorescence of monocytes, and lack thereof in patients with X-linked agammaglobulinemia (XLA), is a useful diagnostic test. Not all of the mutations in *BTK* result in agammaglobulinemia, since some patients have a milder form of hypogammaglobulinemia and low but detectable B-cell counts. These cases should not be confused with common variable immunodeficiency (CVID, see below). About 10% of agammaglobulinemia cases are caused by alterations in genes encoding elements of the pre-B-cell receptor, i.e., the μ heavy chain, the λ5 surrogate light chain, Igα or Igβ, the scaffold protein BLNK, the p85 α subunit of phosphatidylinositol 3 phosphate kinase (P13K), the E47, and the Ikaros transcription factors. In 5% of cases, the defect is unknown. It is noteworthy that agammaglobulinemia can be observed in patients with ICF syndrome, despite the presence of normal peripheral B-cell counts. Lastly, agammaglobulinemia can be a manifestation of a myelodysplastic syndrome (associated or not with neutropenia). Treatment of agammaglobulinemic patients is based on immunoglobulin replacement (see below). Profound

hypogammaglobulinemia is also observed in adults, in association with thymoma.

Hyper-IgM (HIGM) Syndromes *HIGM* is a rare B-cell PID characterized by defective Ig CSR. It results in very low serum levels of IgG and IgA and elevated or normal serum IgM levels. The clinical severity is similar to that seen in agammaglobulinemia, although chronic lung disease and sinusitis are less frequent and enteroviral infections are uncommon. As discussed above, a diagnosis of HIGM involves screening for an X-linked CD40L deficiency and an autosomal recessive CD40 deficiency, which affect both B and T cells. In 50% of cases affecting only B cells, these isolated HIGM syndromes result from mutations in the gene encoding activation-induced deaminase, the protein that induces CSR in B-cell germinal centers. These patients usually have enlarged lymphoid organs. In the other 50% of cases, the etiology is unknown (except for rare UNG and PMS2 deficiencies). Furthermore, IgM-mediated autoimmunity and lymphomas can occur in HIGM syndrome. It is noteworthy that HIGM can result from fetal rubella syndrome or can be a predominant immunologic feature of other PIDs, such as the immunodeficiency associated with ectodermic anhydrotic hypoplasia X-linked NEMO deficiency and the combined T- and B-cell PIDs caused by DNA repair defects such as AT and Cernunnos deficiency.

Common Variable Immunodeficiency CVID is an ill-defined condition characterized by low serum levels of one or more Ig isotypes. Its prevalence is estimated to be 1 in 20,000. The condition is recognized predominantly in adults, although clinical manifestations can occur earlier in life. Hypogammaglobulinemia is associated with at least partially defective antibody production in response to vaccine antigens. B lymphocyte counts are often normal but can be low. Besides infections, CVID patients may develop lymphoproliferation (splenomegaly), granulomatous lesions, colitis, antibody-mediated autoimmune disease, and lymphomas that define disease prognosis. A family history is found in 10% of cases. A clear-cut dominant inheritance pattern is found in some families, whereas recessive inheritance is observed more rarely. In most cases, no molecular cause can be identified. A small number of patients in Germany were found to carry mutations in the *ICOS* gene encoding a T-cell membrane protein that contributes to B-cell activation and survival. In 10% of patients with CVID, monoallelic or biallelic mutations of the gene encoding TACI (a member of the tumor necrosis factor [TNF] receptor family that is expressed on B cells) have been found. In fact, heterozygous TACI mutations correspond to a genetic susceptibility factor, since similar heterozygous mutations are found in 1% of controls. NFkB1 transcription factor mutations have been found in a small fraction of patients with CVID. The B-cell activating factor (BAFF) receptor was found to be defective in a kindred with CVID, although not all individuals carrying the mutation have CVID. A group of patients with hypogammaglobulinemia and lymphoproliferation was shown to exhibit dominant gain-of-function mutations in the *PIK3CD* gene encoding the p110δ form of P13 kinase or in the *PI3KR1* gene encoding the regulatory p85α subunit of PI3 kinase. Rare cases of hypogammaglobulinemia were found to be associated with CD19, CD20, CD21, and CD81 deficiencies. These patients have B cells that can be identified by typing for other B-cell markers.

A diagnosis of CVID should be made after excluding the presence of hypomorphic mutations associated with agammaglobulinemia or more subtle T-cell defects; this is particularly the case in children. It is possible that many cases of CVID result from a constellation of factors, rather than a single genetic defect. Hypogammaglobulinemia can be associated with neutropenia and lymphopenia in the WHIM syndrome caused by a dominant gain-of-function mutation of *CXCR4*, resulting in cell retention in the bone marrow.

Selective Ig Isotype Deficiencies *IgA deficiency* and CVID represent polar ends of a clinical spectrum due to the same underlying gene defect(s) in a large subset of these patients. IgA deficiency is the most common PID; it can be found in 1 in every 600 individuals. It is asymptomatic in most cases; however, individuals may present with increased numbers of acute and chronic respiratory infections that may lead to bronchiectasis. In addition, over their lifetime, these patients experience an increased susceptibility to drug allergies, atopic disorders, and autoimmune diseases. Symptomatic IgA deficiency is probably related to CVID, since it can be found in relatives of patients with CVID. Furthermore, IgA deficiency may progress to CVID. It is thus important to assess serum Ig levels in IgA-deficient patients (especially when infections occur frequently) in order to detect changes that should prompt the initiation of immunoglobulin replacement. Selective IgG2 (+G4) deficiency (which in some cases may be associated with IgA deficiency) can also result in recurrent sinopulmonary infections and should thus be specifically sought in this clinical setting. These conditions are ill-defined and often transient during childhood. A pathophysiologic explanation has not been found.

Selective Antibody Deficiency to Polysaccharide Antigens Some patients with normal serum Ig levels are prone to *S. pneumoniae* and *H. influenzae* infections of the respiratory tract. Defective production of antibodies against polysaccharide antigens (such as those in the *S. pneumoniae* cell wall) can be observed and is probably causative. This condition may correspond to a defect in marginal zone B cells, a B-cell subpopulation involved in T-independent antibody responses.

Immunoglobulin Replacement IgG antibodies have a half-life of 21–28 days. Thus, injection of plasma-derived polyclonal IgG containing a myriad of high-affinity antibodies can provide protection against disease-causing microorganisms in patients with defective IgG antibody production. This form of therapy should not be based on laboratory data alone (i.e., IgG and/or antibody deficiency) but should be guided by the occurrence or not of infections; otherwise, patients might be subjected to unjustified IgG infusions. Immunoglobulin replacement can be performed by IV or subcutaneous routes. In the former case, injections have to be repeated every 3–4 weeks, with a residual target level above 800 mg/mL in patients who had very low IgG levels prior to therapy. Subcutaneous injections are typically performed once a week, although the frequency can be adjusted on a case-by-case basis. A trough level above 800 mg/mL is desirable. Whatever the mode of administration, the main goal is to reduce the frequency of the respiratory tract infections and prevent chronic lung and sinus disease. The two routes appear to be equally safe and efficacious, and so the choice should be left to the preference of the patient.

In patients with chronic lung disease, chest physical therapy with good pulmonary toilet and the use of antibiotics, notably azithromycin, are also needed. Immunoglobulin replacement is well tolerated by most patients, although the selection of the best-tolerated Ig preparation may be necessary in certain cases. Since IgG preparations contain a small proportion of IgAs, caution should be taken in patients with residual antibody production capacity and a complete IgA deficiency, as these subjects may develop anti-IgA antibodies that can trigger anaphylactic shock. These patients should be treated with IgA-free IgG preparations. Immunoglobulin replacement is a lifelong therapy; its rationale and procedures have to be fully understood and mastered by the patient and his or her family in order to guarantee the strict observance required for efficacy.

PRIMARY IMMUNODEFICIENCIES AFFECTING REGULATORY PATHWAYS (TABLE 351-1)

An increasing number of PIDs have been found to cause homeostatic dysregulation of the immune system, either alone or in association with increased vulnerability to infections. Defects of this type affecting the innate immune system and autoinflammatory syndromes will not be covered in this chapter. However, three specific entities (hemophagocytic lymphohistiocytosis [HLH], lymphoproliferation, and autoimmunity) will be described below.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

HLH is characterized by an unremitting activation of CD8+ T lymphocytes and macrophages that leads to organ damage (notably in the

liver, bone marrow, and central nervous system). This syndrome results from a broad set of inherited diseases, most of which impair T and NK lymphocyte cytotoxicity. The manifestations of HLH are often induced by a viral infection. EBV is the most frequent trigger. In severe forms of HLH, disease onset may start during the first year of life or even (in rare cases) at birth.

Diagnosis relies on the identification of the characteristic symptoms of HLH (fever, hepatosplenomegaly, edema, neurologic diseases, blood cytopenia, increased liver enzymes, hypofibrinogenemia, high triglyceride [hyper ferritinemia] levels, elevated markers of T-cell activation, and hemophagocytic features in the bone marrow or cerebrospinal fluid). Functional assays of postactivation cytotoxic granule exocytosis (CD107 fluorescence at the cell membrane) can suggest genetically determined HLH. The conditions can be classified into three subsets:

1. Familial HLH with autosomal recessive inheritance, including perforin deficiency (30% of cases) that can be recognized by assessing intracellular perforin expression; Munc13-4 deficiency (30% of cases); syntaxin 11 deficiency (10% of cases); Munc18-2 deficiency (20% of cases); and a few residual cases that lack a known molecular defect.
2. HLH with partial albinism. Three conditions combine HLH and abnormal pigmentation, where hair examination can help in the diagnosis: Chédiak-Higashi syndrome, Griscelli syndrome, and Hermansky-Pudlak syndrome type II. Chédiak-Higashi syndrome is also characterized by the presence of giant lysosomes within leukocytes **(Chap. 64)**, in addition to a primary neurologic disorder with slow progression of symptoms over time.
3. XLP is characterized in most patients by the induction of HLH following EBV infection, while other patients develop progressive hypogammaglobulinemia similar to what is observed in CVID and/or certain lymphomas. XLP is caused by a mutation in the *SH2DIA* gene that encodes the adaptor protein SAP (associated with a SLAM family receptor). Several immunologic abnormalities have been described, including low 2B4-mediated NK cell cytotoxicity, impaired differentiation of NKT cells, defective antigen-induced T-cell death, and defective T-cell helper activity for B cells. A related disorder (XLP2) has recently been described. It is also X-linked and induces HLH (frequently after EBV infection), although the clinical manifestation may be less pronounced. The condition is associated with a deficiency of the antiapoptotic molecule XIAP. The pathophysiology of XLP2 remains unclear; however, it may be related to control of inflammation in macrophages as there is a functional link between XIAP and NLRC4, an inflammasome component, in which gain of function can also induce HLH. XLP2 is also frequently associated with colitis.

HLH is a life-threatening complication. The treatment of this condition requires aggressive immunosuppression with either the cytotoxic agent etoposide or anti–T-cell antibodies; specific therapy targeting IFN-γ, which is critical in causing HLH, is an additional option to consider. Once remission has been achieved, HSCT should be performed, since it provides the only curative form of therapy. Of note, acquired forms of HLH are more commonly observed in adults as a complication of infection, malignancies or autoimmune diseases or sometimes on its own.

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

Autoimmune lymphoproliferative syndrome (ALPS) is characterized by nonmalignant T and B lymphoproliferation causing splenomegaly and enlarged lymph nodes; 70% of patients also display autoimmune manifestations such as autoimmune cytopenias, Guillain-Barré syndrome, uveitis, and hepatitis **(Chaps. 66 and 349)**. A hallmark of ALPS is the presence of CD4–CD8– TCRαβ+ T cells (2–50%) in the blood of affected individuals. Hypergammaglobulinemia involving IgG and IgA is also frequently observed. The syndrome is caused by a defect in Fas-mediated apoptosis of lymphocytes, which can thus accumulate and mediate autoimmunity. Furthermore, ALPS can lead to malignancies.

Most patients carry a heterozygous mutation in the gene encoding Fas that is characterized by dominant inheritance and variable penetrance, depending on the nature of the mutation. A rare and severe form of the disease with early onset can be observed in patients carrying a biallelic mutation of Fas, which profoundly impairs the protein's expression and/or function. Fas-ligand, caspase 10, caspase 8, and somatic neuroblastoma RAS viral oncogene homologue (NRAS) and KRAS mutations have also been reported in a few cases of ALPS. Many cases of ALPS have not been precisely delineated at the molecular level. A B cell–predominant ALPS has recently been found associated with a protein kinase Cδ gene mutation. Treatment of ALPS is essentially based on the use of proapoptotic drugs, which need to be carefully administered in order to avoid toxicity.

COLITIS, AUTOIMMUNITY, AND PRIMARY IMMUNODEFICIENCIES

Several PIDs (most of which are T cell–related) can cause severe gut inflammation. The prototypic example is *immunodysregulation polyendocrinopathy enteropathy X-linked syndrome* (IPEX), characterized by a widespread inflammatory enteropathy, food intolerance, skin rashes, autoimmune cytopenias, and diabetes. The syndrome is caused by loss-of-function mutations in the gene encoding the transcription factor FOXP3, which is required for the acquisition of effector function by regulatory T cells. In most cases of IPEX, CD4+CD25+ regulatory T cells are absent from the blood. This condition has a poor prognosis and requires aggressive immunosuppression. The only possible curative approach is allogeneic HSCT. IPEX-like syndromes that lack a FOXP3 mutation have also been described. In some cases, CD25 (IL-2 receptor α subunit) and CD122 (IL-2 receptor β subunit) deficiencies have been found. Defective IL-2 receptor expression also impairs regulatory cell expansion/function. This functional T-cell deficiency means that IL-2 receptor–deficient patients are also at increased risk of opportunistic infections. It is noteworthy that abnormalities in regulatory T cells have been described in other PID settings, such as in Omenn syndrome, STAT5b deficiency, STIM1 (Ca flux) deficiency, and WAS; these abnormalities may account (at least in part) for the occurrence of inflammation and autoimmunity. The autoimmune features observed in a small fraction of patients with DiGeorge's syndrome may have the same cause. Severe, early-onset inflammatory gut disease has been described in patients with a deficiency in the IL-10 receptor or IL-10.

Dominant mutations in genes encoding the regulatory molecule CTLA-4, recessive mutations in the gene encoding LRBA (a molecule involved in recycling of CTLA-4), as well as dominant gain-of-function mutation of STAT3 cause a multifaceted lymphoproliferative and autoimmune syndrome, frequently involving inflammatory bowel disease that can be associated with hypogammaglobulinemia. Molecular diagnosis is required before adapted targeted therapies are undertaken.

A distinct autoimmune entity is observed in *autoimmune polyendocrinopathy candidiasis ectodermal dysplasia* (APECED) syndrome, which is characterized by autosomal recessive inheritance. It consists of multiple autoimmune manifestations that can affect solid organs in general and endocrine glands in particular. Mild, chronic *Candida* infection is often associated with this syndrome. The condition is due to mutations in the autoimmune regulator (*AIRE*) gene and results in impaired thymic expression of self-antigens by medullary epithelial cells and impaired negative selection of self-reactive T cells that leads to autoimmune manifestations.

A combination of hypogammaglobulinemia, autoantibody production, cold-induced urticaria or skin granulomas, or autoinflammation has been reported and has been termed *PLCγ2-associated antibody deficiency and immune dysregulation* (PLAID or APLAID).

CONCLUSION

The variety and complexity of the clinical manifestations of the many different PIDs strongly indicate that it is important to raise awareness of these diseases. Indeed, early diagnosis is essential for establishing an appropriate therapeutic regimen. Hence, patients with suspected PIDs must always be referred to experienced clinical centers that are able to perform appropriate molecular and genetic tests. A precise molecular diagnosis is not only necessary for initiating the most suitable treatment, but is also important for genetic counseling and prenatal diagnosis.

One pitfall that may hamper diagnosis is the high variability that is associated with many PIDs. Variable disease expression can result from the differing consequences of various mutations associated with a given condition, as exemplified by WAS and, to a lesser extent, XLA. There can also be effects of modifier genes (as also suspected in XLA) and environmental factors such as EBV infection that can be the main trigger of disease in XLP conditions. Furthermore, it has recently been established that somatic mutations in an affected gene can attenuate the phenotype of a number of T-cell PIDs. This has been described for ADA deficiency, X-linked SCID, RAG deficiencies, NF-κB essential modulator (NEMO) deficiency, and, most frequently, WAS. In contrast, somatic mutations can create disease states analogous to PID, as reported for ALPS. Lastly, cytokine-neutralizing autoantibodies can mimic a PID, as shown for IFN-γ.

Many aspects of the pathophysiology of PIDs are still unknown, and the disease-causing gene mutations have not been identified in all cases (as illustrated by CVID and IgA deficiency). However, our medical understanding of PIDs has now reached the stage where scientifically based approaches to the diagnosis and treatment of these diseases can be implemented. A genetic diagnosis has become a milestone step in the care of PID patients.

352 Urticaria, Angioedema, and Allergic Rhinitis

Katherine L. Tuttle, Joshua A. Boyce

INTRODUCTION

The term *atopy* implies a tendency to manifest asthma, rhinitis, urticaria, food allergy, and atopic dermatitis alone or in combination, in association with the presence of allergen-specific IgE. However, individuals without an atopic background may also develop hypersensitivity reactions, particularly urticaria and anaphylaxis, associated with the presence of IgE. Since mast cells are key effector cells in allergic rhinitis and asthma, and the dominant effector in urticaria, anaphylaxis, and systemic mastocytosis, mast cell developmental biology, activation pathway, product profile, and target tissues will be considered in the introduction to these clinical disorders. Dysregulation of mast cell development seen in mastocytosis will be covered in a separate chapter.

The binding of IgE to human mast cells and basophils, a process termed *sensitization*, prepares these cells for subsequent antigen-specific activation. The high-affinity Fc receptor for IgE, designated FcεRI, is composed of one α, one β, and two disulfide-linked γ chains, which together cross the plasma membrane seven times. The α chain is responsible for IgE binding, and the β and γ chains provide for signal transduction that follows the aggregation of the sensitized tetrameric receptors by polymeric antigen. The binding of IgE stabilizes the α chain at the plasma membrane, thus increasing the density of FcεRI receptors at the cell surface while sensitizing the cell for effector responses. This accounts for the correlation between serum IgE levels and the numbers of FcεRI receptors detected on circulating basophils. Signal transduction is initiated through the action of a Src family–related tyrosine kinase termed Lyn that is constitutively associated with the β chain. Lyn transphosphorylates the canonical immunoreceptor tyrosine-based activation motifs (ITAMs) of the β and γ chains of the receptor, resulting in recruitment of more active Lyn to the β chain and of Syk tyrosine kinase. The phosphorylated tyrosines in the ITAMs function as binding sites for the tandem *src* homology two (SH2) domains within Syk. Syk activates not only phospholipase Cγ, which associates with the linker of activated T cells at the plasma membrane, but also phosphatidylinositol 3-kinase to provide phosphatidylinositol-3,4,5-trisphosphate, which allows membrane targeting of the Tec family kinase Btk and its activation by Lyn. In addition, the Src family tyrosine kinase Fyn becomes activated after aggregation of IgE receptors and phosphorylates the adapter protein Gab2 that enhances activation of phosphatidylinositol 3-kinase. Indeed, this additional input is essential for mast cell activation, but it can be partially inhibited by Lyn, indicating that the extent of mast cell activation is in part regulated by the interplay between these Src family kinases. Activated phospholipase Cγ cleaves phospholipid membrane substrates to provide inositol-1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerols (1,2-DAGs) to mobilize intracellular calcium and activate protein kinase C, respectively. The subsequent opening of calcium-regulated activated channels provides the sustained elevations of intracellular calcium required to recruit the mitogen-activated protein kinases ERK, JNK, and p38 (serine/threonine kinases), which provide cascades to augment arachidonic acid release and to mediate nuclear translocation of transcription factors for various cytokines. The calcium ion–dependent activation of phospholipases cleaves membrane phospholipids to generate lysophospholipids, which, like 1,2-DAG, may facilitate the fusion of the secretory granule perigranular membrane with the cell membrane, a step that releases the membrane-free granules containing the preformed mast cell mediators.

The secretory granule of the human mast cell has a crystalline structure. IgE-dependent cell activation results in solubilization and

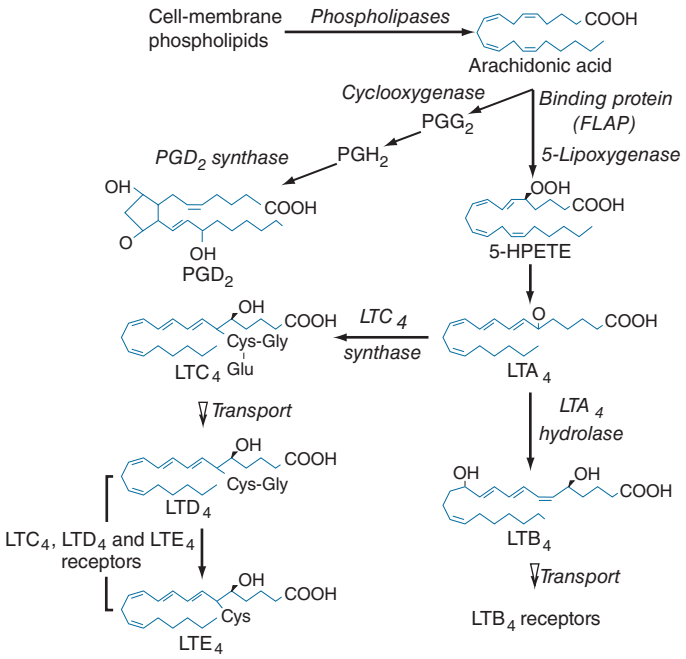

FIGURE 352-1 Pathways for biosynthesis and release of membrane-derived lipid mediators from mast cells. In the 5-lipoxygenase pathway, leukotriene A_4 (LTA_4) is the intermediate from which the terminal-pathway enzymes generate the distinct final products, leukotriene C_4 (LTC_4) and leukotriene B_4 (LTB_4), which leave the cell by separate saturable transport systems. Gamma glutamyl transpeptidase and a dipeptidase then cleave glutamic acid and glycine from LTC_4 to form LTD_4 and LTE_4, respectively. The major mast cell product of the cyclooxygenase system is PGD_2.

swelling of the granule contents within the first minute of receptor perturbation; this reaction is followed by the ordering of intermediate filaments about the swollen granule, movement of the granule toward the cell surface, and fusion of the perigranular membrane with that of other granules and with the plasmalemma to form extracellular channels for mediator release while maintaining cell viability.

In addition to exocytosis, aggregation of FcεRI initiates two additional pathways for generation of bioactive products, namely, lipid mediators, chemokines, and cytokines. Cytokines elaborated by mast cells include tumor necrosis factor α (TNF-α), interleukin (IL) 1, IL-6, IL-4, IL-5, IL-13, and granulocyte-macrophage colony-stimulating factor (GM-CSF).

Lipid mediator generation **(Fig. 352-1)** involves translocation of calcium ion–dependent cytosolic phospholipase A_2 to the outer nuclear membrane, with subsequent release of arachidonic acid for metabolic processing by the distinct prostanoid and leukotriene pathways. The constitutive prostaglandin endoperoxide synthase-1 (PGHS-1/cyclooxygenase-1) and the de novo inducible PGHS-2 (cyclooxygenase-2) convert released arachidonic acid to the sequential intermediates, prostaglandins G_2 and H_2. The glutathione-dependent hematopoietic prostaglandin D_2 (PGD_2) synthase then converts PGH_2 to PGD_2, the predominant mast cell prostanoid. The PGD_2 receptor DP_1 is expressed by platelets, natural killer cells, dendritic cells, and epithelial cells, whereas DP_2 is expressed by T_H2 lymphocytes, innate lymphoid type 2 cells, eosinophils, and basophils. Mast cells also generate thromboxane A_2 (TXA_2), a short lived but powerful mediator that induces bronchoconstriction and platelet activation through the T prostanoid (TP) receptor.

For leukotriene biosynthesis, the released arachidonic acid is metabolized by 5-lipoxygenase (5-LO) in the presence of an integral nuclear membrane protein, 5-LO activating protein (FLAP). The calcium ion–dependent translocation of 5-LO to the nuclear membrane converts the arachidonic acid to the sequential intermediates, 5-hydroperoxyeicosatetraenoic acid (5-HPETE) and leukotriene (LT) A_4. LTA_4 is conjugated with reduced glutathione by LTC_4 synthase, an integral nuclear membrane protein homologous to FLAP. Intracellular LTC_4 is released by a carrier-specific export step for extracellular metabolism to the additional cysteinyl leukotrienes, LTD_4 and LTE_4, by the sequential removal of glutamic acid and glycine. Alternatively, cytosolic LTA_4 hydrolase converts some LTA_4 to the dihydroxy leukotriene LTB_4, which also undergoes specific export. Two receptors for LTB_4, BLT_1 and BLT_2, mediate chemotaxis of human neutrophils. Two receptors for the cysteinyl leukotrienes, $CysLT_1$ and $CysLT_2$, are present on smooth muscle of the airways and the microvasculature and on hematopoietic cells such as macrophages, eosinophils, and mast cells. Whereas the $CysLT_1$ receptor has a preference for LTD_4 and is blocked by the receptor antagonists in clinical use, the $CysLT_2$ receptor is equally responsive to LTD_4 and LTC_4, is unaffected by these antagonists, and is a negative regulator of the function of the $CysLT_1$ receptor. LTD_4, acting at $CysLT_1$ receptors, is the most potent known bronchoconstrictor, whereas LTE_4 induces a vascular leak and mediates the recruitment of eosinophils to the bronchial mucosa. Recently, GPR99, initially identified as a receptor for α-ketoglutarate, was identified as an LTE_4 receptor. The lysophospholipid formed during the release of arachidonic acid from 1-*O*-alkyl-2-acyl-*sn*-glyceryl-3-phosphorylcholine can be acetylated in the second position to form platelet-activating factor (PAF). Serum levels of PAF correlated positively with the severity of anaphylaxis to peanut in a recent study, whereas the levels of PAF acetyl hydrolase (a PAF-degrading enzyme) were inversely related to the same outcome.

Human mast cells express receptors for anaphylatoxin, C5a and C3a, toll-like receptors, receptors for epithelial alarmins thymic stromal lymphopoietin (TSLP) and IL-33, and a newly recognized Mas-related G protein–coupled receptor (MRGPX2), all which activate mast cells in an IgE-dependent manner. MRGPX2 is a target of many small-molecule drugs with a central tetrahydroisoquinoline motif, such as ciprofloxacin and rocuronium, which may explain the observed episodes of anaphylaxis to these medications without evidence of IgE-mediated hypersensitivity.

Unlike most other cells of bone marrow origin, mast cells circulate as committed progenitors lacking their characteristic secretory granules. These committed progenitors express c-*kit*, the receptor for stem cell factor (SCF). Unlike most other lineages, they retain and increase c-*kit* expression with maturation. The SCF interaction with c-*kit* is an absolute requirement for the development of both constitutive connective tissue and skin mast cells and for the accumulation of mast cells at mucosal surfaces during T_H2-type immune responses. Several T cell–derived cytokines (IL-3, IL-4, IL-5, and IL-9) can potentiate SCF-dependent mast cell proliferation and/or survival in vitro in mice and humans. Indeed, mast cells are absent from the intestinal mucosa in clinical T-cell deficiencies but are present in the submucosa. Historical mast cell classification has been based on the immunodetection of secretory granule neutral proteases. Mast cells in the lung parenchyma and intestinal mucosa selectively express tryptase, and those in the intestinal and airway submucosa, perivascular spaces, skin, lymph nodes, and breast parenchyma express tryptase, chymase, and carboxypeptidase A (CPA). Selective environmental cues, such as T_H2 inflammation, can lead to different protease expression; in the mucosal epithelium of severe asthmatics and apical epithelium of nasal polyps, mast cells can express tryptase and CPA without chymase. The secretory granules of mast cells selectively positive for tryptase exhibit closed scrolls with a periodicity suggestive of a crystalline structure by electron microscopy, whereas the secretory granules of mast cells with multiple proteases are scroll-poor, with an amorphous or lattice-like appearance. In addition to immunodetection of proteases, expression profiling through single-cell RNA sequencing methods has further elucidated different mast cell populations.

Mast cells are distributed at cutaneous and mucosal surfaces and in submucosal tissues about venules and could influence the entry of foreign substances by their rapid response capability **(Fig. 352-2)**. Upon stimulus-specific activation and secretory granule exocytosis, histamine and acid hydrolases are solubilized, whereas the neutral proteases, which are cationic, remain largely bound to the anionic proteoglycans, heparin and chondroitin sulfate E, with which they function as a complex. Histamine and the various lipid mediators (PGD_2,

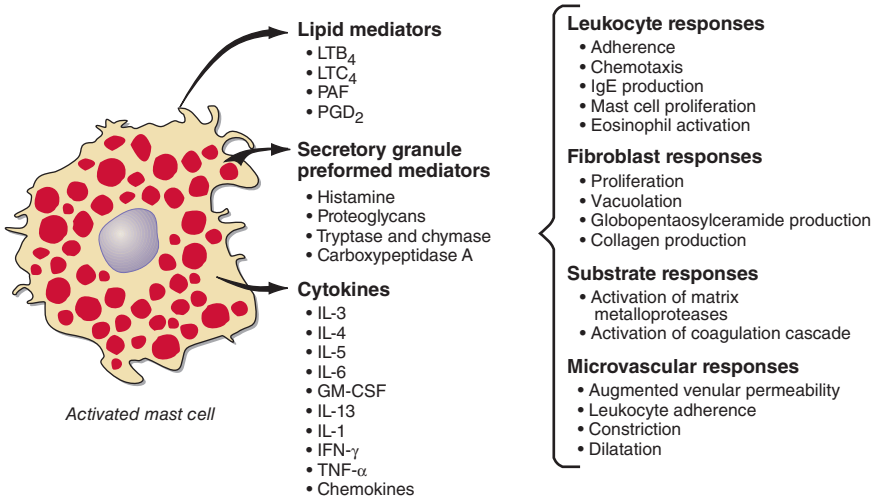

FIGURE 352-2 Bioactive mediators of three categories generated by IgE-dependent activation of murine mast cells can elicit common but sequential target cell effects leading to acute and sustained inflammatory responses. GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; IFN, interferon; LT, leukotriene; PAF, platelet-activating factor; PGD_2, prostaglandin D_2; TNF, tumor necrosis factor.

$LTC_4/D_4/E_4$, PAF) alter venular permeability, thereby allowing influx of plasma proteins such as complement and immunoglobulins, whereas LTB_4 mediates leukocyte–endothelial cell adhesion and subsequent directed migration (chemotaxis). The accumulation of leukocytes and plasma opsonins facilitates defense of the microenvironment. The inflammatory response can also be detrimental, as in asthma, where the smooth-muscle constrictor activity of the cysteinyl leukotrienes is evident and much more potent than that of histamine.

The cellular component of the mast cell–mediated inflammatory response is augmented and sustained by cytokines and chemokines. IgE-dependent activation of human skin mast cells in situ elicits TNF-α production and release, which in turn induces endothelial cell responses favoring leukocyte adhesion. Similarly, activation of purified human lung mast cells or cord blood–derived cultured mast cells in vitro results in substantial production of proinflammatory (TNF-α) and immunomodulatory cytokines (IL-4, IL-5, IL-13) and chemokines. Bronchial biopsy specimens from patients with asthma reveal that mast cells are immunohistochemically positive for IL-4 and IL-5, but that the predominant localization of IL-4, IL-5, and GM-CSF is to T cells, defined as T_H2 by this profile. IL-4 modulates the T-cell phenotype to the T_H2 subtype, determines the isotype switch to IgE (as does IL-13), and upregulates FcεRI-mediated expression of cytokines by mast cells based on in vitro studies.

An immediate and late cellular phase of allergic inflammation can be induced in the skin, nose, or lung of some allergic humans with local allergen challenge. The immediate phase in the nose involves pruritus and watery discharge; in the lung, it involves bronchospasm and mucus secretion; and in the skin, it involves a wheal-and-flare response with pruritus. Diminished nasal patency, reduced pulmonary function, or erythema with swelling at the skin site in a late-phase response at 6–8 h is associated with biopsy findings of infiltrating and activated T_H2 cells, eosinophils, basophils, and some neutrophils. The progression from early mast cell activation to late cellular infiltration has been used as an experimental surrogate of rhinitis or asthma. However, in asthma, there is an intrinsic hyperreactivity of the airways independent of the associated inflammation. Moreover, early- and late-phase responses (at least in the lung) are far more sensitive to blockade of IgE-dependent mast cell activation (or actions of histamine and cysteinyl leukotrienes) than are spontaneous or virally induced asthma exacerbations.

Consideration of the mechanism of immediate-type hypersensitivity diseases in the human has focused largely on the IgE-dependent recognition of otherwise innocuous substances. A region of chromosome 5 (5q23-31) contains genes implicated in the control of IgE levels including IL-4 and IL-13, as well as IL-3 and IL-9, which are involved in mucosal mast cell hyperplasia, and IL-5 and GM-CSF, which are central to eosinophil development and their enhanced tissue viability. Genes with linkage to the specific IgE response to particular allergens include those encoding the major histocompatibility complex (MHC) and certain chains of the T-cell receptor (TCR-αδ). The complexity of atopy and the associated diseases includes susceptibility, severity, and therapeutic responses, each of which is among the separate variables modulated by both innate and adaptive immune stimuli.

The induction of allergic disease requires sensitization of a predisposed individual to a specific allergen. The greatest propensity for the development of atopic allergy occurs in childhood and early adolescence. The allergen is processed by antigen-presenting cells of the monocytic lineage (particularly dendritic cells) located throughout the body at epithelial surfaces that contact the outside environment, such as the nose, lungs, eyes, skin, and intestine. These antigen-presenting cells present the epitope-bearing peptides via their MHC to T helper cells and their subsets. The T-cell response depends both on cognate recognition and on the cytokine microenvironment provided by the antigen-presenting dendritic cells, with IL-4 directing a T_H2 subset, interferon (IFN) γ a T_H1 profile, and IL-6 with transforming growth factor β (TGF-β) a T_H17 subset. Allergens can induce an epithelial alarmin response, with expression of IL-25, TSLP, and IL-33, which stimulate group 2 innate lymphoid cells, which can generate large quantities of IL-5 and IL-13. Allergens also contain pattern recognition ligands that facilitate the immune response by direct initiation of cytokine generation from innate cell types such as basophils, mast cells, eosinophils, and others. The T_H2 response is associated with activation of specific B cells that can also present allergens or that transform into plasma cells for antibody production. Synthesis and release into the plasma of allergen-specific IgE results in sensitization of FcεR1-bearing cells such as mast cells and basophils, which become activated on exposure to the specific allergen. In certain diseases, including those associated with atopy, the monocyte and eosinophil populations can express a trimeric FcεR1, which lacks the β chain, and yet respond to its aggregation.

URTICARIA AND ANGIOEDEMA

DEFINITION

Urticaria and angioedema represent the same pathophysiologic process occurring at different levels of the skin. Urticaria involves dilation of vascular structures in the superficial dermis, while angioedema originates from the deeper dermis and subcutaneous tissues. Not surprisingly, they often appear together, with roughly 40% of patients reporting both, and affect >20% of the population at some time during their life span. Urticaria can occur on any area of the body

as well-circumscribed wheals with erythematous raised serpiginous borders and blanched centers that may coalesce to become giant wheals. Urticarial lesions last for <24 h, are intensely pruritic, frequently migrate around the body, and leave no bruising or scarring. Angioedema is marked by dramatic swelling with more pain than pruritus and minimal erythema, which may develop with a pruritic prodrome and takes hours to days to resolve. Acute urticaria and/or angioedema are episodes that occur for <6 weeks' duration, whereas attacks persisting for >6 weeks are designated chronic.

PREDISPOSING FACTORS AND ETIOLOGY

Acute or chronic urticaria and/or angioedema can occur at any point in the life span with the third to fifth decades the most common for chronic disease. Women are affected more often than men with a slight predominance for those with a history of atopy. Acute urticaria is most often the result of exposure to a food, environmental, or drug allergen or viral infection, while chronic urticaria is often idiopathic. More than two-thirds of new-onset urticaria cases are ultimately diagnosed as acute.

The classification of urticaria-angioedema presented in **Table 352-1** focuses on the different mechanisms for eliciting clinical disease and can be useful for differential diagnosis.

Additional etiologies include physical stimuli such as cold, heat, solar UV radiation, exercise, and mechanical irritation. The physical urticarias can be distinguished by the precipitating event and other aspects of the clinical presentation. *Dermatographism*, which occurs in 2–5% of the population, is defined by the appearance of a linear wheal with surrounding erythema at the site of a brisk stroke with a firm object **(Fig. 352-3)**. Dermatographism has a prevalence that peaks in the second to third decades. It is not influenced by atopy and has a duration generally of <5 years. *Pressure urticaria*, which often accompanies chronic idiopathic urticaria, presents in response to a sustained stimulus such as a shoulder strap or belt, running (feet), or manual labor (hands). *Cholinergic urticaria* is distinctive in that the pruritic wheals are of small size (1–2 mm) and are surrounded by a large area of erythema; attacks are precipitated by fever, a hot bath or shower, or exercise and are presumptively attributed to a rise in core body temperature. *Exercise-induced anaphylaxis* can be precipitated by exertion alone or can be dependent on food ingestion prior to exercise. There is an association with the presence of IgE specific for α-5 gliadin, a component of wheat. The clinical presentation can be limited to flushing, erythema, and pruritic urticaria but may progress to angioedema of the face, oropharynx, larynx, or intestine and/or to vascular collapse; it is distinguished from cholinergic urticaria by presenting with wheals of conventional size and by not occurring with passive heating. *Solar urticaria* is subdivided into six groups by the response to specific portions of the light spectrum. *Cold urticaria* is local at body areas exposed to low ambient temperature or cold objects but can progress to vascular collapse with immersion in cold water (swimming). *Vibratory urticaria and angioedema* may occur after years of occupational exposure or can be idiopathic; it may be accompanied by cholinergic urticaria. In rare cases, variants of cold and vibratory urticaria are inherited and syndromic conditions, with mutations in the NLRP3 component of inflammasome leading to familial cold autoinflammatory syndrome, and mutations in the mast cell mechanoreceptor ADGRE2 associated with familial vibratory urticaria. Other rare forms of physical allergy, always defined by stimulus-specific elicitation, include *local heat urticaria*, *aquagenic urticaria* from contact with water of any temperature (sometimes associated with polycythemia vera), and *contact urticaria* from direct interaction with some chemical substance (such as latex).

FIGURE 352-3 Dermographic urticarial lesion induced by stroking the forearm lightly with the edge of a tongue blade. The photograph, taken after 10 min, demonstrates a prominent wheal-and-flare reaction in the shape of a *hashtag*. *(Photograph provided by Katherine N. Cahill, MD, Harvard Medical School.)*

Isolated Angioedema Angioedema without urticaria can be idiopathic or due to the generation of bradykinin in the setting of C1 inhibitor (C1INH) deficiency that may be inborn as an autosomal dominant mutation or may be acquired through the appearance of an autoantibody in the setting of malignancy or autoimmune disease. The angiotensin-converting enzyme (ACE) inhibitors can provoke a similar clinical presentation in 0.2–0.7% of exposed patients due to delayed degradation of bradykinin. Black race, organ transplant, female gender, smoking, and increasing age are known risk factors for ACE inhibitor–related angioedema.

TABLE 352-1 Classification of Urticaria and/or Angioedema

ACUTE	CHRONIC
Drug reactions	Idiopathic—subset with autoimmune component
Including (but not limited to): antimicrobials, nonsteroidal anti-inflammatory drugs (NSAIDs), contrast media, angiotensin-converting enzyme (ACE) inhibitors, etc.	Collagen vascular disease—urticarial vasculitis and other small vessel vasculitis
Food reactions	Physical stimuli
Inhalation or contact with environmental allergens	Dermographism
Transfusion reactions	Cholinergic urticaria
Stinging and biting insects	Vibration, cold, pressure, water (aquagenic)
Toxin (scombroid)	Sun (solar)
Infections—viral, bacterial, parasitic	Mastocytosis (cutaneous or systemic)
	Hereditary
	Hereditary angioedema (HAE)
	C3b inhibitor deficiency
	CIAS1-associated periodic fever syndromes (familial cold urticaria, Muckle-Wells syndrome)
	Schnitzler's syndrome
	Hypereosinophilic syndrome
	Gleich's syndrome

CLINICAL PRESENTATION AND PATHOPHYSIOLOGY

Urticarial eruptions are distinctly pruritic, may involve any area of the body from the scalp to the soles of the feet, and appear in crops of 12- to 36-h duration, with old lesions fading as new ones appear. Most of the physical urticarias (cold, cholinergic, dermatographism) are an exception, with individual lesions lasting <2 h. Neither urticaria nor angioedema lesions are symmetric or dependent in distribution. The most common sites for angioedema are often periorbital and perioral. Angioedema of the upper respiratory tract may be life-threatening due to transient laryngeal obstruction, whereas gastrointestinal involvement may present with abdominal colic, with or without nausea and vomiting, and can result in unnecessary surgical intervention. No residual scarring occurs with either urticaria or angioedema unless there is an underlying vasculitic process.

The pathology is characterized by edema of the superficial dermis in urticaria and of the subcutaneous tissue and deep dermis in angioedema. Collagen bundles in affected areas are widely separated, and the venules are sometimes dilated. Any perivenular infiltrate consists of lymphocytes, monocytes, eosinophils, and neutrophils that are present in varying combination and numbers.

The best evidence for IgE and mast cell involvement in urticaria and angioedema is *cold urticaria*. Cryoglobulins or cold agglutinins are present in up to 5% of these patients. Ice cube placement on the

volar forearm precipitates urticaria or angioedema within minutes of the challenge. Histologic studies reveal marked mast cell degranulation with associated edema of the dermis and subcutaneous tissues. Elevated levels of histamine have been found in the plasma of venous effluent and in the fluid of suction blisters at experimentally induced lesional sites in patients with cold urticaria, dermographism, pressure urticaria, vibratory angioedema, light urticaria, and heat urticaria. By ultrastructural analysis, the pattern of mast cell degranulation in cold urticaria resembles an IgE-mediated response with solubilization of granule contents, fusion of the perigranular and cell membranes, and discharge of granule contents, whereas in a dermatographic lesion, there is additional superimposed zonal (piecemeal) degranulation. Elevations of plasma histamine levels with biopsy-proven mast cell degranulation have also been demonstrated with generalized attacks of *cholinergic urticaria*.

Up to 45% of patients with chronic urticaria have an autoimmune cause for their disease including autoantibodies to IgE or to the α chain of FcεRI. In some patients, autologous serum injected into their own skin can induce a wheal-and-flare reaction involving mast cell activation. The presence of these antibodies can also be recognized by their capacity to release histamine or induce activation markers such as CD63 or CD203 on basophils. An association with antibodies to microsomal peroxidase and/or thyroglobulin has been observed with both clinically significant Hashimoto's thyroiditis as well as a euthyroid state.

The urticaria and angioedema associated with classic serum sickness or with hypocomplementemic cutaneous necrotizing angiitis (urticarial vasculitis) are believed to be immune-complex-mediated diseases.

Isolated Angioedema Hereditary angioedema (HAE) is a fully penetrant, autosomal dominant disease due to a mutation in the *SERPING1* gene leading to a deficiency of C1INH (type 1) in ~85% of patients or to a dysfunctional protein (type 2) in the remainder affecting 1:30,000–80,000 in the general population. A third, less common type of HAE has been described in which C1INH function is normal, and the causal lesion is a mutant form of factor XII, which leads to generation of excessive bradykinin. C1INH deficiency can also develop in a sporadic acquired form as a result of excessive consumption of C1INH due either to formation of immune complexes or to the generation of an autoantibody directed to C1INH in the setting of lymphoproliferative or autoimmune disease. C1INH blocks the catalytic function of activated factor XII (Hageman factor) and of kallikrein, as well as the C1r/C1s components of C1, with the common result of degrading bradykinin. During clinical attacks of angioedema, C1INH function or levels fall, patients develop elevated plasma levels of bradykinin leading to angioedema, and excessive activation of C1 results in a decline in C4 and C2 levels.

The use of ACE inhibitors results in impaired bradykinin degradation, which explains the idiosyncratic angioedema that can occur in ACE inhibitor–exposed patients with a normal C1INH. Bradykinin-mediated angioedema, whether caused by ACE inhibitors or by C1INH deficiency, is noteworthy for the conspicuous absence of concomitant urticaria or pruritus, the frequent involvement of the gastrointestinal tract, and the duration of symptoms >24 h.

DIAGNOSIS

The classification of urticaria and angioedema as presented in Table 352-1 in terms of duration can facilitate identification of possible mechanisms. History alone of self-limited episodes can be sufficient to make a diagnosis in the setting of acute disease triggered by drug, environmental, or food allergen with history-directed confirmatory skin testing or assay for serum allergen-specific IgE. Direct reproduction of the lesion in physical urticarias is particularly valuable because it so often establishes the cause of the lesion. In chronic urticaria/angioedema, initial diagnostic testing should be guided by history and physical exam. Practice guidelines provide clinicians two options if history and physical exam are unrevealing: no laboratory testing or limited testing, which includes complete blood count with assessment for eosinophilia, erythrocyte sedimentation rate, and thyroid-stimulating hormone level. The vast majority of chronic urticaria is associated with no laboratory abnormality. Urticarial lesions that last longer than 36 h, result in scarring, and are reported as painful and not pruritic warrant biopsy to evaluate for cellular infiltration, nuclear debris, and fibrinoid necrosis of the venules consistent with urticarial vasculitis. Chronic angioedema without urticaria warrants assessment of complement levels. Concomitant flushing and hyperpigmented papules that urticate with stroking in the absence of angioedema raise the question of mastocytosis. An appropriate travel history should trigger an evaluation for parasites.

The diagnosis of HAE is suggested not only by family history but also by the lack of pruritus and of urticarial lesions, the prominence of recurrent gastrointestinal attacks of colic, and episodes of laryngeal edema. Laboratory diagnosis depends on demonstrating a deficiency of C1INH antigen (type 1) or a nonfunctional protein (type 2) by a catalytic inhibition assay. C4 and C2 are chronically depleted and fall further during attacks due to the activation of additional C1. Patients with the acquired forms of C1INH deficiency have the same clinical manifestations but differ in the lack of a familial element. Furthermore, their sera exhibit a reduction of C1 function and C1q protein as well as C1INH, C4, and C2. Lastly, type 3 HAE is associated with normal levels of complement proteins and a factor XII gene mutation.

TREATMENT

Urticaria and Angioedema

For most forms of urticaria, H_1 antihistamines effectively attenuate both urtication and pruritus; long-acting, nonsedating agents, such as loratadine, desloratadine, and fexofenadine, or low-sedating agents, such as cetirizine or levocetirizine, generally are used first and can be increased to up to four times daily dosing. Earlier generation antihistamines, such as chlorpheniramine or diphenhydramine, are sedating, and they induce psychomotor impairment, including reduced eye-hand coordination and machine operating skills. Their anticholinergic (muscarinic) effects include visual disturbance, urinary retention, and constipation. Clinical practice guidelines indicate that the addition of an H_2 antagonist such as ranitidine or famotidine in conventional dosages and a $CysLT_1$ receptor antagonist, such as montelukast 10 mg daily or zafirlukast 20 mg twice a day, may add benefit when H_1 antihistamines are inadequate. For chronic urticaria that has failed to respond to the above combinations, monoclonal anti-IgE antibodies such as omalizumab are now the next line of therapy. Older agents with antihistamine properties such as doxepin, cyproheptadine, and hydroxyzine have proven effective when H_1 antihistamines fail but are less effective than omalizumab and are sedating.

Topical glucocorticoids are of no value, and systemic glucocorticoids are generally avoided in idiopathic, allergen-induced, or physical urticarias due to their long-term toxicity. Systemic glucocorticoids are useful in the management of patients with pressure urticaria, vasculitic urticaria (especially with eosinophil prominence), idiopathic angioedema with or without urticaria, or chronic urticaria that responds poorly to conventional treatment and should be considered in any patient with debilitating disease. With persistent vasculitic urticaria, hydroxychloroquine, dapsone, or colchicine may be added to the regimen before or along with systemic glucocorticoids. Cyclosporine is efficacious for patients with chronic idiopathic urticaria that is severe and poorly responsive to other modalities and/or when glucocorticoids are a requirement.

BRADYKININ-MEDIATED ANGIOEDEMA

Infusion of plasma-derived C1INH protein and lanadelumab, a monoclonal antiplasma kallikrein antibody, is approved for prophylaxis of HAE attacks. Administration of plasma-derived or recombinant C1INH protein, a bradykinin 2 receptor antagonist (icatibant), or a kallikrein inhibitor (ecallantide) may be used for treatment of an acute attack of HAE. Older, less expensive

preventative options include attenuated androgens, which stimulate production by the normal gene of an amount of functional C1INH. The antifibrinolytic agent ε-aminocaproic acid may be used for preoperative prophylaxis but is contraindicated in patients with thrombotic tendencies or arterial atherosclerosis. Fresh frozen plasma infusion can be used for acute attacks in a setting that lacks access to newer modalities. Published studies are conflicting on the efficacy of bradykinin 2 receptor antagonists and C1INH protein in the treatment of ACE inhibitor–induced angioedema. Treatment of the underlying autoimmune disease or malignancy is indicated for acquired C1INH deficiency.

ALLERGIC RHINITIS

DEFINITION

Rhinitis is characterized by sneezing; rhinorrhea; obstruction of the nasal passages; conjunctival, nasal, and pharyngeal itching; and lacrimation and can be classified as allergic or nonallergic. A clinical history of rhinitis symptoms occurring in a temporal relationship to allergen exposure and documentation of sensitization to an environmental allergen are required for a diagnosis of allergic rhinitis. Although commonly seasonal due to elicitation by airborne pollens, it can be perennial in an environment of chronic exposure to house dust mites, animal danders, or insect (cockroach) products. The overall prevalence in North America has increased in the past 20 years and is 10–30%, with the peak prevalence of >30% occurring in the fifth decade.

PREDISPOSING FACTORS AND ETIOLOGY

Allergic rhinitis generally occurs in atopic individuals, often in association with atopic dermatitis, food allergy, urticaria, and/or asthma (Chap. 287). Up to 50% of patients with allergic rhinitis manifest asthma, whereas 70–80% of individuals with asthma and 80% of individuals with chronic bilateral sinusitis experience allergic rhinitis. Female sex, particulate air pollution exposure, and maternal tobacco smoking increase the risk of developing allergic rhinitis.

Wind-pollinated trees, grasses, and weeds produce sufficient quantities of pollen suitable for wide distribution by air currents to elicit seasonal allergic rhinitis. The dates of pollination of these species historically varied little from year to year in a particular locale but may be quite different in another climate. In the temperate areas of North America, trees typically pollinate from March through May, grasses in June and early July, and weeds from mid-August to early October. Molds, which are widespread in nature because they occur in soil or decaying organic matter, propagate spores in a pattern that depends on climatic conditions. Climate change is impacting these patterns with early tree pollination and prolonged ragweed season with the delay of the first frost. In laboratory studies, exposure to high carbon dioxide concentrations increases pollen production in ragweed and timothy grass. Perennial allergic rhinitis occurs in response to allergens that are present throughout the year, including animal dander, cockroach-derived proteins, mold spores, or dust mites such as *Dermatophagoides farinae* and *Dermatophagoides pteronyssinus*. Dust mites are scavengers of human skin and excrete cysteine protease allergens in their feces.

PATHOPHYSIOLOGY AND MANIFESTATIONS

Episodic rhinorrhea, sneezing, obstruction of the nasal passages with lacrimation, and pruritus of the conjunctiva, nasal mucosa, and oropharynx are the hallmarks of allergic rhinitis. The nasal mucosa is pale and boggy, the conjunctiva congested and edematous, and the pharynx generally unremarkable. Swelling of the turbinates and mucous membranes with obstruction of the sinus ostia and eustachian tubes precipitates secondary infections of the sinuses and middle ear, respectively. A growing number of patients with seasonal allergic rhinitis demonstrate pollen-associated food allergen syndrome characterized by oropharyngeal pruritus and/or mild swelling following the ingestion of plant-based foods in the same plant family as a tree, grass, or weed, which contain cross-reacting allergens.

The nose presents a large mucosal surface area through the folds of the turbinates and serves to adjust the temperature and moisture content of inhaled air and to filter out particulate materials >10 μm in size by impingement in a mucous blanket; ciliary action moves the entrapped particles toward the pharynx. Entrapment of pollen and digestion of the outer coat by mucosal enzymes such as lysozymes release protein allergens. The initial interaction occurs between the allergen and intraepithelial mast cells and then proceeds to involve deeper perivenular mast cells, both of which are sensitized with specific IgE. During the symptomatic season when the mucosae are already swollen and hyperemic, there is enhanced adverse reactivity to the seasonal pollen as well as irritants such as tobacco smoke and fragrances. Biopsy specimens of nasal mucosa during seasonal rhinitis show submucosal edema with infiltration by eosinophils, along with some basophils and neutrophils.

The mucosal surface fluid contains IgA and IgE, which apparently arrives by diffusion from plasma cells in proximity to mucosal surfaces. IgE fixes to mucosal and submucosal mast cells, and the intensity of the clinical response to inhaled allergens is quantitatively related to the naturally occurring pollen dose. In sensitive individuals, the introduction of allergen into the nose is associated with sneezing, nasal obstruction, and discharge, and the fluid contains histamine, PGD_2, and leukotrienes. Thus, the mast cells of the nasal mucosa and submucosa generate and release mediators through IgE-dependent reactions that are capable of producing tissue edema and eosinophilic infiltration.

DIAGNOSIS

The diagnosis of seasonal allergic rhinitis depends largely on an accurate history of occurrence coincident with the pollination of the offending weeds, grasses, or trees. The continuous character of perennial allergic rhinitis due to contamination of the home or place of work makes historic analysis difficult, but there may be variability in symptoms that can be related to exposure to animal dander, dust mite and/or cockroach allergens, fungal spores, or work-related allergens such as latex. Patients with perennial rhinitis commonly develop the problem in adult life and manifest nasal congestion and a postnasal discharge, often associated with thickening of the sinus membranes demonstrated by radiography. Perennial nonallergic rhinitis with eosinophilia syndrome (NARES) occurs in the middle decades of life and is characterized by nasal obstruction, anosmia, chronic sinusitis, and prominent eosinophilic nasal discharge in the absence of allergen sensitization. The term *vasomotor rhinitis* or *perennial nonallergic rhinitis* designates a condition of enhanced reactivity of the nasopharynx in which a symptom complex resembling perennial allergic rhinitis occurs with nonspecific stimuli, including chemical odors, temperature and humidity variations, and position changes but occurs without tissue eosinophilia or an allergic etiology. Other entities to be excluded are structural abnormalities of the nasopharynx; exposure to irritants; gustatory rhinitis associated with cholinergic activation that occurs while eating or ingesting alcohol; hypothyroidism; upper respiratory tract infection; pregnancy with prominent nasal mucosal edema; prolonged topical use of α-adrenergic agents in the form of nasal sprays (rhinitis medicamentosa); and the use of certain systemic agents such as β-adrenergic antagonists, ACE inhibitors, direct vasodilators (hydralazine), α_1-adrenergic receptor antagonists, estrogens, progesterone, nonsteroidal anti-inflammatory drugs, gabapentin, phosphodiesterase-5 inhibitors, and psychotropics (risperidone, chlorpromazine, amitriptyline).

The nasal secretions of allergic patients are rich in eosinophils, and a modest peripheral eosinophilia can be observed. Local or systemic neutrophilia implies infection. Total serum IgE is frequently elevated, but the demonstration of immunologic specificity for IgE is critical to an etiologic diagnosis. A skin test by the intracutaneous route (puncture or prick) with the allergens of interest provides a rapid and reliable approach to identifying allergen-specific IgE that has sensitized cutaneous mast cells. A positive intracutaneous skin test with 1:10–1:20 weight/volume of extract has a high predictive value for the presence of allergy. An intradermal test with a 1:500–1:1000 dilution of

0.05 mL may follow if indicated by history when the intracutaneous test is negative, but while more sensitive, it is less reliable due to the reactivity of some asymptomatic individuals at the test dose.

Newer methodology for detecting total IgE, including the development of enzyme-linked immunosorbent assays (ELISAs) employing anti-IgE bound to either a solid-phase or a liquid-phase particle, provides rapid and cost-effective determinations. Measurements of specific anti-IgE in serum are obtained by its binding to an allergen and quantitation by subsequent uptake of labeled anti-IgE. As compared to the skin test, the assay of specific IgE in serum is less sensitive but has high specificity.

TREATMENT

Allergic Rhinitis

Although allergen avoidance is the most cost-effective means of managing allergic rhinitis, only in the case of animal dander and possibly dust mites is it feasible. Treatment with pharmacologic agents represents the standard initial approach to seasonal or perennial allergic rhinitis. Oral long-acting H_1 antihistamines, such as fexofenadine, loratadine, desloratadine, cetirizine, and levocetirizine, are effective for nasopharyngeal itching, sneezing, and watery rhinorrhea and for such ocular manifestations as itching, tearing, and erythema, but they are less efficacious for the nasal congestion. They reduce nasal and ocular symptoms by about one-third. These antihistamines are less lipophilic and more H_1 selective, thus minimizing their ability to cross the blood-brain barrier and therefore diminishing their sedating and anticholinergic effect; they do not differ appreciably in efficacy for relief of rhinitis and/or sneezing.

Intranasal high-potency glucocorticoids are the most effective drugs available for the relief of established rhinitis, seasonal or perennial, and are effective in relieving nasal congestion as well as ocular symptoms. They provide efficacy with substantially reduced side effects as compared with this same class of agent administered orally. Their most frequent side effect is local irritation, with fungal overgrowth being a rare occurrence. The currently available intranasal glucocorticoids—beclomethasone, flunisolide, triamcinolone, budesonide, fluticasone propionate, fluticasone furoate, ciclesonide, and mometasone furoate—are equally effective for nasal symptom relief, including nasal congestion; these agents all achieve up to 70% overall symptom relief with some variation in the time period for onset of benefit. The nasal antihistamines azelastine and olopatadine may benefit individuals with nonallergic vasomotor rhinitis as well as have additive benefit to intranasal steroids in allergic rhinitis, but they have an adverse effect of dysgeusia (taste perversion) in some patients. Alternative nasal decongestants include α-adrenergic agents such as phenylephrine or oxymetazoline; however, the duration of their efficacy is limited because of rebound rhinitis (i.e., 7- to 14-day use can lead to rhinitis medicamentosa) and such systemic responses as hypertension. Oral α-adrenergic agonist decongestants containing pseudoephedrine can improve management of nasal congestion, generally in combination with an antihistamine. These pseudoephedrine combination products can cause insomnia and are precluded from use in patients with narrow-angle glaucoma, urinary retention, severe hypertension, marked coronary artery disease, or a first-trimester pregnancy. The $CysLT_1$ antagonist montelukast is approved for treatment of both seasonal and perennial rhinitis. However, it is less effective than H_1 antihistamines and nasal glucocorticoids, and reports of neuropsychiatric events have led to increased U.S. Food and Drug Administration precautions. Cromolyn sodium nasal spray inhibits mast cell degranulation and can be used prophylactically on a continuous basis during the season or as needed before a known exposure. Topical ipratropium is an anticholinergic agent effective in reducing rhinorrhea, including that of patients with perennial nonallergic symptoms, and it can be additionally efficacious when combined with intranasal glucocorticoids. For concomitant allergic conjunctivitis, topical treatment with cromolyn sodium is effective in treating mild allergic symptoms, and topical antihistamines such as olopatadine, azelastine, ketotifen, or epinastine administered to the eye provide rapid relief of itching and redness and are more effective than oral antihistamines.

Immunotherapy Immunotherapy consists of repeated exposure to the allergen(s) considered to be specifically responsible for the symptom complex. Two forms of immunotherapy, subcutaneous (SCIT) and sublingual (SLIT), are currently available. Randomized, controlled studies of ragweed, grass, dust mite, and cat dander allergens administered via SCIT for treatment of allergic rhinitis have demonstrated significant improved symptom control over medications alone with the advantage of providing a durable benefit, as well as a reduction in asthma symptoms, medication use, and bronchial hyperreacticity in allergic asthma. Clinical practice guidelines recommend a duration of SCIT is 3–5 years, with discontinuation being based on minimal symptoms over two consecutive seasons of exposure to the allergen. Clinical benefit appears related to the administration of a high dose of relevant allergen, gradually uptitrating concentration and advancing from weekly to monthly intervals. SCIT injections occur in a licensed treatment site; 2–3% of SCIT patients experience a systemic reaction, including anaphylaxis, over a 12-month period. The majority of these reactions occur soon after injection, and thus, patients should remain at the treatment site for at least 30 min after allergen administration so that any systemic reactions can be managed. Local reactions with erythema and induration are not uncommon and may persist for 1–3 days. SLIT is prepared as a tablet to be dissolved under the tongue at home after the first dose. The efficacy of SLIT is comparable to SCIT but only for the three allergen formulations currently available: dust mite, timothy/northern grasses, and short ragweed. Systemic reactions are less frequent with SLIT, but transient oral pruritus is common. Immunotherapy is contraindicated in patients with significant cardiovascular disease or unstable asthma. Severe cases of anaphylaxis have occurred after allergen immunotherapy when patients were taking a β-adrenergic blocking agent. Thus, immunotherapy should be conducted with caution in any patient requiring β-adrenergic blocking therapy due to the difficulty in managing an anaphylactic complication.

Immunotherapy should be reserved for clearly documented seasonal or perennial rhinitis that is clinically related to defined allergen exposure with confirmation by the presence of allergen-specific IgE through skin or in vitro specific IgE testing. The response to immunotherapy is associated with a complex of cellular and humoral effects that includes a modulation in T lymphocyte cytokine production and allergen-specific IgG_4 expansion. Systemic treatment with omalizumab, an anti-IgE monoclonal antibody, is efficacious for allergic rhinitis and can be used with immunotherapy to enhance safety and efficacy. However, current approval is only for treatment of patients with persistent allergic asthma not controlled by inhaled glucocorticoid therapy or chronic idiopathic urticaria not controlled by oral H_1 antihistamines.

A sequence for the management of allergic or perennial rhinitis based on an allergen-specific diagnosis and stepwise management as required for symptom control would include the following: (1) identification of the offending allergen(s) by history with confirmation of the presence of allergen-specific IgE by skin test and/or serum assay; (2) avoidance of the offending allergen; and (3) medical management in a stepwise fashion **(Fig. 352-4)**. Mild intermittent symptoms of allergic rhinitis are treated with oral antihistamines, oral $CysLT_1$ receptor antagonists, intranasal antihistamines, or intranasal cromolyn. Moderate to more severe allergic rhinitis is managed with intranasal glucocorticoids plus oral antihistamines, oral $CysLT_1$ receptor antagonists, or antihistamine-decongestant combinations. Persistent or seasonal allergic rhinitis, rhinoconjunctivitis, or asthma that remains uncontrolled with maximal medical therapy merit consideration of allergen-specific immunotherapy.

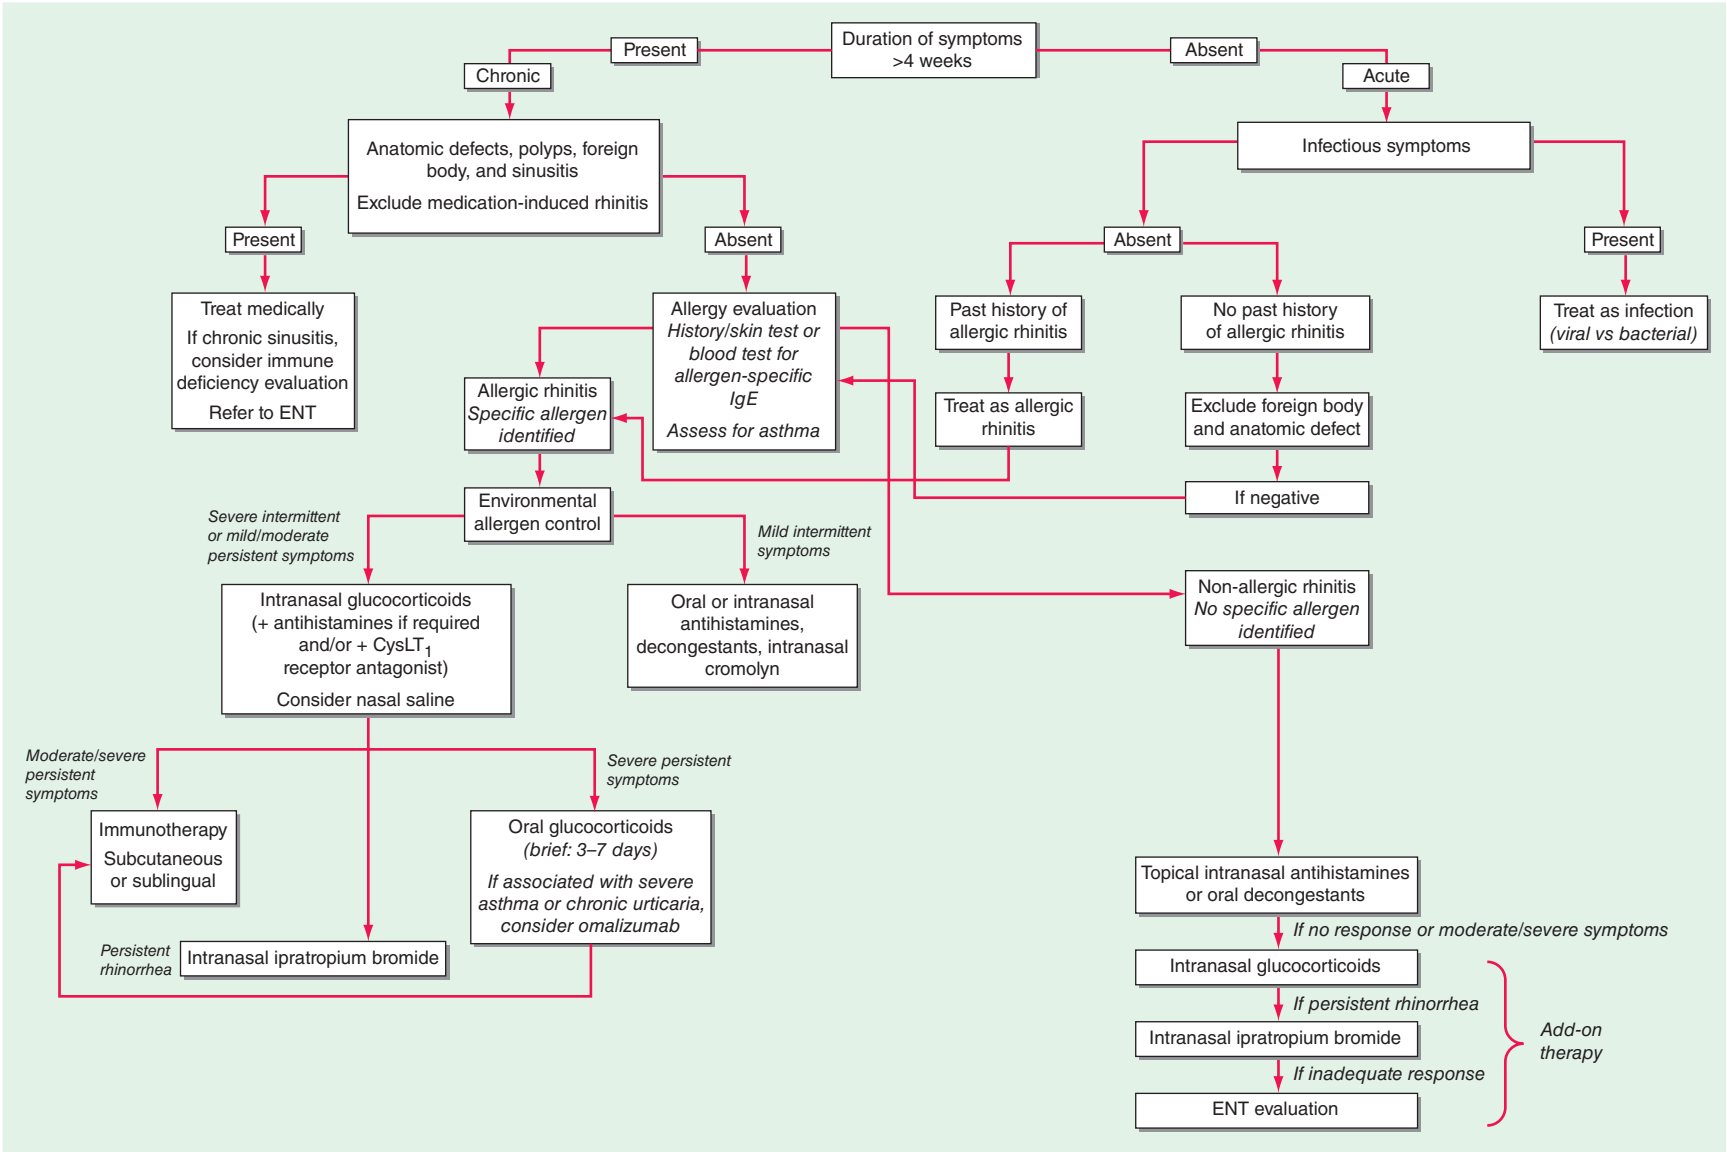

FIGURE 352-4 Algorithm for the diagnosis and management of rhinitis. Persistent is defined as >4 days per week for >4 weeks. Moderate/severe is defined as abnormal sleep, impaired daily activities (school, work, sport, leisure), and/or troublesome symptoms. CysLT, cysteinyl leukotriene; ENT, ear, nose, and throat; IgE, immunoglobulin E.

353 Anaphylaxis

David Hong, Joshua A. Boyce

BACKGROUND

Anaphylaxis is a potentially life-threatening systemic allergic reaction involving one or more organ systems that typically occurs within seconds to minutes of exposure to the anaphylactic trigger, most often a drug, food, or Hymenoptera sting. The term *anaphylaxis* was first described in 1902 by Charles Richet and Paul Portier who attempted to immunize dogs against sea anemone toxin in the same way Pasteur was able to vaccinate individuals against the smallpox virus. To their surprise, repeated administration of small, sublethal doses of sea anemone toxin reliably induced acute-onset death when readministered 2–3 weeks after initial "vaccination" to the toxin. The phenomenon was termed ana (anti)-phylaxis ("protection or guarding") because vaccination with anemone toxin resulted in the opposite intended immune effect. Charles Richet was awarded the Nobel Prize in Physiology or Medicine in 1913 for this work, which led to further insights into hypersensitivity and mast cell biology.

CLINICAL MANIFESTATIONS

While 80–90% of anaphylactic episodes are uniphasic, about 10–20% of cases are biphasic, in which anaphylactic symptoms return about an hour or longer after resolution of initial symptoms. Anaphylactic reactions are particularly dangerous when hypotension or hypoxia occurs, leading potentially to cardiovascular collapse or respiratory failure, respectively. There may be upper or lower airway obstruction or both. Laryngeal edema may be experienced as a "lump" in the throat, hoarseness, or stridor, whereas bronchial obstruction is associated with a feeling of tightness in the chest and/or audible wheezing. Patients with underlying asthma are predisposed to severe involvement of the lower airways and increased mortality associated with anaphylaxis. In fatal cases with clinical bronchial obstruction, the lungs show marked hyperinflation on gross and microscopic examination. The microscopic findings in the bronchi, however, are limited to luminal secretions, peribronchial congestion, submucosal edema, and eosinophilic infiltration, and the acute emphysema is attributed to intractable bronchospasm that subsides with death. Angioedema resulting in death by mechanical obstruction occurs in the epiglottis and larynx; however, the process also is evident in the hypopharynx and to some extent in the trachea. On microscopic examination, there is wide separation of the collagen fibers and the glandular elements; vascular congestion and eosinophilic infiltration also are present. Patients dying of vascular collapse without antecedent hypoxia from respiratory insufficiency have visceral congestion with a presumptive loss of intravascular fluid volume. The associated electrocardiographic abnormalities, with or without infarction, in some patients may reflect a primary cardiac event mediated by mast cells (which are prominent near the coronary vessels) or may be secondary to a critical reduction in blood volume.

Gastrointestinal manifestations represent another severe presentation of anaphylaxis and include nausea, vomiting, crampy abdominal pain, and/or fecal incontinence. Angioedema of the bowel wall may also cause sufficient intravascular volume depletion to precipitate cardiovascular collapse.

Cutaneous manifestations are among the most common presentations of anaphylaxis (>90% of cases). Symptoms include urticarial eruptions, flushing with diffuse erythema, and/or a feeling of generalized warmth. Urticarial eruptions are intensely pruritic and may be localized or disseminated. They may coalesce to form giant hives but seldom persist beyond 48 h.

PATHOPHYSIOLOGY

Many of the important early mediators of anaphylaxis are derived from mast cells, basophils, and eosinophils. Mast cells and basophils contain preformed granules composed of histamine, proteases (tryptase, chymase), proteoglycans (heparin, chondroitin sulfate), and tumor necrosis factor-α, which are rapidly released into surrounding tissue upon cell activation, a process known as degranulation. Mast cells, basophils, and eosinophils are also sources of arachidonic acid–derived products, which include cysteinyl leukotrienes, prostaglandins, and platelet-activating factor (PAF). Histamine release results in flushing, urticaria, pruritus, and, in high concentrations, hypotension and tachycardia. Cysteinyl leukotrienes and prostaglandin D_2 cause bronchoconstriction and increased microvascular permeability. Prostaglandin D_2 causes cutaneous flushing and attracts eosinophils and basophils to the site of mast cell activation. Serum PAF levels correlate with anaphylaxis severity and are inversely proportional to the constitutive level of PAF acetylhydrolase, which is necessary for PAF inactivation. Tryptase and chymase can activate complement and coagulation pathways. Activation of these pathways results in production of the anaphylotoxins, C3a and C5a, and activation of the kallikrein-kinin system, which regulates blood pressure and vascular permeability. The actions of these anaphylactic mediators are likely additive or synergistic at the target tissues.

PREDISPOSING FACTORS AND MECHANISMS

Because the most dangerous manifestations of anaphylaxis involve the cardiovascular and/or respiratory systems, preexisting asthma and underlying cardiovascular disease could lead to more rapid decompensation from anaphylaxis. Atopy is not generally thought to be a risk factor for anaphylaxis from drug reactions or Hymenoptera stings, but it is associated with radiocontrast sensitivity, exercise-induced anaphylaxis, idiopathic anaphylaxis, and allergy to foods or latex. Severe Hymenoptera-induced anaphylaxis (generally with prominent hypotension) can be a presenting feature of underlying systemic mastocytosis. Hymenoptera allergy is also more likely in patients whose occupations (i.e., beekeepers, trash haulers, and landscape workers) place them in regular proximity to stinging insects. Most commonly, allergen-induced cross-linking of IgE-bound FcεRI receptors on mast cells and basophils initiates the signal transduction events leading to hypersensitivity syndromes, including anaphylaxis. The generation of allergen-specific IgE is the end result of sensitization via the adaptive immune system. While the mechanisms underlying sensitization are beyond the scope of this chapter, environmental factors, innate immune responses, and cytokines are among the many variables leading to antigen-specific IgE production by B cells and plasma cells. IgE-mediated drug allergies are most common with antibiotics and certain chemotherapy drugs, though theoretically, they can occur with almost any medication. As is the case with environmental allergies, repeated exposure to the allergy-causing antigen is an important risk factor to keep in mind when evaluating patients with anaphylaxis. In

the case of allergy to carboplatin, the incidence of hypersensitivity is 27% in patients who have had ≥7 lifetime infusions and as high as 46% in patients who have had ≥15 lifetime infusions. Similarly, patients with cystic fibrosis have a relatively high incidence of allergic reactions to IV antibiotics that they receive periodically for intermittent "clean-outs" to maintain airway clearance. Drugs can also function as haptens that form immunogenic conjugates with host proteins. The conjugating hapten may be the parent compound, a nonenzymatically derived storage product, or a metabolite formed in the host. Recombinant biologics can also induce the formation of IgE against the proteins or against glycosylated structures that serve as immunogens. Outbreaks of anaphylaxis to the epidermal growth factor receptor (EGFR) antibody cetuximab have been reported in association with elevated titers of serum IgE to alpha-1,3-galactose (alpha-gal), an oligosaccharide found in nonprimate mammals. Cetuximab is derived from a mouse cell line expressing a transferase that tags the Fab′ portion of the cetuximab heavy chain with alpha-gal. Interestingly, patients with a history of multiple bites from *Amblyomma americanum* ticks commonly found in the Carolinas, Arkansas, and Tennessee are more likely to have anti-alpha-gal IgE as compared with control patients living outside those states. Some individuals who become sensitized to alpha-gal can develop episodes of delayed-onset anaphylaxis to meat from beef, lamb, and pork.

Non-IgE-mediated mast cell activation secondary to certain drugs is clinically indistinguishable from classical IgE-mediated hypersensitivity reactions, but it can occur with first known exposure since there is no prior need for mast cell sensitization by IgE. MRGPRX2, a G protein–coupled receptor that is highly expressed in skin mast cells, has been shown in mouse models and in vitro studies using human cells to induce mast cell activation and mediator release secondary to neuromuscular blocking drugs (NMBDs), quinolones, and icatibant. These findings are clinically significant since NMBDs are a relatively common cause of perioperative anaphylaxis and in other settings requiring endotracheal intubation and quinolones are a commonly used antibiotic family. Icatibant, a bradykinin-2 receptor antagonist administered by subcutaneous injection for the treatment of acute attacks of hereditary angioedema, is known to frequently result in local injection site reactions. Another example of non-IgE-mediated anaphylaxis is demonstrated with paclitaxel, a chemotherapy agent most commonly used in combination with carboplatin to treat ovarian cancer. It is derived from yew tree bark and needles that require polyethoxylated castor oil (Cremophor) to be solubilized into aqueous solution. Cremophor has been shown in vitro to activate the complement cascade, resulting in complement-dependent histamine release from mast cells and basophils. A version of paclitaxel that is solubilized by being bound to albumin nanoparticles, Abraxane, has a far lower rate of hypersensitivity, especially for patients who have had infusion reactions to Cremophor-solubilized paclitaxel. Reactions to radiocontrast and vancomycin are other examples of non-IgE-mediated hypersensitivity. Opiates and nonsteroidal anti-inflammatory drugs (NSAIDs) are other drug categories that can have similar adverse reactions.

DIAGNOSIS

The diagnosis of an anaphylactic reaction depends primarily on a history revealing the onset of symptoms and signs within seconds to minutes after the putative trigger is encountered. An exception is delayed anaphylaxis to meats in alpha-gal–sensitized patients. Every attempt to identify the specific cause or causes should be made to minimize the risk of recurrent anaphylaxis. If a particular drug or food is suspected, skin or serum-specific IgE testing can be useful to confirm clinical suspicions. If a specific trigger cannot be identified by history or testing, a workup of underlying baseline atopic diatheses may be useful to identify risk factors that could play a potential contributory role. In the acute setting, laboratory biomarkers of mast cell degranulation may be useful to document the severity of an anaphylactic episode. The most obvious serum biomarker to assay, histamine, has an extremely short half-life with a measurable time-window that expires <1 h from the onset of anaphylaxis. A more practical and useful biomarker is serum tryptase, which peaks 60–90 min after the onset of anaphylaxis and can be measured as long as 5 h after the onset of anaphylaxis. It may be useful to follow-up an elevated tryptase measurement in the acute setting with another measurement when the patient is clinically stable to establish a baseline reference. An elevated baseline tryptase level may warrant further workup for mastocytosis, especially if the presenting reaction occurred in the setting of Hymenoptera sting.

TREATMENT

Early recognition of an anaphylactic reaction and appropriate intervention are critically important because severe, even fatal, complications can occur within minutes after symptoms first appear. The treatment of first choice is intramuscular administration of 0.3–0.5 mL of 1:1000 (1 mg/mL) epinephrine, with repeated doses at 5- to 20-min intervals as needed for a severe reaction. The failure to use epinephrine within the first 20 min of symptoms is a risk factor for poor clinical outcomes in various studies of anaphylaxis. Another important variable that may affect anaphylaxis survival is body posture, as an upright or sitting posture may lead to "empty ventricle syndrome" in which there is insufficient venous return to the heart from sudden-onset hypotension secondary to intravascular volume depletion. Epinephrine can further accelerate empty ventricle syndrome due to its chronotropic effects. For this reason, it is recommended that patients who suffer from anaphylaxis be placed in the supine position before receiving epinephrine. IV fluids and vasopressor agents may be administered in the acute medical setting if intractable hypotension occurs. Epinephrine provides both α- and β-adrenergic effects, resulting in vasoconstriction, bronchial smooth-muscle relaxation, and attenuation of enhanced venular permeability. Beta blockers may attenuate this response; therefore, an alternative antihypertensive may be considered in patients at high risk of needing emergency epinephrine. Oxygen alone via a nasal catheter or with nebulized albuterol may be helpful; however, either endotracheal intubation or a tracheostomy is mandatory for oxygen delivery if progressive hypoxia develops. Ancillary agents such as antihistamines, glucocorticoids, and bronchodilators are also useful therapeutics to treat urticaria/angioedema and bronchospasm once the patient is hemodynamically stable.

PREVENTION

Avoidance The simplest, most straightforward approach to the long-term management of a patient with a history of anaphylaxis is strict avoidance of known anaphylactic triggers and education on acute management, specifically, instructing the patient on proper use and indications for use of self-administered epinephrine. Lifelong avoidance is not easy if the trigger is an occupational exposure, Hymenoptera sting, a common food (i.e., peanut), or a drug representing the sole or best therapeutic option for the patient. Special management options may exist for these patients.

Venom Immunotherapy Patients with only large local reactions to Hymenoptera stings are unlikely to have anaphylaxis with subsequent stings. However, patients of any age who have had documented anaphylaxis should be formally evaluated and started on venom immunotherapy (VIT) if skin or serologic IgE testing confirms the history. Immunotherapy is a means of "tolerizing" patients to allergen by means of serial subcutaneous administration of escalating doses of extract containing relevant allergen until a target maintenance dose is achieved. As in the case of Richet's unfortunate dogs, anaphylaxis can sometimes occur during the course of administering immunotherapy extracts, so formulating extracts and administering them is typically done under the care of a specialist familiar with this type of treatment. In the case of Hymenoptera allergy, patients receive VIT extracts containing actual Hymenoptera venom with a maintenance dose equivalent to 2–5 stings. The recommended duration of treatment is 3–5 years; however, some patients who have experienced severe respiratory or cardiovascular anaphylaxis are put on lifelong therapy.

Preventative Tolerance Induction IgE sensitization to foods occurs most frequently in infants and young children, especially those

with atopic dermatitis, and is a risk factor for anaphylaxis (although detection of specific IgE through skin or serum testing has relatively poor predictive value). While most allergy to egg, milk, soy, and/or wheat resolves spontaneously during childhood, ~80% of children with peanut allergy remain sensitive for life. A sharp rise in the prevalence of peanut allergy was also observed in the late 1990s to early 2000s, especially in countries with Western diets where the average age of peanut introduction was age ≥3 years. Curiously, in cultures where peanut was introduced much earlier into children's diets, the prevalence of peanut allergy remained low. The landmark Learning Early About Peanut Allergy (LEAP) study demonstrated that early introduction of peanut protein to the diet of high-risk infants (4–11 months of age with atopic dermatitis and/or egg allergy) prevented the development of most (80% or more) peanut allergy compared with children who did not consume peanuts (avoidance group), even when IgE sensitization (based on positive skin test) had already developed at the time of study entry. While the induction of tolerance at an early age seems to be key to preventing clinical reactivity later in life, it is not yet clear if this principle holds true for other foods commonly associated with hypersensitivity reactions.

Desensitization For patients who have experienced anaphylaxis from drug allergy and whose treatment regimen requires the administration of the offending drug, desensitization may be a short-term treatment option to prevent reactions. Desensitization elicits a temporary state of tolerance to the drug in sensitized, clinically reactive patients. While it has been a proven technique for penicillin-allergic patients for decades, desensitization has more recently been proven to be effective for certain chemotherapy agents, especially platin-based chemotherapy agents that can induce IgE-mediated sensitization with repeated exposures. The exact mechanisms underlying desensitization are not fully understood; however, temporary tolerance can be achieved through the serial administration of gradually escalating doses of drug, starting from extremely low doses, over the course of hours. So long as the patient continues to receive the drug in question at regular intervals based on drug half-life, a "desensitized" state can also be maintained until the drug is no longer needed. While drug desensitization certainly works for IgE-mediated reactions, it has been performed in cases of non-IgE-mediated anaphylaxis from Cremophor-solubilized paclitaxel as described earlier in this chapter. Desensitization has also been shown by multiple groups to prevent non-IgE-mediated reactions from a variety of biologic agents, various chemotherapy drugs, and NSAIDs. Given the complexity and variety of possible drug reactions, the decision to desensitize, challenge, or avoid should be made in conjunction with an allergy specialist for complete evaluation and proper risk stratification of the different possible approaches to take.

354 Mastocytosis

Matthew P. Giannetti, Joshua A. Boyce

DEFINITION AND EPIDEMIOLOGY

Mastocytosis is defined by accumulation of clonally expanded mast cells in tissues such as skin, bone marrow, liver, spleen, and gut. Diagnostically, mast cell expansion is most readily identified in skin and/or bone marrow. Mastocytosis occurs at any age and has a slight preponderance in males. The prevalence of mastocytosis is estimated at ~1 in 10,000 people. Most forms of the disease are characterized by somatic gain-of-function mutations in the stem cell factor receptor (*KIT*) gene. Familial occurrence is rare, and atopy is not increased compared with the general population.

CLASSIFICATION AND PATHOPHYSIOLOGY

A consensus classification for mastocytosis recognizes cutaneous mastocytosis with variants, five systemic forms, and the rarest variant, mast cell sarcoma **(Table 354-1)**.

Cutaneous mastocytosis is the most common diagnosis in children and indicates disease limited to skin with absence of pathologic infiltrates in internal organs. It is usually diagnosed within the first year of life with demonstration of fixed, maculopapular, polymorphic, and hyperpigmented lesions (maculopapular cutaneous mastocytosis [MPCM], formerly known as urticaria pigmentosa), mastocytoma(s), or diffuse cutaneous mastocytosis. Although mast cell accumulation is limited to the skin, children often have systemic symptoms. Systemic mastocytosis (SM) refers to involvement of a noncutaneous site (usually bone marrow). There are five distinct variants of SM. *Indolent systemic mastocytosis* (ISM) accounts for the majority of adult patients. ISM is diagnosed when there is no evidence of an associated hematologic disorder, mast cell leukemia, or organ dysfunction due to mast cell infiltration. ISM is associated with a normal life expectancy. *Smoldering systemic mastocytosis* (SSM) is characterized by high mast cell burden as evidenced by a bone marrow infiltration of >30% and a baseline serum tryptase >200 ng/mL (B findings), but absence of *systemic mastocytosis associated with clonal hematologic non–mast cell lineage disease* (SM-AHNMD) or *aggressive systemic mastocytosis* (ASM) **(Table 354-2)**. In SM-AHNMD, the prognosis is determined by the nature of the associated disorder, which can range from dysmyelopoiesis to leukemias usually of myeloid origin. In ASM, mast cell infiltration/proliferation occurs in multiple organs such as liver, spleen, gut, bone, and bone marrow resulting in one or more C findings and a poor prognosis (Table 354-2). *Mast cell leukemia* (MCL) is the rarest form of SM and is invariably fatal at present; the peripheral blood contains circulating, metachromatically staining, atypical mast cells. An aleukemic form of MCL is recognized without circulating mast cells when the percentage of high-grade immature mast cells in bone

TABLE 354-2 B and C Findings for Diagnosis of SSM and ASM

B Findings (2 or more in the absence of any C findings are required for a diagnosis of SSM):

1. MC infiltration in bone marrow biopsy of >30% and a basal serum tryptase level >200 ng/mL
2. Hypercellular bone marrow with signs of dysmyelopoiesis but without cytopenias meeting C criteria or WHO criteria for an MDS or MPN
3. Palpable hepatomegaly, palpable splenomegaly, or lymphadenopathy (on CT or ultrasound: >2 cm) without impaired liver function or hypersplenism

C Findings (1 or more required for a diagnosis of ASM). C findings should be reasonably attributable to high tissue mast cell infiltration.

1. Cytopenia(s): ANC <1000/μL or Hb <10 g/dL or PLT <100,000/μL
2. Hepatomegaly with ascites and impaired liver function
3. Palpable splenomegaly with associated hypersplenism
4. Malabsorption with hypoalbuminemia and weight loss
5. Skeletal lesions: large area(s) of osteolysis with pathologic fractures (presence of osteoporosis alone without osteolytic lesions does not satisfy this criterion)

Abbreviations: ANC, absolute neutrophil count; ASM, aggressive systemic mastocytosis; CT, computed tomography; Hb, hemoglobin; MC, mast cells; MDS, myelodysplastic syndromes; MPN, myeloproliferative disorders; PLT, platelets; SSM, smoldering systemic mastocytosis; WHO, World Health Organization.

marrow smears exceeds 20% in a nonspicular area. Mast cell sarcoma is a rare solid mast cell tumor with malignant invasive features.

Somatic activating mutations in the *KIT* gene are characteristic of mastocytosis. *KIT* D816V is most commonly observed, although other mutations have been reported. *KIT* mutations are found in mast cells and sometimes in multiple other cell lineages in patients with mastocytosis. *KIT* mutations are observed in patients with all forms of SM but are also present in some children with cutaneous mastocytosis in lesional skin, as might be anticipated because mast cells are of bone marrow lineage. Additional mutations in genes such as *TET2, SRSF2, ASLX1*, and *RUNX1* known to be associated with other hematologic neoplastic disorders can be detected in patients, usually with advanced (non-ISM) forms of SM. The prognosis for patients with cutaneous mastocytosis and for almost all patients with ISM is a normal life expectancy, whereas that for patients with SM-AHNMD is determined by the non–mast cell component. ASM and MCL have a poor prognosis, while patients with SSM have an intermediate prognosis. Progression from ISM to a more advanced form is rare (~5% overall); however, patients should be monitored for emergence of hematologic disease and end-organ manifestations of ASM. In infants and children with cutaneous manifestations, namely, maculopapular cutaneous mastocytosis, mastocytoma(s), or bullous lesions, visceral involvement is usually lacking, and spontaneous resolution is common prior to adolescence. Polymorphic maculopapular cutaneous mastocytosis usually resolves spontaneously. Progression from cutaneous mastocytosis (CM) to ISM may occur in ~10% of children, especially in those with high mast cell burden (diffuse cutaneous mastocytosis) or hematologic abnormalities and those who present with smaller uniform lesions with diameters measuring <2 cm (monomorphic cutaneous mastocytosis).

CLINICAL MANIFESTATIONS

The clinical manifestations of SM are due to the release of bioactive substances acting at both local and distal sites, tissue infiltration by mast cells, and the tissue response to the cellular infiltrate. The pharmacologically induced manifestations are intermittent flushing, tachycardia and vascular collapse, gastric distress, crampy lower abdominal pain, and diarrhea. The increased local mast cell burden in the skin (MPCM), bone marrow, and gastrointestinal tract may be a direct cause of pruritus, bone pain, and malabsorption, respectively. Mast cell–mediated fibrotic changes may occur in liver, spleen, and bone marrow but not in gastrointestinal tissue or skin.

The cutaneous lesions of MPCM are reddish-brown macules, papules, or plaques that respond to trauma with urtication and erythema (Darier's sign). Two distinct forms of MPCM are recognized: polymorphic MPCM and monomorphic MPCM. Children with CM may present with MPCM, mastocytomas, or diffuse cutaneous mastocytosis (DCM). Mastocytomas are generally solitary elevated lesions that are yellow, brown, or red in color. Their size may vary from a few millimeters to several centimeters. Rubbing or irritation of the mastocytoma lesion may lead to systemic symptoms such as flushing and urticaria. Children with DCM present without distinct lesions, but rather a generalized thickening of skin and "peau d'orange" appearance due to diffuse mast cell infiltration. DCM may be associated with bullae formation and more severe systemic symptoms, including upper gastrointestinal irritation and vascular collapse in the first few years of life. Maculopapular skin lesions of mastocytosis may be present in patients with adult-onset systemic disease. The apparent incidence of cutaneous lesions is ≥80% in patients with ISM and <50% in those with SM-AHNMD or ASM. In the upper gastrointestinal tract, gastritis and peptic ulcer are significant problems. In the lower intestinal tract, the occurrence of diarrhea and abdominal pain is attributed to increased motility due to mast cell mediators; this problem can be aggravated by malabsorption, which can also cause secondary nutritional insufficiency and osteomalacia. The periportal fibrosis associated with mast cell infiltration may lead to portal hypertension and ascites. In some patients, anaphylaxis with rapid and life-threatening vascular collapse may occur. Anaphylaxis is most commonly induced by Hymenoptera stings, and patients often have evidence of venom-specific IgE. The neuropsychiatric disturbances are clinically most evident as impaired recent memory, decreased attention span, and "migraine-like" headaches. Patients may experience exacerbation of a specific clinical sign or symptom variably with alcohol ingestion, temperature changes, stress, use of mast cell–interactive opioids, or ingestion of nonsteroidal anti-inflammatory drugs (NSAIDs).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Cutaneous mastocytosis is diagnosed by observing the characteristic lesions of MPCM or mastocytoma(s). A skin biopsy may be obtained to confirm these subvariants of CM, whereas patients with suspected DCM and bullous mastocytosis require a skin biopsy to confirm the diagnosis. Although the diagnosis of SM is generally suspected based on clinical history, physical examination findings, and laboratory procedures, it can only be confirmed with a tissue diagnosis. The diagnosis of SM necessitates a bone marrow biopsy to meet the criteria of one major plus one minor or three minor findings **(Table 354-3)**. The major criterion requires mast cell aggregates, often in paratrabecular and perivascular locations with associated lymphocytes and eosinophils. Minor criteria include abnormal "spindled" mast cell morphology, aberrant mast cell membrane immunophenotype (CD25 and/or CD2), or a codon 816 mutation in an extracutaneous tissue. A basal serum total tryptase level is a noninvasive approach to consider before bone marrow biopsy. The pro-β and α forms of tryptase are elevated in more than one-half of patients with SM and provide a minor criterion; the fully processed ("mature") β form is increased in patients undergoing an anaphylactic reaction. A rare histopathologic subvariant called *well-differentiated systemic mastocytosis* (WDSM) is characterized by clusters of mature-appearing, fully granulated and round mast cells, lack of aberrant CD25 and CD2 expression, and lack of D816V *KIT* mutation in most patients. These patients often have a history of

TABLE 354-3 Diagnostic Criteria for Systemic Mastocytosis[a]

Major:

- Multifocal dense infiltrates of mast cells (>15 mast cells per aggregate) in bone marrow or other extracutaneous tissues

Minor:

- Abnormal mast cell morphology (spindle shape, bi- or multilobed or eccentric nucleus, hypogranulated cytoplasm)
- Aberrant mast cell surface phenotype with expression of CD25 (IL-2 receptor alpha chain) and/or CD2
- Detection of codon 816 mutation in peripheral blood cells, bone marrow cells, or an extracutaneous lesional tissue
- Total serum tryptase >20 ng/mL

[a]Diagnosis requires either the major criterion and one minor criterion or three minor criteria.

childhood-onset cutaneous disease, and their mast cells may display aberrant CD30 expression and other markers of clonality such as atypical (non-D816V) *KIT* mutations. Additional studies directed by the presentation include a bone densitometry, bone scan, or skeletal survey; computed tomography scan or endoscopy; and a neuropsychiatric evaluation. Osteoporosis is increased in mastocytosis and may lead to pathologic fractures.

Some patients presenting with recurrent mast cell activation symptoms (particularly anaphylaxis with hypotensive syncope) have been found to have underlying mastocytosis. A subset of these patients may be found to have evidence of a clonal hematologic process such as the D816V *KIT* mutation or aberrant mast cells displaying CD25, but lack other diagnostic criteria for SM. Such patients are termed to have *monoclonal mast cell activation syndrome*.

The differential diagnosis requires the exclusion of other disorders. A 24-h urine assessment of 5-hydroxy-indoleacetic acid and metanephrines should exclude a carcinoid tumor and pheochromocytoma, respectively. Hereditary α-tryptasemia may be characterized by symptoms of mast cell activation in addition to multisystem involvement and elevated baseline serum tryptase. These patients have autosomal dominant inheritance of α-tryptase gene duplications at the TPSAB1 locus. Most patients with recurrent IgE-induced or idiopathic anaphylaxis present with urticaria, angioedema, and/or bronchospasm, which are not typical manifestations of anaphylaxis in SM.

TREATMENT

Mastocytosis

The management of SM is symptom control using a stepwise symptom/sign–directed approach. Medications include an H_1 antihistamine for flushing and pruritus, an H_2 antihistamine or proton pump inhibitor for gastric acid hypersecretion, oral cromolyn sodium for diarrhea and abdominal pain, and occasionally aspirin (in those who are known to be tolerant of NSAIDs) for severe flushing to block biosynthesis of prostaglandin D_2. Systemic glucocorticoids appear to alleviate malabsorption. Mast cell cytoreductive therapy consisting of midostaurin, avapritinib, IFN-α, or cladribine is generally reserved for advanced, nonindolent variants of SM. Midostaurin and avapritinib are small-molecule tyrosine kinase inhibitors with activity against both mutated *KIT* D816V and wild-type *KIT* and should be considered as a first-line therapy for these disease variants. The efficacy of cytoreductive therapy in mastocytosis is variable, perhaps because of side effects that limit dosages. Imatinib is not effective in most cases as the D816V *KIT* mutation mediates resistance. Combination chemotherapy is appropriate for the frank leukemias. Stem cell transplantation has been shown to be effective in a small subset of patients with advanced mastocytosis. A self-injectable epinephrine prescription is recommended for most patients due to increased incidence of anaphylaxis. Patients with a history of systemic Hymenoptera venom reaction should be evaluated for venom-specific IgE and placed on lifelong venom immunotherapy if positive.

355 Autoimmunity and Autoimmune Diseases

Betty Diamond, Peter E. Lipsky

One of the central features of the immune system is the capacity to mount an inflammatory response to potentially harmful foreign materials while avoiding damage to self-tissues. Whereas recognition of self plays an important role in shaping the repertoires of immune receptors on both T and B cells and in clearing apoptotic and other tissue debris from sites throughout the body, the development of potentially harmful immune responses to self-antigens is, in general, prohibited. The essential feature of an *autoimmune disease* is that tissue injury is caused by the immunologic reaction of the organism against its own tissues. *Autoimmunity*, on the other hand, refers merely to the presence of antibodies or T lymphocytes that react with self-antigens and does not necessarily imply that the self-reactivity has pathogenic consequences. Autoimmunity is present in all individuals and increases with age; however, autoimmune disease occurs only in those individuals in whom the breakdown of one or more of the basic mechanisms regulating immune tolerance results in self-reactivity that can cause tissue damage.

Polyreactive autoantibodies that recognize many host antigens are present throughout life. These antibodies are usually of the IgM heavy chain isotype and are encoded by nonmutated germline immunoglobulin variable region genes. These antibodies are essential, as they remove apoptotic debris through non-inflammatory pathways. Expression of these autoantibodies may be increased after some inciting events. When autoimmunity is induced by an inciting event, such as infection or tissue damage from trauma or ischemia, the autoreactivity is generally self-limited. When such autoimmunity does persist, however, pathology may or may not result. Moreover, even in the presence of organ pathology, it may be difficult to determine whether the damage is mediated by autoreactivity or an ongoing pathologic process related to the inciting trigger. Individuals with autoimmune disease may have numerous autoantibodies, only some or even none of which may be pathogenic. For example, patients with systemic sclerosis may have a wide array of antinuclear antibodies that are important in disease classification but are not clearly pathogenic; in contrast, patients with pemphigus may also exhibit a wide array of autoantibodies, one of which (antibody to desmoglein 1 and 3) is known to be pathogenic.

MECHANISMS OF AUTOIMMUNITY

Since Ehrlich first postulated the existence of mechanisms to prevent the generation of self-reactivity in the early 1900s, there has been a progressive increase in understanding of this prohibition in parallel with a progressive increase in understanding of the immune system. Burnet's clonal selection theory included the idea that interaction of lymphoid cells with their specific antigens during fetal or early postnatal life would lead to deletion of such "forbidden clones." This idea was refuted, however, when it was shown that autoimmune diseases could be induced in experimental animals by simple immunization

TABLE 355-1 Mechanisms Preventing Autoimmunity

procedures, that autoantigen-binding cells could be demonstrated easily in the circulation of normal individuals, and that self-limited autoimmune phenomena frequently developed after tissue damage from infection or trauma. These observations indicated that clones of cells capable of responding to autoantigens were present in the repertoire of antigen-reactive cells in normal adults and suggested that mechanisms in addition to clonal deletion were responsible for preventing their activation.

Currently, three general processes are thought to be involved in the maintenance of selective unresponsiveness to autoantigens **(Table 355-1)**: (1) sequestration of self-antigens, rendering them inaccessible to the immune system; (2) specific unresponsiveness (tolerance or anergy) of relevant T or B cells; and (3) limitation of potential reactivity by regulatory mechanisms. Derangements of these normal processes may predispose to the development of autoimmunity **(Table 355-2)**. In general, induction of autoimmunity requires both an exogenous trigger, such as bacterial or viral infection or cigarette smoking or a perturbation of the microbiome, and the presence of endogenous abnormalities in the cells of the immune system. A number of exogenous triggers have been identified. For example, microbial superantigens, such as staphylococcal protein A and staphylococcal enterotoxins, are substances that can stimulate a broad range of T and B cells through specific interactions with selected families of immune receptors, irrespective of their antigen specificity. If autoantigen-reactive T and/or B cells express these receptors, autoimmunity may be induced by stimulation with these substances. Alternatively, molecular mimicry or cross-reactivity between a microbial product and a self-antigen may lead to activation of autoreactive lymphocytes. One of the best examples of autoreactivity and autoimmune disease resulting from molecular mimicry is rheumatic fever, in which antibodies to the M protein of streptococci cross-react with myosin, laminin, and other matrix proteins as well as with neuronal antigens. Deposition of these autoantibodies in the heart initiates an inflammatory response, whereas their penetration into the brain can result in Sydenham's chorea. Molecular mimicry between microbial proteins and host tissues has been reported in type 1 diabetes mellitus, rheumatoid arthritis, systemic lupus erythematosus (SLE), celiac disease, and multiple sclerosis. It is presumed that infectious agents may be able to overcome self-tolerance because they possess *pathogen-associated molecular patterns* (PAMPs). These molecules (e.g., bacterial endotoxin, RNA, or DNA) exert adjuvant-like effects on the immune system by interacting with *Toll-like receptors* (TLRs) and other *pattern recognition receptors* (PRRs) that increase the immunogenicity and immunostimulatory capacity of the microbial material. The adjuvants activate dendritic cells, which in turn stimulate the activation of previously quiescent lymphocytes that recognize both microbial antigens and self-antigens. Alternatively, PAMPs can activate PRRs on tissue epithelial cells, which then activate dendritic cells. Cellular and tissue damage can result in release of *damage-associated molecular patterns* (DAMPs), including DNA, RNA nucleosomes, and other tissue debris, which may activate cells of the inflammatory and immune systems through engagement of the same array of PRRs. This pathway may lead to autoimmune disease in individuals who have impairments in mechanisms for clearance of tissue debris.

Although previous work focused on the role of pathogenic microorganisms in triggering autoimmunity, more recent studies have focused on the role of the microbiome, the collection of nonpathogenic microorganisms that reside on various body surfaces. It has become clear that the interaction between specific constituents of these microbiota and the immune system can shape the nature of the immune response to either favor or discourage immune/inflammatory responses. Thus, some genera within the microbiome may favor a nonresponsive state dominated by regulatory T cells, whereas others may favor the development of T effector cells and a proinflammatory state. Gender bias in autoimmune conditions may also be favored by differences in the dominant organisms within the microbiome.

Endogenous derangements of the immune system also contribute to the loss of immunologic tolerance to self-antigens and the development of autoimmunity (Table 355-2). Some autoantigens reside in immunologically privileged sites, such as the brain or the anterior chamber of the eye. These sites are characterized by the inability of engrafted tissue to elicit immune responses. Immunologic privilege results from a number of events, including the limited entry of proteins from those sites into lymphatics, the local production of immunosuppressive cytokines such as transforming growth factor β, and the local expression of molecules (including Fas ligand and PD-1 ligand) that can induce apoptosis or quiescence of activated T cells. Lymphoid cells remain in a state of immunologic ignorance (neither activated nor anergized) with regard to proteins expressed uniquely in immunologically privileged sites. If the privileged site is damaged by trauma or inflammation or if T cells are activated elsewhere, proteins expressed at this site can become immunogenic and be the targets of immunologic assault. In multiple sclerosis and sympathetic ophthalmia, for example, antigens uniquely expressed in the brain and eye, respectively, become the target of activated T cells.

Alterations in antigen presentation may also contribute to autoimmunity. Peptide determinants (*epitopes*) of a self-antigen that are not routinely presented to lymphocytes may be recognized as a result of altered proteolytic processing of the molecule and the ensuing presentation of novel peptides (*cryptic epitopes*). When B cells rather than dendritic cells present self-antigen, they may also present cryptic epitopes that can activate autoreactive T cells. These cryptic epitopes will not previously have been available to affect the silencing of autoreactive lymphocytes. Furthermore, once there is immunologic recognition of one protein component of a multimolecular complex, reactivity may be induced to other components of the complex after

   C. Increased B-cell function
      1. B-cell activating factor
      2. Costimulatory molecules
   D. Apoptotic defects or defects in clearance of apoptotic material
   E. Cytokine imbalance
   F. Altered immunoregulation

internalization and presentation of all molecules within the complex (epitope spreading). Finally, inflammation, environmental agents, drug exposure, or normal senescence may cause a posttranslational alteration in proteins, resulting in the generation of immune responses that cross-react with normal self-proteins. For example, the induction and/or release of protein arginine deiminase enzymes results in the conversion of arginine residues to citrullines in a variety of proteins, thereby altering their capacity to induce immune responses. Production of antibodies to citrullinated proteins has been observed in rheumatoid arthritis and chronic lung disease as well as in normal smokers. These antibodies can contribute to organ pathology. Alterations in the availability and presentation of autoantigens may be important components of immunoreactivity in certain models of organ-specific autoimmune diseases. In addition, these factors may be relevant to an understanding of the pathogenesis of various drug-induced autoimmune conditions. However, the diversity of autoreactivity manifesting in non-organ-specific systemic autoimmune diseases suggests that these conditions may result from a more general activation of the immune system rather than from an alteration in individual self-antigens.

Many autoimmune diseases are characterized by the presence of antibodies that react with antigens present in apoptotic material. Defects in the clearance of apoptotic material have been shown to elicit autoimmunity and autoimmune disease in a number of animal models. Moreover, such defects have been found in patients with SLE. Apoptotic debris that is not cleared quickly by the immune system can function as endogenous ligands for a number of PRRs on dendritic cells and B cells. Under such circumstances, dendritic cells and/or B cells are activated, and an immune response to apoptotic debris can develop. In addition, the presence of uncleared extracellular apoptotic material within germinal centers of secondary lymphoid organs in patients with SLE may facilitate the direct activation of autoimmune B-cell clones. Similarly, cellular contents, including nuclear material, released from neutrophils undergoing a form of cell death referred to as NETosis, may be particularly immunogenic.

Deficiency in C1q, likewise, can predispose or exacerbate autoimmunity. C1q assists in the clearance of apoptotic debris and NETotic material binding to IgM autoantibodies and to inhibitory receptors on monocytes and dendritic cells. If C1q is not present, a mechanism of immune suppression is lost. Moreover, if antibodies have undergone class switch recombination to IgG, the apoptotic debris containing immune complexes will engage activating Fc receptors on myeloid cells to induce an inflammatory response. Studies in a number of experimental models have suggested that intense stimulation of T lymphocytes can produce nonspecific signals that directly lead to polyclonal B-cell activation with the formation of multiple autoantibodies and bypass the need for antigen-specific helper T cells. For example, antinuclear, antierythrocyte, and antilymphocyte antibodies are produced during the chronic graft-versus-host reaction. In addition, autoimmune hemolytic anemia and immune complex–mediated glomerulonephritis can be induced in this manner. Direct stimulation of B lymphocytes can also lead to the production of autoantibodies. Thus, the administration of polyclonal B-cell activators, such as bacterial endotoxin, to normal mice leads to the production of a number of autoantibodies, including those to DNA and IgG (rheumatoid factor). A variety of genetic modifications resulting in hyperresponsiveness of B cells also can lead to the production of autoantibodies and, in animals of appropriate genetic background, a lupus-like syndrome. Moreover, excess B-cell activating factor (BAFF), a B-cell survival-promoting cytokine, can impair B-cell tolerance, cause T cell–independent B-cell activation, and lead to the development of autoimmunity. SLE can also be induced in mice through exuberant dendritic cell activation, through a redundancy of TLR7 and transposition to the Y chromosome (as in BXSB-Yaa mice), or through exposure to CpG, a ligand for TLR9. The ensuing induction of inflammatory mediators can cause a switch from the production of nonpathogenic IgM autoantibodies to the production of pathogenic IgG autoantibodies in the absence of antigen-specific T-cell help. Aberrant selection of the B- or T-cell repertoire at the time of antigen receptor expression can also predispose to autoimmunity. For example, B-cell immunodeficiency caused by an absence of the B-cell receptor–associated kinase (Bruton's tyrosine kinase) leads to X-linked agammaglobulinemia. This syndrome is characterized by reduced B-cell numbers. This leads to high levels of BAFF, which alter B-cell selection and result in greater survival of autoreactive B cells. Likewise, negative selection of autoreactive T cells in the thymus requires expression of the autoimmune regulator (*AIRE*) gene that enables the expression of tissue-specific proteins in thymic medullary epithelial cells. Peptides from these proteins are expressed in the context of major histocompatibility complex (MHC) molecules and mediate the central deletion of autoreactive T cells. The absence of *AIRE* gene expression leads to a failure of negative selection of autoreactive cells, autoantibody production, and severe inflammatory destruction of multiple organs. Individuals deficient in *AIRE* gene expression develop autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED).

Primary alterations in the activity of T and/or B cells, cytokine imbalances, or defective immunoregulatory circuits may also contribute to the emergence of autoimmunity. Diminished production of tumor necrosis factor (TNF) and interleukin (IL) 10 has been reported to be associated with the development of autoimmunity. Overproduction or therapeutic administration of type 1 interferon has also been associated with autoimmunity. Overexpression of costimulatory molecules on T cells similarly can lead to autoantibody production.

Autoimmunity may also result from an abnormality of immunoregulatory mechanisms. Observations made in both human autoimmune disease and animal models suggest that defects in the generation and expression of regulatory T-cell (Treg) activity may allow the production of autoimmunity. It has been appreciated that the IPEX (immunodysregulation, polyendocrinopathy, enteropathy X-linked) syndrome results from the failure to express the *FOXP3* gene, which encodes a molecule critical in the differentiation of Tregs. Administration of normal Tregs or of factors derived from them can prevent the development of autoimmune disease in rodent models of autoimmunity, and allogeneic stem cell transplantation ameliorates human IPEX. Abnormalities in the function of Tregs have been noted in a number of human autoimmune diseases, including rheumatoid arthritis and SLE, although it remains uncertain whether these functional abnormalities are causative or are secondary to inflammation. One of the mechanisms by which Tregs control immune/inflammatory responses is by the production of the cytokine IL-10. In this regard, children with a deficiency in the expression of IL-10 or the IL-10 receptor develop inflammatory bowel disease that mimics Crohn's disease and that can be cured by allogeneic stem cell transplantation. Furthermore, recent data indicate that B cells may also exert regulatory function, largely through the production of IL-10. Deficiency of IL-10-producing regulatory B cells can prolong the course of multiple sclerosis in an animal model, and such cells are thought to be functionally diminished in human SLE. Finally, myeloid cells can inhibit immune responses. Depending on the microenvironment and cytokine stimulation, macrophages can functionally differentiate into classical M1 or inflammatory macrophages with enhanced microbicidal and cytotoxic activities or alternatively activated or M2 macrophages with anti-inflammatory and reparative capabilities. Abnormalities in this balance have been noted to contribute to animal models of autoimmunity and to human disease where a switch from M2-like to M1-like macrophages seems to be involved in development of disease activity in SLE. Importantly, C1q helps maintain macrophages in a quiescent state. Of note, dendritic cells also begin as tolerogenic cells but become immunogenic with activation. This pathway to autoimmunity has become important with the widespread use of checkpoint inhibitor therapy for cancer, which leads to autoimmune symptoms in up to one-third of recipients.

It should be apparent that no single mechanism can explain all the varied manifestations of autoimmunity or autoimmune disease. Furthermore, genetic evaluation has shown that convergence of a number of abnormalities is most often required for the induction of an autoimmune disease. Additional factors that appear to be important determinants in the induction of autoimmunity include age, sex (many autoimmune diseases are far more common in women), exposure to infectious agents, and environmental contacts. How these disparate

factors affect the capacity to develop self-reactivity is currently being investigated intensively.

GENETIC CONSIDERATIONS

Evidence in humans that there are susceptibility genes for autoimmunity comes from family studies and especially from studies of twins. Studies in type 1 diabetes mellitus, rheumatoid arthritis, multiple sclerosis, and SLE have shown ~15–30% disease concordance in monozygotic twins, whereas the figure is <5% for dizygotic twins. The occurrence of different autoimmune diseases within the same family has suggested that certain susceptibility genes may predispose to a variety of autoimmune diseases. Many hundreds of genetic polymorphisms associated with one or more autoimmune diseases have been identified to date. As predicted, some genes are associated with multiple autoimmune diseases, whereas others are specifically associated with only one autoimmune condition. Moreover, recent genetic evidence suggests that clusters of genetic risk factors can commonly be found in groups of autoimmune diseases. For example, one group of genetic risk factors is most frequently associated with Crohn's disease, psoriasis, and multiple sclerosis, whereas a second is most strongly associated with celiac disease, rheumatoid arthritis, and SLE. These results imply that autoimmune diseases with widely different clinical presentations and patterns of organ involvement may involve similar immunopathogenic pathways or endophenotypes. For example, the same allele of the gene encoding PTPN22 is associated with multiple autoimmune diseases. Its product is a phosphatase expressed by a variety of hematopoietic cells that downregulates antigen receptor–mediated stimulation of T and B cells. The risk allele is associated with type 1 diabetes mellitus, rheumatoid arthritis, and SLE in some populations. In recent years, genome-wide association studies have demonstrated a variety of other genes that are involved in human autoimmune diseases. Importantly, the genetic contribution to autoimmune disease differs somewhat in people of different ancestries. Most genes individually confer a relatively low risk for autoimmune diseases and are found in normal individuals but, in aggregate, are associated with substantial risk of disease. In addition, most polymorphisms associated with autoimmune diseases are in noncoding regions of DNA, implying that protein expression levels rather that altered function might convey most genetic risk for autoimmune diseases. Abnormalities in epigenetics or the mechanisms, such as cellular metabolism, controlling and influencing gene expression have also been implicated in contributing to autoimmune diseases. No single gene or epigenetic modification has been identified that is essential for autoimmune diseases. In addition to this evidence from humans, certain inbred mouse strains reproducibly develop specific spontaneous or experimentally induced autoimmune diseases, whereas others do not. These findings have now led to a search for genes that might be protective.

The strongest consistent association for susceptibility to autoimmune disease is with particular MHC alleles. It has been suggested that the association of MHC genotype with autoimmune disease relates to differences in the ability of different allelic variations of MHC molecules to present autoantigenic peptides to autoreactive T cells. An alternative hypothesis involves the role of MHC alleles in shaping the T-cell receptor repertoire during T-cell ontogeny in the thymus. In addition, specific MHC gene products may themselves be the source of peptides that can be recognized by T cells. Cross-reactivity between such MHC peptides and peptides derived from proteins produced by common microbes may trigger autoimmunity by molecular mimicry. Finally, there appears to be a contribution from non-MHC genes encoded within the MHC locus. However, MHC genotype alone does not determine the development of autoimmunity. Identical twins are far more likely to develop the same autoimmune disease than MHC-identical nontwin siblings. Studies of the genetics of type 1 diabetes mellitus, SLE, rheumatoid arthritis, and multiple sclerosis in humans and mice have identified several independently segregating disease susceptibility loci in addition to the MHC. Genes that encode molecules of the innate immune response are also involved in autoimmunity. In humans, inherited homozygous deficiency of the early proteins of the classic pathway of complement (C1q, C4, or C2) as well as genes involved in the type 1 interferon pathway are very strongly associated with the development of SLE.

IMMUNOPATHOGENIC MECHANISMS IN AUTOIMMUNE DISEASES

The mechanisms of tissue injury in autoimmune diseases can be divided into antibody-mediated and cell-mediated processes. Representative examples are listed in **Table 355-3**.

The pathogenicity of autoantibodies can be mediated through several mechanisms, including opsonization of soluble factors or cells, activation of an inflammatory cascade via the complement system, and interference with the physiologic function of soluble molecules or cells or immune complex–mediated activation of cells through engagement of activating Fc receptors.

In autoimmune thrombocytopenic purpura, opsonization of platelets targets them for elimination by phagocytes. Likewise, in autoimmune hemolytic anemia, binding of immunoglobulin to red cell membranes leads to phagocytosis and lysis of the opsonized cell. Goodpasture's syndrome, a disease characterized by lung hemorrhage and

TABLE 355-3 Mechanisms of Tissue Damage in Autoimmune Disease

EFFECTOR	MECHANISM	TARGET	DISEASE
Autoantibody	Blocking or inactivation	α Chain of the nicotinic acetylcholine receptor	Myasthenia gravis
		Phospholipid–β_2-glycoprotein I complex	Antiphospholipid syndrome
		Insulin receptor	Insulin-resistant diabetes mellitus
		Intrinsic factor	Pernicious anemia
	Stimulation	TSH receptor (LATS)	Graves' disease
		Proteinase-3 (ANCA)	Granulomatosis with polyangiitis
		Epidermal cadherin	Pemphigus vulgaris
		Desmoglein 3	
	Complement activation	α_3 Chain of collagen IV	Goodpasture's syndrome
	Immune complex formation	Double-stranded DNA	Systemic lupus erythematosus
		Immunoglobulin	Rheumatoid arthritis
	Opsonization	Platelet GpIIb:IIIa	Autoimmune thrombocytopenic purpura
		Rh antigens, I antigen	Autoimmune hemolytic anemia
	Antibody-dependent cellular cytotoxicity	Thyroid peroxidase, thyroglobulin	Hashimoto's thyroiditis
T cells	Cytokine production		Rheumatoid arthritis, multiple sclerosis, type 1 diabetes mellitus
	Cellular cytotoxicity		Type 1 diabetes mellitus

Abbreviations: ANCA, antineutrophil cytoplasmic antibody; LATS, long-acting thyroid stimulator; TSH, thyroid-stimulating hormone.

severe glomerulonephritis, represents an example of antibody binding leading to local activation of complement and neutrophil accumulation and activation. The autoantibody in this disease binds to the α_3 chain of type IV collagen in the basement membrane. In SLE, activation of the complement cascade at sites of immunoglobulin deposition in renal glomeruli is considered to be a major mechanism of renal damage. Moreover, the DNA- and RNA-containing immune complexes in SLE activate TLR9 and TLR7, respectively, in plasmacytoid dendritic cells and promote the production of type 1 interferon and proinflammatory cytokines conducive to amplification of the autoimmune response.

Autoantibodies can also interfere with normal physiologic functions of cells or soluble factors. Autoantibodies to hormone receptors can lead to stimulation of cells or to inhibition of cell function through interference with receptor signaling. For example, long-acting thyroid stimulators—autoantibodies that bind to the receptor for thyroid-stimulating hormone (TSH)—are present in Graves' disease and function as agonists, causing the thyroid to respond as if there were an excess of TSH. Alternatively, antibodies to the insulin receptor can cause insulin-resistant diabetes mellitus through receptor blockade. In myasthenia gravis, autoantibodies to the acetylcholine receptor can be detected in 85–90% of patients and are responsible for muscle weakness. The exact location of the antigenic epitope, the valence and affinity of the antibody, and perhaps other characteristics determine whether activation or blockade results from antibody binding.

Antiphospholipid antibodies are associated with thromboembolic events in primary and secondary antiphospholipid syndrome and have also been associated with fetal loss. The major antibody is directed to the phospholipid–β_2-glycoprotein I complex and appears to exert a procoagulant effect. In pemphigus vulgaris, autoantibodies bind to desmoglein 1 and 3, components of the epidermal cell desmosome, and play a role in the induction of the disease. These antibodies exert their pathologic effect by disrupting cell–cell junctions through stimulation of the production of epithelial proteases, with consequent blister formation. Cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA), found in granulomatosis with polyangiitis, is an antibody to an intracellular antigen, the 29-kDa serine protease (proteinase-3). In vitro experiments have shown that IgG anti-c-ANCA causes cellular activation and degranulation of primed neutrophils.

It is important to note that autoantibodies of a given specificity may cause disease only in genetically susceptible hosts, as has been shown in experimental models of myasthenia gravis, SLE, rheumatic fever, and rheumatoid arthritis. Furthermore, once organ damage is initiated, new inflammatory cascades are initiated that can sustain and amplify the autoimmune process. Finally, some autoantibodies seem to be markers for disease but have, as yet, no known pathogenic potential.

In many autoimmune diseases, myeloid cells play an essential role as effector cells of inflammation. M1-like macrophages activated by cytokines, such as type 2 interferon, immune complexes through activating Fc receptors, or surface or intracellular TLRs can produce a number of inflammatory cytokines, including IL-1, TNF, and IL-6, that contribute to tissue inflammation.

AUTOIMMUNE DISEASES

Manifestations of autoimmunity are found in a large number of pathologic conditions. However, their presence does not necessarily imply that the pathologic process is an autoimmune disease. A number of attempts to establish formal criteria for the classification of diseases as autoimmune have been made, but none is universally accepted. One set of criteria is shown in **Table 355-4**; however, this scheme should be viewed merely as a guide in consideration of the problem.

To classify a disease as autoimmune, it is necessary to demonstrate that the immune response to a self-antigen causes the observed pathology. Initially, the detection of antibodies to the affected tissue in the serum of patients suffering from various diseases was taken as evidence that these diseases had an autoimmune basis. However, such autoantibodies can also be found when tissue damage is caused by trauma or infection and, in these cases, are secondary to tissue damage. Thus, autoimmunity must be shown to be pathogenic before a disease is categorized as autoimmune.

TABLE 355-4 Human Autoimmune Disease: Presumptive Evidence for Immunologic Pathogenesis

Major Criteria
1. Presence of autoantibodies or evidence of cellular reactivity to self
2. Documentation of relevant autoantibody or lymphocytic infiltrate in the pathologic lesion
3. Demonstration that relevant autoantibody or T cells can cause tissue pathology
a. Transplacental transmission
b. Adaptive transfer into animals
c. In vitro impact on cellular function
Supportive Evidence
1. Reasonable animal model
2. Beneficial effect from immunosuppressive agents
3. Association with other evidence of autoimmunity
4. No evidence of infection or other obvious cause

To confirm autoantibody pathogenicity, it may be possible to transfer disease to experimental animals by the administration of autoantibodies from a patient leading to the development of pathology in the recipient that is similar to that seen in the patient. This scenario has been documented, for example, in Graves' disease. Some autoimmune diseases can be transferred from mother to fetus and are observed in the newborn babies. The symptoms of the disease in the newborn usually disappear as the levels of maternal antibody decrease. An exception, however, is congenital heart block, in which damage to the developing conducting system of the heart follows in utero transfer of anti-Ro antibody from the mother to the fetus. This antibody transfer can result in a permanent developmental defect in the heart.

In most situations, the critical factors that determine when the development of autoimmunity results in autoimmune disease have not been delineated. The relationship of autoimmunity to the development of autoimmune disease may be associated with the fine specificity of the antibodies and their isotype or T cells or their specific effector capabilities. In many circumstances, a mechanistic understanding of the pathogenic potential of autoantibodies has not been established. In some autoimmune diseases, biased production of cytokines by helper T (T_H) cells may play a role in pathogenesis. In this regard, T cells can differentiate into specialized effector cells that predominantly produce interferon γ (T_H1), IL-4 (T_H2), or IL-17 (T_H17) or that provide help to B cells (T follicular helper [Tfh]) **(Chap. 349)**. T_H1 cells facilitate macrophage activation and classic cell-mediated immunity, whereas T_H2 cells are thought to have regulatory functions and are involved in the resolution of normal immune responses as well as in the development of responses to a variety of parasites. T_H17 cells produce a number of inflammatory cytokines, including IL-17 and IL-22, and seem to be prominently involved in host resistance to certain fungal infections. Tfh cells help B cells by constitutively producing IL-21. In a number of autoimmune diseases, such as rheumatoid arthritis, multiple sclerosis, type 1 diabetes mellitus, ankylosing spondylitis, and Crohn's disease, there appears to be biased differentiation of T_H1 and T_H17 cells, with resultant organ damage. Studies suggest an accentuated differentiation of T_H17 cells associated with animal models of inflammatory arthritis, whereas increased differentiation of Tfh cells has been associated with SLE. Importantly, genetically determined or environmentally induced features of the target organ may determine susceptibility of the target organ to autoantibodies or autoreactive T cell–mediated damage.

ORGAN-SPECIFIC VERSUS SYSTEMIC AUTOIMMUNE DISEASES

The spectrum of autoimmune diseases ranges from conditions specifically affecting a single organ to systemic disorders that involve many organs **(Table 355-5)**. Hashimoto's autoimmune thyroiditis is an example of an organ-specific autoimmune disease **(Chap. 382)**. In this disorder, a specific lesion in the thyroid is associated with infiltration of mononuclear cells and damage to follicular cells. Antibody to thyroid constituents can be demonstrated in nearly all cases. Other

TABLE 355-5 Diseases on the Autoimmune Spectrum

Organ Specific	
Graves' disease	Vitiligo
Hashimoto's thyroiditis	Autoimmune hemolytic anemia
Autoimmune polyglandular syndrome	Autoimmune thrombocytopenic purpura
Type 1 diabetes mellitus	Pernicious anemia
Insulin-resistant diabetes mellitus	Myasthenia gravis
Immune-mediated infertility	Multiple sclerosis
Autoimmune Addison's disease	Guillain-Barré syndrome
Pemphigus vulgaris	Stiff-man syndrome
Pemphigus foliaceus	Acute rheumatic fever
Dermatitis herpetiformis	Sympathetic ophthalmia
Autoimmune alopecia	Goodpasture's syndrome
Primary biliary cirrhosis	
Organ Nonspecific (Systemic)	
Systemic lupus erythematosus	Granulomatosis with polyangiitis
Rheumatoid arthritis	Antiphospholipid syndrome
Systemic necrotizing vasculitis	Sjögren's syndrome

organ- or tissue-specific autoimmune disorders include pemphigus vulgaris, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, Goodpasture's syndrome, myasthenia gravis, and sympathetic ophthalmia. One important feature of some organ-specific autoimmune diseases is the tendency for overlap, such that an individual with one specific syndrome is more likely to develop a second syndrome. For example, there is a high incidence of pernicious anemia in individuals with autoimmune thyroiditis. More striking is the tendency for individuals with an organ-specific autoimmune disease to develop multiple other manifestations of autoimmunity without the development of associated organ pathology. Thus, as many as 50% of individuals with pernicious anemia have non-cross-reacting antibodies to thyroid constituents, whereas patients with myasthenia gravis may develop antinuclear antibodies, antithyroid antibodies, rheumatoid factor, antilymphocyte antibodies, and polyclonal hypergammaglobulinemia. Part of the explanation may relate to the genetic elements shared by individuals with these different diseases.

Systemic autoimmune diseases differ from organ-specific diseases in that pathologic lesions are found in multiple diverse organs and tissues. The hallmark of these conditions is the demonstration of associated relevant autoimmune manifestations that are likely to have an etiologic role in organ pathology. SLE represents the prototype of these disorders because of its abundant autoimmune manifestations that characteristically involve the kidneys, joints, skin, serosal surfaces, blood vessels, and central nervous system **(Chap. 356)**. The disease is associated with a vast array of autoantibodies whose production appears to be a part of a generalized hyperreactivity of the humoral immune system. Other features of SLE include generalized B-cell hyperresponsiveness and polyclonal hypergammaglobulinemia. Current evidence suggests that both hypo- and hyperresponsiveness to antigen can lead to survival and activation of autoreactive B cells in SLE. The autoantibodies in SLE are thought to arise as part of an accentuated T cell–dependent B-cell response since most pathogenic anti-DNA autoantibodies exhibit evidence of extensive somatic hypermutation.

TREATMENT

Autoimmune Diseases

Treatment of autoimmune diseases can focus on suppressing the induction of autoimmunity, restoring normal regulatory mechanisms, or inhibiting the effector mechanisms. To decrease the number or function of autoreactive cells, immunosuppressive or ablative therapies are most commonly used. In recent years, cytokine blockade has been demonstrated to be effective in preventing immune activation in some diseases or in inhibiting the extensive inflammatory effector mechanisms characteristic of these diseases. New therapies have also been developed to target lymphoid cells more specifically by blocking a costimulatory signal needed for T- or B-cell activation, by blocking the migratory capacity of lymphocytes, or by eliminating the effector T cells or B cells. The efficacy of these therapies in some diseases—e.g., SLE (belimumab), rheumatoid arthritis (TNF neutralization, IL-6 receptor blockade, CD28 competition, B-cell depletion, IL-1 neutralization), psoriasis (IL-12/23 depletion, TNF neutralization), and inflammatory bowel disease (TNF neutralization, IL-12/23 neutralization)—has been demonstrated. Small molecules that block cytokine signaling pathways by blocking the Janus kinase (JAK) family of kinases have also entered the clinic. Biologicals that delete B cells have demonstrated efficacy in a number of autoimmune diseases characterized by pathogenic effector T cells, highlighting the importance of B cells as antigen-presenting cells. Finally, there is renewed interest in cellular therapies in autoimmune diseases, including hematopoietic stem cell reconstitutions and treatment with immunosuppressive mesenchymal stem cells. Therapies that prevent target organ damage or support target organ function also remain important in the management of autoimmune disease.

356 Systemic Lupus Erythematosus

Bevra Hannahs Hahn, Maureen McMahon

DEFINITION AND PREVALENCE

Systemic lupus erythematosus (SLE) is an autoimmune disease in which organs and cells undergo damage initially mediated by tissue-binding autoantibodies and immune complexes. In most patients, autoantibodies are present for a few years before the first clinical symptom appears. Ninety percent of patients are women of child-bearing years; people of all genders, ages, and ethnic groups are susceptible. The prevalence of SLE in the United States is 81–144 per 100,000. Prevalence is higher in all nonwhite races/ethnicities compared to whites, with the highest prevalence in African-American and Afro-Caribbean women and the lowest in white men. SLE is 5.5–6.5 times more prevalent in women than in men.

PATHOGENESIS AND ETIOLOGY

The proposed pathogenic mechanisms of SLE are illustrated in **Fig. 356-1**. The abnormal immune responses underlying SLE may be summarized as leading to production of increased quantities and

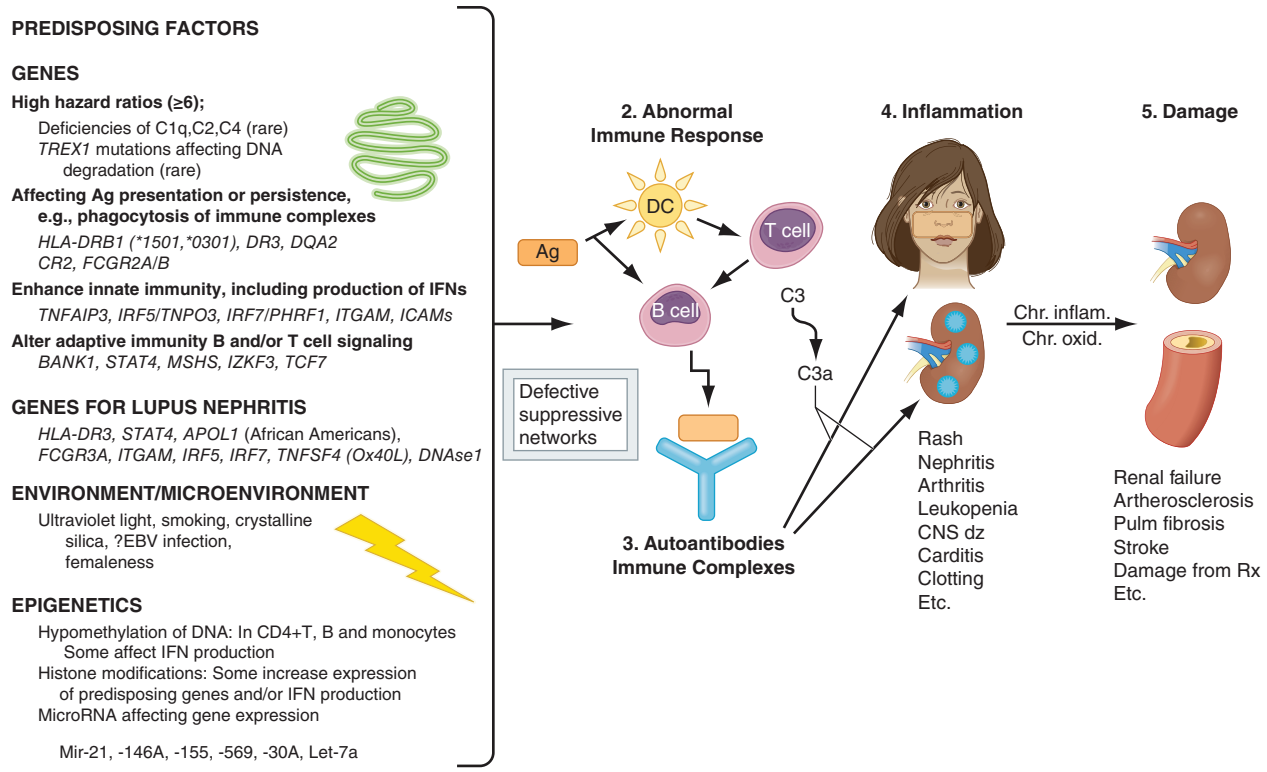

FIGURE 356-1 Pathogenesis of systemic lupus erythematosus (SLE). Pathogenesis is related in large part to production of increased quantities and immunogenic forms of nucleic acids and other self-antigens, which drive autoimmune-inducing activation of innate immunity, autoantibodies, and T cells. Interactions between genes, environment, and epigenetic changes drive increased autophagy, antigen (Ag) presentation, neutrophil NETosis, autoantibody formation with increased plasma cells, and production of pathogenic effector T cells in T_H1, T_H17, and Tfh subsets, and in B-cell subsets with ineffective regulatory networks. Genes confirmed in more than one genome-wide association analysis in multiple racial groups that increase susceptibility to SLE or lupus nephritis (HR ≥1.5) are listed (reviewed in Deng Y, Tsao B: Genetics of Human SLE, in *Dubois Lupus Erythematosus and Related Syndromes,* 9th ed. DJ Wallace, BH Hahn [eds]. Philadelphia, Elsevier, 2019, pp 54-69; and Teruel M, Alarcon-Riquelme ME: The genetic basis of systemic lupus erythematosus: What are the risk factors and what have we learned. J Autoimmun 74:161, 2016. Epigenetics are reviewed in Richardson B: The interaction between environmental triggers and epigenetics in autoimmunity. Clin Immunol 192:1, 2018; and Scharer CD et al: Epigenetic programming underpins B cell dysfunction in human SLE. Nat Immunol 20:1071, 2019. Environmental triggers are reviewed in Gulati G, Brunner HI: Environmental triggers in systemic lupus erythematosus. Semin Arthritis Rheum 47:710, 2018). These result in abnormal immune responses that generate pathogenic autoantibodies and immune complexes that deposit in tissue, activate complement, induce cytokine and chemokine release causing inflammation, and over time lead to irreversible organ damage (reviewed in Arazi A et al: The immune cell landscape in kidneys of patients with lupus nephritis. Nat Immunol 20:902, 2019; and Hahn BH: Pathogenesis of SLE, in *Dubois Lupus Erythematosus and Related Syndromes,* 9th ed. DJ Wallace, BH Hahn [eds]. Philadelphia, Elsevier, 2019; and Anders HJ, Rovin B: A pathophysiology-based approach to diagnosis and treatment of lupus nephritis. Kidney Intl 90:493, 2016). C1q, complement system; C3, complement component; CNS, central nervous system; DC, dendritic cell; EBV, Epstein-Barr virus; HLA, human leukocyte antigen; FcR, immunoglobulin Fc-binding receptor; IL, interleukin; MCP, monocyte chemotactic protein; PTPN, phosphotyrosine phosphatase; UV, ultraviolet.

immunogenic forms of nucleic acids, their accompanying proteins, and other self-antigens, with resultant stimulation of large quantities of autoantibodies. Autoantibodies of SLE are described in Fig. 356-1 and **Table 356-1**.

SLE autoimmunity may begin with activation of innate immunity, partly through binding of DNA, RNA, and proteins by Toll-like receptors in plasmacytoid dendritic cells (pDCs) and monocytes/macrophages. The pDCs (and other cells) produce interferon (IFN) α. Upregulation of genes induced by IFNs (particularly IFN-α) is a genetic "signature" in whole blood, peripheral blood cells, skin lesions, synovium, and kidneys in 50–80% of SLE patients and is particularly associated with active disease. Activated macrophages produce inflammatory cytokines/chemokines such as interleukin (IL) 12, tumor necrosis factor α (TNF-α), and the B-cell maturation/survival factor BLys/BAFF. Furthermore, lupus phagocytic cells have reduced capacity to clear immune complexes, apoptotic cells, and their autoantigen-containing (e.g., DNA/RNA/Ro/La and phospholipid) surface blebs. The result is persistence of large quantities of autoantigens. Neutrophils release immunogenic DNA/protein-containing neutrophil extracellular traps (NETs), and natural killer (NK) cells have reduced ability to kill autoreactive T and B cells or to produce the transforming growth factor β (TGF-β) needed for development of regulatory T cells.

The activated innate immune system interacts with various subsets of the B and T cells of adaptive immunity. SLE peripheral B cells have increased numbers of naïve activated B cells and double-negative B cells (DN2: CD27–CD11c+T-BET+CXCR5–), which are precursors of autoantibody-secreting cells. Both subsets have abnormal epigenetic modifications with more open chromatin than normal B cells and thus are subject to hyperactivation via their B-cell receptors, Toll-like receptor 7 (TLR7), and cytokines such as IL-21. Therefore, SLE B cells are poised to react to their environment with increased autoantibody secretion. Central B cells (germinal center, follicular B cells) also produce autoantibodies. DN2 and isotype-switched memory B cells differentiate into both short-lived (in periphery) and long-lived (in bone marrow) plasma cells that secrete autoantibodies and are elevated in patients with active SLE. B cells not only present antigens, but they also secrete IL-6 and IL-10, which promote autoreactive B-cell survival (as does estrogen). Some B and T lymphocyte subsets have altered metabolism (abnormal mitochondrial electron transport, membrane potential, and oxidative stress), increased glucose utilization, increased pyruvate production, activation of mechanistic target of rapamycin (mTOR), and increased autophagy. Helper T cells are easily activated and driven into either differentiation, activation, or apoptosis. In SLE patients, after peptides bind the T-cell receptor (TCR), T-cell signaling is abnormal, beginning with complexing of TCR with the common chain FcRγ rather than the usual CD3ζ. This results in abnormal elevations of phosphorylated Syk, the P13K/mTORC pathway, CaMKIV, PP2A, and calcineurin, with resultant increased calcium influx. Rho-associated protein kinases (ROCK) pathways are also elevated, probably via cytokine receptors, with increases in STAT3 and therefore in IL-17. The net result is underproduction of IL-2 (needed for survival of T lymphocytes and for generation of regulatory T cells) and elevation

TABLE 356-1 Autoantibodies in Serum or Plasma in Systemic Lupus Erythematosus (SLE)

ANTIBODY	PREVALENCE, %	ANTIGEN RECOGNIZED	CLINICAL UTILITY
Antinuclear antibodies	98	Multiple nuclear	Best screening test; repeated negative tests by immunofluorescence make SLE unlikely. Immunofluorescence is best standard test: titers of 1:80 or higher may separate clinically significant tests from false positives. Has good sensitivity but poor specificity for SLE.
Anti-dsDNA	70	DNA (double-stranded)	High titers are SLE-specific and in some patients correlate with disease activity, nephritis, vasculitis. *Crithidia* immunofluorescence is more specific for SLE than ELISA methods.
Anti-C1q	33	Collagen-like determinants on complement component C1q	Present in 63% of lupus nephritis, associated with active lupus nephritis especially when anti-dsDNA is also present. Correlates with activity of nephritis. Not specific for SLE.
Anti-Sm	25	Protein complexed to 6 species of nuclear U1 RNA	Specific for SLE; no definite clinical correlations; most patients also have anti-RNP; more common in blacks and Asians than whites
Anti-RNP	40	Protein complexed to U1 RNA	Not specific for SLE; high titers associated with syndromes that have overlap features of several rheumatic syndromes including SLE; more common in blacks than whites; correlates with high IFN-induced gene signature
Anti-Ro (SS-A)	30	Protein complexed to hY RNA, primarily 60 kDa and 52 kDa	Not specific for SLE; associated with sicca syndrome, predisposes to subacute cutaneous lupus and neonatal lupus with congenital heart block.
Anti-La (SS-B)	10	47-kDa protein complexed to hY RNA	Usually associated with anti-Ro.
Antihistone	70	Histones associated with DNA (in nucleosome, chromatin)	More frequent in drug-induced lupus than in SLE.
Antiphospholipid	50	Phospholipids, β_2-glycoprotein 1 (β_2G1) cofactor, prothrombin	Three tests available—ELISAs for cardiolipin and β_2G1, sensitive prothrombin time (DRVVT) for lupus anticoagulant; predisposes to clotting, fetal loss, thrombocytopenia.
Antierythrocyte	60	Erythrocyte membrane	Measured as direct Coombs test; a small proportion develops overt hemolysis.
Antiplatelet	30	Surface and altered cytoplasmic antigens on platelets	Associated with thrombocytopenia, but sensitivity and specificity are not good; this is not a useful clinical test.
Antineuronal (includes antiglutamate receptor 2)	60	Neuronal and lymphocyte surface antigens	In some series, a positive test in CSF correlates with active CNS lupus.
Antiribosomal P	20	Protein in ribosomes	In some series, a positive test in serum correlates with depression or psychosis due to CNS lupus.

Abbreviations: CNS, central nervous system; CSF, cerebrospinal fluid; DRVVT, dilute Russell viper venom time; ELISA, enzyme-linked immunosorbent assay.

of IL-17. These changes push the adaptive immune system toward generation of helper T cells (T_H1, Tfh, T_H17) and away from downregulating regulatory T cells. Several of these B- and T-cell pathways are targets of therapeutic interventions in current clinical trials.

Tissue damage begins with deposition of autoantibodies and/or immune complexes, followed by destruction mediated by complement activation and release of cytokines/chemokines. Nonimmune tissue-fixed cells also are activated with resultant inflammation and damage, such as basal cells of the dermis, synovial fibroblasts, renal mesangial cells, podocytes and tubular epithelium, and endothelial cells throughout the body. Meanwhile, the initial immune attack is attracting into the target tissues additional B and T cells, monocytes/macrophages, dendritic cells, and plasma cells. Inflammation also causes release of vasoactive peptides, oxidative damage, and release of growth factors and fibrosing factors. Sclerosis/fibrosis with irreversible tissue damage can occur in multiple tissues including kidneys, lungs, blood vessels, and skin. Each of these processes depends on the individual's genetic background, environmental influences, and epigenetics.

SLE is usually a multigenic disease. Rare single-gene defects confer high hazard ratios (HRs) for SLE (HR 5–25), including homozygous deficiencies of early components of complement (C1q,r,s; C2; C4) and a mutation in *TREX1* (encoding a DNAase) on the X chromosome. In most genetically susceptible individuals, normal alleles, mutations, and/or copy numbers of multiple ancestral genes each contribute a small amount to abnormal immune/inflammation/tissue damage responses; if enough predisposing variations are present, disease results. Approximately 90 genes with normal single nucleotide polymorphisms (SNPs; or mutations or altered copy numbers) increase risk for SLE and/or clinical subsets of SLE and/or irreversible organ damage. They have been identified in recent genome-wide or immunochip association studies in different ancestries. Individually, they confer an HR for SLE of 1.4–3 and, even in combination, account for only 28% of disease susceptibility, suggesting that environmental exposures and epigenetics play major roles. Examples are listed in Fig. 356-1, showing those with HR ≥1.4 and listing them according to their major known functions. Approximately 50% of known predisposing genes influence IFN production or function—the most characteristic increased gene expression pattern of SLE patients. Multiple genes affect final responses: for example, a gene effect in the promoter for *IRF5* that increases IFN production is associated with SLE in all ancestries, but a haplotype containing *IRF5* and transportin 3 (*TNPO3*), which probably further increases IFN responses, is present only in European ancestries. Some polymorphisms influence clinical manifestations; these are listed in Fig. 356-1. Some genes relate to end-organ dysfunction rather than SLE, such as *MYH9/APOL1* associating with end-stage renal disease (ESRD) in all ancestries, whereas *APOL1G1/G2* associates with ESRD (but not SLE) only in African Americans. Such combinations probably account for lupus nephritis being more common and more severe in African Americans than in other races. Some gene effects are in promoter regions (e.g., *MYH9/APOL* and IL-10), and others are conferred by copy numbers (e.g., *C4A, TLR7*). In addition, multiple epigenetic changes characterize SLE, including hypomethylation of DNA-encoding genes, promoter regions, and/or transcription factors in CD4+ T cells, B cells, and monocytes, e.g., genes that control production of type 1 IFNs. In contrast, some DNA regions in SLE B cells are hypermethylated. There are also histone modifications in SLE DNA. Some of these changes are mediated by microRNAs associated with SLE, including some that control DNA methyltransferases (DNMTs; such as mIR-146a), which control methylation of DNA in CD4+ T cells and resultant IFN production. Some gene polymorphisms contribute to several autoimmune diseases, such as *STAT4* and *CTLA4*. Most of these genetic effects influence immune responses to the external and internal environment;

when such responses are abnormal or prolonged, autoimmune disease is favored.

Female sex is permissive for SLE with evidence for hormone effects, genes on the X chromosome, and epigenetic differences between genders playing a role. Females of many mammalian species make higher antibody responses than males. Women exposed to estrogen-containing oral contraceptives or hormone replacement have an increased risk of developing SLE (HR 1.2–2). Estradiol binds to receptors on T and B lymphocytes, increasing activation and survival of those cells, especially autoreactive subsets, thus favoring prolonged immune responses. Genes on the X chromosome that influence SLE, such as *TREX1*, may play a role in gender predisposition, possibly because some genes on the second X in females are not silent. People with XXY karyotype (Klinefelter's syndrome) have a significantly increased risk for SLE.

Several environmental stimuli may influence SLE (Fig. 356-1). Exposure to ultraviolet light causes flares of SLE in ~70% of patients, possibly by increasing apoptosis in skin cells or by altering DNA and intracellular proteins to make them antigenic. Some infections and lupus-inducing drugs activate autoreactive T and B cells; if such cells are not appropriately regulated, prolonged autoantibody production occurs. Most SLE patients have autoantibodies for 3 years or more before the first symptoms of disease, suggesting that regulation controls the degree of autoimmunity for years before quantities and qualities of autoantibodies, activated innate immunity, pathogenic B and T cells, and activated tissue-fixed cells cause clinical disease. Epstein-Barr virus (EBV) may be one infectious agent that can trigger SLE in susceptible individuals. Children and adults with SLE are more likely to be infected by EBV than age-, sex-, and ethnicity-matched controls. EBV contains amino acid sequences that mimic sequences on human spliceosomes (RNA/protein antigens) often recognized by autoantibodies in people with SLE. Current tobacco smoking increases risk for SLE (HR 1.5). Prolonged occupational exposure to crystalline silica (e.g., inhalation of soap powder dust or soil in farming activities) increases risk (HR 4.3) in African-American women. Exposure to pesticides during childhood, both in residential use and in farming, increases the risk of SLE. Long-term exposure to air pollution also increases the risk of SLE. Thus, interplay between genetic susceptibility, environment, gender, race, and abnormal immune responses results in autoimmunity **(Chap. 355)**.

PATHOLOGY

In SLE, biopsies of affected skin show deposition of Ig at the dermal-epidermal junction (DEJ), injury to basal keratinocytes, and inflammation dominated by T lymphocytes in the DEJ and around blood vessels and dermal appendages. Clinically unaffected skin may also show Ig deposition at the DEJ. Lupus skin lesions are characterized by expression of IFN-regulated cytokines and chemokines and by IFN-producing pDCs and keratinocytes. These patterns are not specific for dermatologic SLE; however, they are highly suggestive.

In renal biopsies, the pattern and severity of injury are important in diagnosis and in selecting the best therapy. Most recent clinical studies of lupus nephritis have used the International Society of Nephrology (ISN) and the Renal Pathology Society (RPS) classification **(Table 356-2)**. In the ISN/RPS classification, the addition of "A" for active and "C" for chronic changes gives physicians information regarding the potential reversibility of disease. The system focuses on glomerular disease, although the presence of tubular interstitial and vascular disease, as well as the chronicity score in both glomeruli and interstitium, is important in predicting clinical outcomes. In general, class III and IV disease, as well as class V accompanied by III or IV disease, should be treated with aggressive immunosuppression if possible because there is a high risk for ESRD if patients are untreated or undertreated. In contrast, treatment for lupus nephritis is not recommended in patients with class I or II disease or with extensive irreversible changes (class VI). In the 2019 European League of Rheumatism/American College of Rheumatology (EULAR/ACR) criteria for classification of SLE, a diagnosis can be established on the basis of class III or class IV renal histology in the presence of antinuclear autoantibodies, without meeting additional criteria **(Tables 356-3 and 356-4)**.

TABLE 356-2 Classification of Lupus Nephritis (International Society of Nephrology and Renal Pathology Society)

Class I: Minimal Mesangial Lupus Nephritis
Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence.
Class II: Mesangial Proliferative Lupus Nephritis
Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits. A few isolated subepithelial or subendothelial deposits may be visible by immunofluorescence or electron microscopy, but not by light microscopy.
Class III: Focal Lupus Nephritis
Active or inactive focal, segmental or global endo- or extracapillary glomerulonephritis involving ≤50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations.
Class III (A): Active lesions—focal proliferative lupus nephritis
Class III (A/C): Active and chronic lesions—focal proliferative and sclerosing lupus nephritis
Class III (C): Chronic inactive lesions with glomerular scars—focal sclerosing lupus nephritis
Class IV: Diffuse Lupus Nephritis
Active or inactive diffuse, segmental or global endo- or extracapillary glomerulonephritis involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into diffuse segmental (IV-S) lupus nephritis when ≥50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) lupus nephritis when ≥50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than one-half of the glomerular tuft. This class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation.
Class IV-S (A): Active lesions—diffuse segmental proliferative lupus nephritis
Class IV-G (A): Active lesions—diffuse global proliferative lupus nephritis
Class IV-S (A/C): Active and chronic lesions—diffuse segmental proliferative and sclerosing lupus nephritis
Class IV-G (A/C): Active and chronic lesions—diffuse global proliferative and sclerosing lupus nephritis
Class IV-S (C): Chronic inactive lesions with scars—diffuse segmental sclerosing lupus nephritis
Class IV-G (C): Chronic inactive lesions with scars—diffuse global sclerosing lupus nephritis
Class V: Membranous Lupus Nephritis
Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations. Class V lupus nephritis may occur in combination with class III or IV, in which case both will be diagnosed. Class V lupus nephritis may show advanced sclerosis.
Class VI: Advanced Sclerotic Lupus Nephritis
≥90% of glomeruli globally sclerosed without residual activity.

Note: Indicate and grade (mild, moderate, severe) tubular atrophy, interstitial inflammation and fibrosis, and severity of arteriosclerosis or other vascular lesions.

Source: Reproduced with permission from JJ Weening et al: The classification of glomerulonephritis in systemic lupus erythematosus revisited. Kidney Int 65;521, 2004.

Histologic abnormalities in blood vessels may also determine therapy. Patterns of vasculitis are not specific for SLE but may indicate active disease: leukocytoclastic vasculitis is most common **(Chap. 363)**.

Lymph node biopsies are usually performed to rule out infection or malignancies. In SLE, they show nonspecific diffuse chronic inflammation.

DIAGNOSIS

The diagnosis of SLE is based on characteristic clinical features and autoantibodies. Two classification systems are currently in use: the 2012 Systemic Lupus International Collaborating Clinics (SLICC) criteria and the 2019 EULAR/ACR classification in which clinical manifestations are weighted. Both are shown in Tables 356-3 and 356-4. The SLICC criteria are easier for evaluating an individual patient, but the EULAR/ACR are more current and will probably be used for

TABLE 356-3 Systemic Lupus International Collaborating Clinic Criteria for Classification of Systemic Lupus Erythematosus

CLINICAL MANIFESTATIONS	IMMUNOLOGIC MANIFESTATIONS
Skin	ANA > reference negative value
Acute, subacute cutaneous LE (photosensitive, malar, maculopapular, bullous)	Anti-dsDNA > reference, if by ELISA 2× reference
Chronic cutaneous LE (discoid lupus, panniculitis, lichen planus–like, hypertrophic verrucous, chillblains)	Anti-Sm
Oral or nasal ulcers	Antiphospholipid (any of lupus anticoagulant, false-positive RPR, anticardiolipin, anti–β_2-glycoprotein 1)
Nonscarring alopecia	Low serum complement (C3, C4, or CH50)
Synovitis involving ≥2 joints	Positive direct Coombs test
Serositis (pleurisy, pericarditis)	
Renal	
Prot/Cr ≥0.5	
RBC casts	
Biopsy[a]	
Neurologic	
Seizures, psychosis, mononeuritis, myelitis, peripheral or cranial neuropathies, acute confusional state	
Hemolytic anemia	
Leukopenia (<4000/μL) or lymphopenia (<1000/μL)	
Thrombocytopenia (<100,000/μL)	

[a]Renal biopsy read as systemic lupus qualifies for classification as SLE if any lupus autoantibodies are present, even if total criteria are fewer than 4.

Interpretation: Presence of any four criteria (must have at least 1 in each category) qualifies patient to be classified as having SLE with 93% specificity and 92% sensitivity. American College of Rheumatology is developing new criteria for SLE. For update, see website *Rheumatology.org*.

Abbreviations: ANA, antinuclear antibody; Cr, creatinine; ELISA, enzyme-linked immunosorbent assay; LE, lupus erythematosus; Prot, protein; RBC, red blood cell; RPR, rapid plasma reagin.

Source: M Petri et al: Arthritis Rheum 64:2677, 2012. Because these criteria are relatively new, some currently ongoing clinical studies use prior American College of Rheumatology Criteria; see EM Tan et al: Arthritis Rheum 25:1271, 1982; update MC Hochberg: Arthritis Rheum 40:1725, 1997.

most clinical studies in SLE for the next several years. An algorithm for diagnosis and initial therapy is shown in **Fig. 356-2**. The criteria are intended for diagnosis of SLE in subjects included in studies; the authors use them in individual patients for estimating the probability that a disease is SLE. In the SLICC criteria, any combination of four or more well-documented criteria at any time during an individual's history, with at least one in the clinical and one in the immunologic category, makes it likely that the patient has SLE (specificity 97%, sensitivity 84%%). For EULAR/ACR criteria, a subject must have a positive ANA (≥1:80 by immunofluorescence) and a score of 10 (specificity 97%, sensitivity 93%). In many patients, criteria accrue over time. Antinuclear antibodies (ANAs) are positive in >98% of patients during the course of disease; repeated negative tests by immunofluorescent methods suggest that the diagnosis is not SLE, unless other autoantibodies are present (Fig. 356-2). High-titer IgG antibodies to double-stranded DNA and antibodies to the Sm antigen are both specific for SLE and, therefore, favor the diagnosis in the presence of compatible clinical manifestations. The presence of multiple autoantibodies in an individual without clinical symptoms should not be considered diagnostic for SLE, although such persons are at increased risk.

INTERPRETATION OF CLINICAL MANIFESTATIONS

When a diagnosis of SLE is made, it is important to establish the severity and potential reversibility of the illness and to estimate the possible consequences of various therapeutic interventions. In the following paragraphs, descriptions of some disease manifestations begin with relatively mild problems and progress to those that are more life-threatening.

OVERVIEW AND SYSTEMIC MANIFESTATIONS

At its onset, SLE may involve one or several organ systems; over time, additional manifestations may occur (**Tables** 356-3, 356-4, and **356-5**). Most of the autoantibodies characteristic of each person are present at the time clinical manifestations appear (Tables 356-1, 356-3, and 356-4). Severity of SLE varies from mild and intermittent to severe and fulminant. Systemic symptoms, particularly fatigue and myalgias/arthralgias, are present most of the time. Severe systemic illness requiring high-dose glucocorticoid therapy can occur with fever, prostration, weight loss, and anemia with or without other organ-targeted manifestations. Approximately 85% of patients have either continuing active disease (on current treatment) or one or more flares of active disease annually. Permanent complete remissions (absence of symptoms with no treatment) occur in <5%. Recommended treatment target is remission on therapy (no clinical manifestations; abnormal laboratory tests permitted) or induction of low lupus disease activity. See "Management of Systemic Lupus Erythematosus," below, for more detail.

MUSCULOSKELETAL MANIFESTATIONS

Most people with SLE have intermittent polyarthritis, varying from mild to disabling. Polyarthritis is characterized by soft tissue swelling and tenderness in joints and/or tendons, most commonly in hands, wrists, and knees. Joint deformities (hands and feet) develop in only 10% and are often reducible. Erosions on joint x-rays are rare but can be identified by ultrasound in 10–50% of patients; individuals with erosions may fulfill criteria for both RA and SLE ("rhupus"). If pain persists in a single joint, such as knee, shoulder, or hip, a diagnosis of ischemic necrosis of bone (INB) should be considered, particularly if there are no other manifestations of active SLE. INB prevalence is increased in SLE, especially in patients treated with systemic glucocorticoids. Myositis with clinical muscle weakness, elevated creatine kinase levels, positive magnetic resonance imaging (MRI) scan, and muscle necrosis and inflammation on biopsy can occur, although most patients have myalgias without frank myositis. Glucocorticoid therapies (commonly) and antimalarial therapies (rarely) can cause muscle weakness; these adverse effects must be distinguished from active inflammatory disease.

CUTANEOUS MANIFESTATIONS

Lupus dermatitis can be classified as acute, subacute, or chronic, and there are many different types of lesions encompassed within these groups. Discoid lupus erythematosus (DLE) is the most common chronic dermatitis in lupus; lesions are roughly circular with slightly raised, scaly, hyperpigmented erythematous rims and depigmented, atrophic centers in which all dermal appendages are permanently destroyed. Lesions can be disfiguring, particularly on the face and scalp. Only 5% of people with DLE have SLE (although half have positive ANA); however, among individuals with SLE, as many as 20% have DLE. The most common acute SLE rash is a photosensitive, slightly raised, occasionally scaly erythema on the face (particularly the cheeks and nose—the "butterfly" rash), ears, chin, V region of the neck and chest, upper back, and extensor surfaces of the arms. Worsening of this rash often accompanies flare of systemic disease. Subacute cutaneous lupus erythematosus (SCLE) consists of scaly red patches, similar to psoriasis, or circular, flat, red-rimmed ("annular") lesions. Patients with these manifestations are exquisitely photosensitive; most have antibodies to Ro (SS-A). Other SLE rashes include recurring urticaria, lichen planus–like dermatitis, bullae, and panniculitis ("lupus profundus"). Rashes can be minor or severe; they may be the major disease manifestation. Small ulcerations on the oral or nasal mucosa are common in SLE; the lesions resemble aphthous ulcers and may or may not be painful.

RENAL MANIFESTATIONS

Nephritis is usually the most serious manifestation of SLE, particularly because nephritis and infection are the leading causes of mortality in the first decade of disease. Because nephritis is asymptomatic in most lupus patients, urinalysis should be ordered in any person suspected of having SLE. The classification of lupus nephritis is primarily histologic (see "Pathology," above, and Table 356-2). Renal biopsy

TABLE 356-4 2019 EULAR/ACR Classification Criteria for Systemic Lupus Erythematosus (SLE)

	Positive ANA (titer at least 1:80) is obligatory entry criterion, followed by additive weighted criteria in 7 clinical and 3 immunologic domains. Accumulating ≥10 points classifies as SLE. *All manifestations must be attributable to SLE.*		
	CLINICAL CRITERIA		
DOMAIN	**CRITERIA**	**% OF PATIENTS WITH FEATURE[a]**	**WEIGHT**
Constitutional, 80%	Fever	50	2
Hematologic, 50%	Leukopenia	30	3
	Thrombocytopenia	20	4
	Autoimmune hemolytic anemia	10	4
Neuropsychiatric, 75%	Delirium	5	2
	Psychosis	7	3
	Seizure	11	5
Mucocutaneous, 80%	Nonscarring alopecia	15	2
	Oral ulcers	45	2
	Subcutaneous or discoid lupus	30	4
	Acute cutaneous lupus	70	6
Serosal, 50%	Pleural or pericardial effusion	50	5
	Acute pericarditis	35	6
Musculoskeletal, 95%	Joint involvement	90	6
Renal, 50%	Proteinuria >0.5 g/24 h	50	4
	Renal biopsy class II or V LN	25% of LN	8
	Renal biopsy class III or IV LN	60% of LN	10
	IMMUNOLOGIC CRITERIA		
DOMAIN	**CRITERIA**	**% OF PATIENTS WITH FEATURE[a]**	**WEIGHT**
Antiphospholipids	+ Anticardiolipin, anti–β_2-glycoprotein, or lupus anticoagulant (LAC)	40	2
Complements	Low C3 *or* C4	35	3
	Low C3 *and* C4	30	4
SLE-specific antibodies	Anti-dsDNA or anti-Smith antibodies	40	6

[a]Percentage of SLE patients exhibiting the criterion at any time during disease. Estimated from data provided in pertinent chapters in Wallace DJ, Hahn BH (eds): *Dubois' Lupus Erythematosus and Related Syndromes*, 9th ed. Philadelphia, Elsevier, 2019.

Abbreviations: ACR, American College of Rheumatology; ANA, antinuclear antibody; EULAR, European Union League Against Rheumatism; LN, lupus nephritis.

is recommended for every SLE patient with any clinical evidence of nephritis; results are used to plan current therapies and their duration. Patients with dangerous proliferative forms of glomerular damage (ISN III and IV) usually have microscopic hematuria and proteinuria (>500 mg per 24 h); approximately one-half develop nephrotic syndrome, and most develop hypertension. Overall, in the United States, ~20% of individuals with lupus diffuse proliferative glomerulonephritis (DPGN) die or develop ESRD within 10 years of diagnosis. Such individuals require aggressive control of SLE and of the complications of renal disease and of therapy unless damage is irreversible (Fig. 356-2, **Table 356-6**). African Americans, Hispanics, and Asians/Pacific Islanders are more likely to develop nephritis than Caucasians. African Americans are more likely to develop ESRD than are whites, even with the most current therapies. Approximately 20% of SLE patients with proteinuria (usually nephrotic) have membranous glomerular changes without proliferative changes on renal biopsy. Their outcome is better than for those with DPGN, but patients with class V and nephrotic range proteinuria should be treated in the same way as those with classes III or IV proliferative disease. Lupus nephritis is usually an ongoing disease, with flares requiring re-treatment or increased treatment over many years. For most people with lupus nephritis, accelerated atherosclerosis becomes important after several years of disease; attention must be given to control of systemic inflammation, blood pressure, hyperlipidemia, and hyperglycemia.

NERVOUS SYSTEM MANIFESTATIONS

There are many central nervous system (CNS) and peripheral nervous system manifestations of SLE; in some patients, these are the major cause of morbidity and mortality. It is useful to approach this diagnostically by asking first whether the symptoms result from SLE or another condition (such as infection in immunosuppressed individuals or side effects of therapies). If symptoms are related to SLE, it should be determined whether they are caused by a diffuse process (requiring immunosuppression) or vascular occlusive disease (requiring anticoagulation). The most common manifestation of diffuse CNS lupus is cognitive dysfunction, including difficulties with memory and reasoning. Headaches are also common. When excruciating, they often indicate SLE flare; when milder, they are difficult to distinguish from migraine or tension headaches. Seizures of any type may be caused by lupus; treatment often requires both antiseizure and immunosuppressive therapies. Psychosis can be the dominant manifestation of SLE; it must be distinguished from glucocorticoid-induced psychosis. The latter usually occurs in the first weeks of glucocorticoid therapy, at daily doses of ≥40 mg of prednisone or equivalent; psychosis resolves over several days after glucocorticoids are decreased or stopped. Myelopathy is often disabling; rapid initiation of immunosuppressive therapy including high-dose glucocorticoids is standard of care.

VASCULAR OCCLUSIONS INCLUDING STROKE AND MYOCARDIAL INFARCTIONS

The prevalence of transient ischemic attacks, strokes, and myocardial infarctions is increased in patients with SLE. These vascular events are increased in, but not exclusive to, SLE patients with antibodies to phospholipids (antiphospholipid antibodies) **(Chap. 357)**. Ischemia in the brain can be caused by focal occlusion (either noninflammatory or associated with vasculitis) or by embolization from carotid artery

Lancet published May 7, 2021. For Anifrolumab see Morand EF et al: Trial of anifrolumab in active systemic lupus erythematosus. N Eng J Med 382:211, 2020. ANA, antinuclear antibodies; CBC, complete blood count; MMF, mycophenolate mofetil; Rx, therapy; SLE, systemic lupus erythematosus.

plaque or from vegetations of Libman-Sacks endocarditis. Appropriate tests for antiphospholipid antibodies (see below) and for sources of emboli should be ordered in such patients to estimate the need for, intensity of, and duration of anti-inflammatory and/or anticoagulant therapies. When it is most likely that a cerebral event results from clotting, long-term anticoagulation is the therapy of choice. Two processes can occur at once—vasculitis plus bland vascular occlusions—in which case it is appropriate to treat with anticoagulation plus immunosuppression.

In SLE, myocardial infarctions are primarily manifestations of accelerated atherosclerosis. The increased risk for vascular events is three- to tenfold overall and is highest in women aged <49 years compared to age-matched controls. Characteristics associated with increased risk for atherosclerosis include male gender, older age, hypertension, dyslipidemia, diabetes, dysfunctional proinflammatory high-density lipoproteins, high disease activity, high glucocorticoid dose, and high serum homocysteine and leptin. Statin therapies reduce levels of low-density lipoproteins (LDL) in SLE patients; significant reduction of all-cause mortality by statins has been shown in SLE patients with renal transplants and in an epidemiologic study of a large number of patients in Taiwan.

PULMONARY MANIFESTATIONS

The most common pulmonary manifestation of SLE is pleuritis with or without pleural effusion. This manifestation, when mild, may respond to treatment with nonsteroidal anti-inflammatory drugs (NSAIDs);

TABLE 356-5 Clinical Manifestations of SLE and Prevalence over the Entire Course of Disease[a]

MANIFESTATION	PREVALENCE, %
Systemic: Fatigue, malaise, fever, anorexia, weight loss	95
Musculoskeletal	95
Arthralgias/myalgias	95
Polyarthritis	60
Hand deformities	10

Renal	30–50
Proteinuria ≥500 mg/24 h, cellular casts	30–60
Nephrotic syndrome	25
End-stage renal disease	5–10
Gastrointestinal	40
Nonspecific (nausea, mild pain, diarrhea)	30
Abnormal liver enzymes	40
Vasculitis	5
Thrombosis	15
Venous	10
Arterial	5
Ocular	15
Sicca syndrome	15
Conjunctivitis, episcleritis	10
Vasculitis	5

[a]Numbers indicate percentage of patients who have the manifestation at some time during the course of illness.

Abbreviations: ARDS, acute respiratory distress syndrome; SLE, systemic lupus erythematosus; TIA, transient ischemic attack.

when more severe, patients require a brief course of glucocorticoid therapy. Pulmonary infiltrates also occur as a manifestation of active SLE and are difficult to distinguish from infection on imaging studies. Life-threatening pulmonary manifestations include interstitial inflammation leading to fibrosis (histologic pattern mimics usual diffuse interstitial pneumonitis), shrinking lung syndrome, and intra-alveolar hemorrhage; all of these probably require early aggressive immunosuppressive therapy as well as supportive care. Pulmonary arterial hypertension occurs in a small proportion of SLE patients and should be treated in the same way as idiopathic pulmonary hypertension.

CARDIAC MANIFESTATIONS

Pericarditis is the most frequent cardiac manifestation; it usually responds to anti-inflammatory therapy and infrequently leads to tamponade. More serious cardiac manifestations are myocarditis and fibrinous endocarditis of Libman-Sacks. Myocardial inflammation can be associated with left ventricular dysfunction and heart failure. Overall, lupus patients have a 2.7-fold higher risk of developing heart failure compared with the general population. Arrhythmias are frequent. Endocardial involvement can lead to valvular insufficiencies, most commonly of the mitral or aortic valves, or to embolic events. It has not been proven that glucocorticoid or other immunosuppressive therapies lead to improvement of lupus myocarditis or endocarditis, but it is usual practice to administer a trial of high-dose steroids along with appropriate supportive therapy for heart failure, arrhythmia, or embolic events. As discussed above, patients with SLE are at increased risk for myocardial infarction, usually due to accelerated atherosclerosis, which probably results from immune attack, chronic inflammation, and/or chronic oxidative damage to arteries.

HEMATOLOGIC MANIFESTATIONS

The most frequent hematologic manifestation of SLE is anemia, usually normochromic normocytic, reflecting chronic illness and consequent impaired utilization of iron. Hemolysis can be rapid in onset and severe, requiring high-dose glucocorticoid therapy. Leukopenia is also common and almost always consists of lymphopenia, not granulocytopenia; lymphopenia rarely predisposes to infections and by itself usually does not require therapy. Thrombocytopenia may be a recurring problem. If platelet counts are >40,000/μL and abnormal bleeding is absent, therapy may not be required. High-dose glucocorticoid therapy (e.g., 1 mg/kg per day of prednisone or equivalent) is usually effective for the first few episodes of severe thrombocytopenia. Recurring or prolonged hemolytic anemia or thrombocytopenia, or disease requiring an unacceptably high dose of daily glucocorticoids, should be treated with additional strategies such as rituximab, platelet growth factors, and/or splenectomy (see "Management of Systemic Lupus Erythematosus" below).

GASTROINTESTINAL MANIFESTATIONS

Nausea, sometimes with vomiting, and diarrhea can be manifestations of an SLE flare. Diffuse abdominal pain can be caused by autoimmune peritonitis and/or intestinal vasculitis. Increases in serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are common when SLE is active. These manifestations usually improve promptly during systemic glucocorticoid therapy. Vasculitis involving the intestine can be life-threatening; perforations, ischemia, bleeding, and sepsis are frequent complications. Aggressive immunosuppressive therapy with high-dose glucocorticoids is recommended for short-term control; evidence of recurrence is an indication for additional immunosuppression.

OCULAR MANIFESTATIONS

Sicca syndrome (Sjögren's syndrome; Chap. 361) and nonspecific conjunctivitis are common in SLE and rarely threaten vision. In contrast, retinal vasculitis and optic neuritis are serious manifestations: blindness can develop over days to weeks. Aggressive immunosuppression is recommended, although there are no controlled trials to prove effectiveness. Complications of systemic and intraorbital glucocorticoid therapy include cataracts (common) and glaucoma.

TABLE 356-6 Medications for the Management of SLE

MEDICATION	DOSE RANGE	DRUG INTERACTIONS	SERIOUS OR COMMON ADVERSE EFFECTS
NSAIDs, salicylates (Ecotrin[a] and St. Joseph's aspirin[a] approved by FDA for use in SLE)	Doses toward upper limit of recommended range usually required	A2R/ACE inhibitors, glucocorticoids, fluconazole, methotrexate, thiazides	NSAIDs: Higher incidence of aseptic meningitis, elevated liver enzymes, decreased renal function, vasculitis of skin; entire class, especially COX-2-specific inhibitors, may increase risk for myocardial infarction
			Salicylates: ototoxicity, tinnitus
			Both: GI events and symptoms, allergic reactions, dermatitis, dizziness, acute renal failure, edema, hypertension
Topical glucocorticoids	Mid potency for face; mid to high potency for other areas	None known	Atrophy of skin, contact dermatitis, folliculitis, hypopigmentation, infection
Topical sunscreens	SPF 15 at least; 30+ preferred	None known	Contact dermatitis
Hydroxychloroquine[a] (quinacrine can be added or substituted)	200–400 mg qd (100 mg qd); do not exceed 5.0 mg/kg actual weight	Contraindicated use with QT-prolonging agents (e.g., donepezil, amiodarone) and with aurothioglucose. Caution with cyclosporine, cimetidine, digoxin, ampicillin, lanthanum, antacids, kaolin.	Retinal damage, agranulocytosis, aplastic anemia, ataxia, cardiomyopathy, dizziness, myopathy, ototoxicity, peripheral neuropathy, pigmentation of skin, seizures, thrombocytopenia; quinacrine usually causes diffuse yellow skin coloration
DHEA (dehydroepiandrosterone)	200 mg qd	Unclear	Acne, menstrual irregularities, high serum levels of testosterone
Methotrexate (for dermatitis, arthritis)	10–25 mg once a week, PO or SC, with folic acid; decrease dose if CrCl <60 mL/min	Acitretin, leflunomide, NSAIDs and salicylates, penicillins, probenecid, sulfonamides, trimethoprim. Caution with interventions that can suppress bone marrow or cause liver toxicity.	Anemia, bone marrow suppression, leukopenia, thrombocytopenia, hepatotoxicity, nephrotoxicity, infections, neurotoxicity, pulmonary fibrosis, pneumonitis, severe dermatitis, seizures, pseudolymphoma
Glucocorticoids, oral[a] (several specific brands are approved by FDA for use in SLE)	Prednisone, prednisolone: 0.5–1 mg/kg per day for severe SLE 0.07–0.3 mg/kg per day or qod for milder disease. Taper to 7.5 mg daily or less if possible.	A2R/ACE antagonists, antiarrhythmics class III, cyclosporine, NSAIDs and salicylates, phenothiazines, phenytoins, quinolones, rifampin, risperidone, thiazides, sulfonylureas, warfarin	Infection, VZV infection, hypertension, hyperglycemia, hypokalemia, acne, allergic reactions, anxiety, aseptic necrosis of bone, cushingoid changes, CHF, fragile skin, insomnia, menstrual irregularities, mood swings, osteoporosis, psychosis
Methylprednisolone sodium succinate, IV[a] (FDA approved for lupus nephritis)	For severe disease, 0.5–1 g IV qd × 3 days	As for oral glucocorticoids	As for oral glucocorticoids (if used repeatedly); anaphylaxis
Cyclophosphamide[b] IV	Low dose (for whites of northern European backgrounds): 500 mg every 2 weeks for 6 doses, then begin maintenance with MMF or AZA. High dose: 7–25 mg/kg every month × 6; consider mesna administration with dose	Allopurinol, bone marrow suppressants, colony-stimulating factors, doxorubicin, rituximab, succinylcholine, zidovudine	Infection, VZV infection, bone marrow suppression, leukopenia, anemia, thrombocytopenia, hemorrhagic cystitis (less with IV), carcinoma of the bladder, alopecia, nausea, diarrhea, malaise, malignancy, ovarian and testicular failure. Ovarian failure is probably not a problem with low dose.
Oral cyclophosphamide	1.5–3 mg/kg per day; decrease dose for CrCl <25 mL/min		
Mycophenolate mofetil (MMF)[b] or mycophenolic acid (MPA)	MMF: 2–3 g/d PO total given bid for induction therapy, 1–2 g/d total given bid for maintenance therapy; max 1 g bid if CrCl <25 mL/min. Begin with low dose and increase every 1–2 weeks to minimize GI side effects. Start treatment at 0.5 g bid. If used with calcineurin inhibitor, target dose of mycophenolate is 1 g bid. MPA: 360–1080 mg bid; caution if CrCl <25 mL/min	Acyclovir, antacids, azathioprine, bile acid–binding resins, ganciclovir, iron, salts, probenecid, oral contraceptives	Infection, leukopenia, anemia, thrombocytopenia, lymphoma, lymphoproliferative disorders, malignancy, alopecia, cough, diarrhea, fever, GI symptoms, headache, hypertension, hypercholesterolemia, hypokalemia, insomnia, peripheral edema, elevated liver enzymes, tremor, rash. Limited data suggest Asians should begin treatment with doses not exceeding 2 g daily to reduce adverse events.
Azathioprine (AZA)[b]	2–3 mg/kg per day PO for induction; 1–2 mg/kg per day for maintenance; decrease frequency of dose if CrCl <50 mL/min	ACE inhibitors, allopurinol, bone marrow suppressants, interferons, mycophenolate mofetil, rituximab, warfarin, zidovudine	Infection, VZV infection, bone marrow suppression, leukopenia, anemia, thrombocytopenia, pancreatitis, hepatotoxicity, malignancy, alopecia, fever, flulike illness, GI symptoms
Belimumab	10 mg/kg IV weeks 0, 2, and 4, then monthly *or* subcutaneous 200 mg each week	IVIg, live vaccines (contraindicated), tofacitinib	Infusion reactions, allergy, infections, headache and diffuse body aching
Rituximab (for patients resistant to above therapies)	375 mg/m^2 every week × 4 or 1 g every 2 weeks × 2	IVIg, live vaccines (contraindicated), infliximab, cisplatin (renal failure), tofacitinib	Infection (including PML), infusion reactions, headache, arrhythmias, allergic responses

(*Continued*)

TABLE 356-6 Medications for the Management of SLE (Continued)

MEDICATION	DOSE RANGE	DRUG INTERACTIONS	SERIOUS OR COMMON ADVERSE EFFECTS
Tacrolimus	Trough blood level should not exceed 5.5 ng/mL to minimize toxicity. Begin dose at 1 mg bid	Increases risk for QT interval prolongation (e.g., hydroxychloroquine); interferes with drugs using CYP3A pathway; caution with fluconazole, ritonavir, voriconazole, clotrimazole, metronidazole, omeprazole, fentanyl, ketoconazole, caspofungin, amiodarone. Do not ingest grapefruit or pomegranate juice while taking tacrolimus.	Infection, nephrotoxicity, neural toxicity
Voclosporin with MMF	Three 7.9 mg capsules bid, do not use if GFR <45 mL/min	Do not use with strong CYP3A4 inhibitors/inducers Do not use with cytoxan	Infection, hypertension, hyper kalemia, decrease GFR, tremor May cause fetal harm.
Anifrolumab	300 mg i.v. every 4 weeks	Do not use with other biologics Reduce dose if eGFR is less than 60 mL/min/1.73 m^2 BSA	Infection, herpes zoster, bronchitis, infusion reactions, anaphylaxis

[a]Indicates medication is approved for use in SLE by the U.S. Food and Drug Administration. [b]Indicates the medication has been used with glucocorticoids in the trials showing efficacy.

Abbreviations: A2R, angiotensin II receptor; ACE, angiotensin-converting enzyme; CHF, congestive heart failure; CrCl, creatinine clearance; FDA, U.S. Food and Drug Administration; GI, gastrointestinal; IVIg, intravenous immunoglobulin; NSAIDs, nonsteroidal anti-inflammatory drugs; PML, progressive multifocal leukoencephalopathy; SLE, systemic lupus erythematosus; SPF, sun protection factor; VZV, varicella-zoster virus.

LABORATORY TESTS

Laboratory tests serve (1) to establish or rule out the diagnosis; (2) to follow the course of disease and, in particular, to suggest that a flare is occurring or organ damage is developing; and (3) to identify adverse effects of therapies.

TESTS FOR AUTOANTIBODIES (TABLES 356-1 AND 356-3)

Diagnostically, the most important autoantibodies are ANA because the test is positive in >95% of patients, usually at the onset of symptoms. A few patients develop ANA within 1 year of symptom onset; repeated testing may thus be useful. ANA tests using immunofluorescent methods are more reliable than enzyme-linked immunosorbent assays (ELISAs) and/or bead assays, which have less specificity. ANA-negative lupus exists but is rare in adults and is usually associated with other autoantibodies (anti-Ro or anti-DNA). High-titer IgG antibodies to double-stranded DNA (dsDNA) (but not to single-stranded DNA) are specific for SLE. ELISA and immunofluorescent reactions of sera with the dsDNA in the flagellate *Crithidia luciliae* have ~60% sensitivity for SLE. Titers of anti-dsDNA vary over time. In some patients, increases in quantities of anti-dsDNA herald a flare, particularly of nephritis or vasculitis, and especially when associated with declining levels of C3 or C4 complement. Antibodies to Sm are also specific for SLE and assist in diagnosis; anti-Sm antibodies do not usually correlate with disease activity or clinical manifestations. Antiphospholipid antibodies are not specific for SLE, but their presence fulfills one classification criterion, and they identify patients at increased risk for venous or arterial clotting, thrombocytopenia, and fetal loss. There are three widely accepted tests that measure different antibodies (anticardiolipin, anti-β_2-glycoprotein, and the lupus anticoagulant). ELISA is used for anticardiolipin and anti-β_2-glycoprotein (both internationally standardized with good reproducibility); a sensitive phospholipid-based activated prothrombin time such as the dilute Russell venom viper test is used to identify the lupus anticoagulant. The higher the titers of IgG anticardiolipin (>40 IU is considered high), and the greater the number of different antiphospholipid antibodies that are detected, the greater is the risk for a clinical episode of clotting. Quantities of antiphospholipid antibodies may vary markedly over time; repeated testing is justified if clinical manifestations of the antiphospholipid syndrome (APS) appear (Chap. 357). To classify a patient as having APS, with or without SLE, by international criteria requires the presence of one or more clotting episodes and/or repeated fetal losses plus at least two positive tests for antiphospholipid antibodies, at least 12 weeks apart; however, many patients with APS do not meet these stringent criteria, which are intended for inclusion of patients into studies.

An additional autoantibody test with predictive value (not used for diagnosis) detects anti-Ro/SS-A, which indicates increased risk for neonatal lupus, sicca syndrome, and SCLE. Women with child-bearing potential and SLE should be screened for antiphospholipid antibodies and anti-Ro, because both antibodies have the potential to cause fetal harm.

Antibodies to C1q are not specific or sensitive for SLE; however, they are highly associated with active lupus nephritis and may fluctuate as the activity of nephritis changes.

STANDARD TESTS FOR DIAGNOSIS

Screening tests for complete blood count, platelet count, and urinalysis may detect abnormalities that contribute to the diagnosis and influence management decisions.

TESTS FOR FOLLOWING DISEASE COURSE

It is useful to follow tests that indicate the status of organ involvement known to be present during SLE flares. These might include urinalysis for hematuria and proteinuria, hemoglobin levels, platelet counts, and serum levels of creatinine or albumin. There is great interest in identification of additional markers of disease activity. Candidates include levels of anti-DNA and anti-C1q antibodies, several components of complement (C3 is most widely available), activated complement products (an assay is commercially available that measures binding to the C4d receptor on erythrocytes and B cells), IFN-inducible gene expression in peripheral blood cells, serum levels of BLyS (B lymphocyte stimulator, also called BAFF), and urinary levels of TNF-like weak inducer of apoptosis (TWEAK), neutrophil gelatinase-associated lipocalin (NGAL), or monocyte chemotactic protein 1 (MCP-1). None is uniformly agreed upon as a reliable indicator of flare or of response to therapeutic interventions. It is likely that a panel of multiple proteins and nuclear products (and possibly levels of selected miRNAs and methylation profiles of DNA) will be developed to predict both impending flare and response to recently instituted therapies. Increased quantities of plasma cells, and increased expression of their gene signatures in whole blood, are associated with active disease and flares, but measurements are not commercially available. For now, the physician should determine for each patient whether certain available laboratory test changes predict flare (falling complement, rising anti-DNA, increased proteinuria, worsening anemia, etc.). If so, altering therapy in response to these changes may be advisable (30 mg of prednisone daily for 2 weeks has been shown to prevent flares in patients with rising anti-DNA plus falling complement). In addition, given the increased prevalence of atherosclerosis in SLE, it is advisable to follow the recommendations of the National Cholesterol Education Program for testing and treatment, including scoring of SLE as an independent risk factor, similar to diabetes mellitus.

MANAGEMENT OF SYSTEMIC LUPUS ERYTHEMATOSUS

There is no cure for SLE, and complete sustained remissions are rare. There is an international effort to encourage practitioners and patients to aim for low-level disease activity (LLDAS), meaning mild symptoms

on the lowest possible doses of medications. LLDAS scoring uses Systemic Lupus Erythematosus Disease Activity Score-2K (SLEDAI-2K; Touma Z et al, Lupus 19:49, 2010). SLEDAI-2K is a widely used measure of SLE disease activity; scores >3 reflect clinically active disease. For example, active arthritis scores 4 points, rash 2 points, pleurisy 2 points, proteinuria 4 points, vasculitis 8 points, low complement 2 points, and leukopenia 1 point. LLDAS is defined currently as (1) a SLEDAI-2K score ≤4; (2) no new lupus disease activity compared with the previous visit; (3) physician's global assessment ≤1 (scale 0–3); (4) current prednisone dose ≤7.5 mg daily; and (5) well-tolerated stable doses of antimalarials and/or immunosuppressives. LLDAS can be achieved in 50–80% of patients and, if sustained for 2 or more years (possible in ~30%), associates with significantly less accrual of damage and better quality of life. Therefore, the physician should plan to induce improvement of acute flares and then maintain improvements with strategies that suppress symptoms to an acceptable level and prevent organ damage. Chronic prednisone doses should be tapered to the lowest doses possible (ideally ≤7.5 mg). Therapeutic choices depend on (1) whether disease manifestations are life-threatening or likely to cause organ damage, justifying aggressive therapies; (2) whether manifestations are potentially reversible; and (3) the best approaches to preventing complications of disease and its treatments. Therapies, doses, and adverse effects are listed in Table 356-6.

CONSERVATIVE THERAPIES FOR MANAGEMENT OF NON-LIFE-THREATENING DISEASE

Among patients with fatigue, pain, and autoantibodies indicative of SLE but without major organ involvement, management can be directed to suppression of symptoms. Analgesics and antimalarials are mainstays. NSAIDs are useful analgesics/anti-inflammatories, particularly for arthritis/arthralgias. However, two major issues indicate caution in using NSAIDs. First, SLE patients compared with the general population are at increased risk for NSAID-induced aseptic meningitis, elevated serum transaminases, hypertension, and renal dysfunction. Second, all NSAIDs, particularly those that inhibit cyclooxygenase-2 specifically, may increase risk for myocardial infarction. Acetaminophen to control pain may be a good strategy, but NSAIDs are more effective in some patients. The relative hazards of NSAIDs compared with low-dose glucocorticoid therapy have not been established. Antimalarials (hydroxychloroquine, chloroquine, and quinacrine) often reduce disease symptoms. Withdrawal of hydroxychloroquine results in increased numbers of disease flares. Hydroxychloroquine prolongs survival and reduces accrual of tissue damage, including renal damage. Some experts recommend a hydroxychloroquine blood level of ≥750 ng/mL to optimize responses in active SLE; after achieving response, doses should be reduced. Because of potential retinal toxicity (occurring in 6% of patients after cumulative doses of 1000 g, ~5 years of continuing therapy), patients receiving antimalarials should undergo ophthalmologic examinations annually. One clinical trial showed that administration of dehydroepiandrosterone reduced activity of mild disease. If quality of life is inadequate despite these conservative measures, treatment with low doses of systemic glucocorticoids may be necessary. Belimumab (anti-Baff) and anifrolumab (anti-IFN type 1 receptor) are biologics that are each effective for patients with persistent disease activity and fatigue despite standard therapies; SLE patients most likely to respond to belimumab have robust clinical activity (SLEDAI-2K score of ≥10), positive anti-DNA, and low serum complement. See above under "Management of Systemic Lupus Erythematosus" for more details regarding SLEDAI-2K. Lupus dermatitis should be managed with topical sunscreens, anti-malarials, topical glucocorticoids, and/or tacrolimus and, if severe or unresponsive, systemic glucocorticoids with or without mycophenolate mofetil, azathioprine, methotrexate, or belimumab. Anifrolumab has been highly effective in patients with lupus dermatitis.

LIFE-THREATENING SLE: PROLIFERATIVE FORMS OF LUPUS NEPHRITIS

Guidelines for management of lupus nephritis have been published: see Tables 356-3 and 356-6 and Figure 356-2. The mainstay of treatment for any inflammatory life-threatening or organ-threatening manifestations of SLE is systemic glucocorticoids (0.5–1 mg/kg per day PO or 500–1000 mg of methylprednisolone sodium succinate IV daily for 3 days followed by 0.5–1 mg/kg of daily prednisone or equivalent). Evidence that glucocorticoid therapy is life-saving comes from retrospective studies from the predialysis era; survival was significantly better in people with DPGN treated with high-dose daily glucocorticoids (40–60 mg of prednisone daily for 4–6 months) versus lower doses. Currently, high doses are recommended for much shorter periods; recent trials of interventions for severe SLE use 4–6 weeks of 0.5–1 mg/kg per day of prednisone or equivalent. Thereafter, doses are tapered as rapidly as the clinical situation permits, usually to a maintenance dose ≤7.5 mg of prednisone or equivalent per day. Many patients with an episode of severe SLE require many years of maintenance therapy with low-dose glucocorticoids. Frequent attempts to gradually reduce the glucocorticoid requirement are recommended because virtually everyone develops important adverse effects (Table 356-6). High-quality clinical studies regarding initiating therapy for severe, active SLE with IV pulses of high-dose glucocorticoids are not available. The use of IV pulses of glucocorticoids must be tempered by safety considerations, such as the presence of conditions adversely affected by glucocorticoids (e.g., infection, hyperglycemia, hypertension, osteoporosis). One open trial showed high response rates in patients with lupus nephritis treated with mycophenolate mofetil plus rituximab, without maintenance daily glucocorticoids; how widely this can be used is unclear.

Cytotoxic/immunosuppressive agents added to glucocorticoids are recommended to treat serious SLE. Almost all prospective controlled trials in SLE involving such agents have been conducted in combination with glucocorticoids in patients with lupus nephritis. Therefore, the following recommendations apply to treatment of nephritis. Either cyclophosphamide (an alkylating agent) or mycophenolate mofetil (a relatively lymphocyte-specific inhibitor of inosine monophosphatase and therefore of purine synthesis) is an acceptable choice for induction of improvement in severely ill patients; azathioprine (a purine analogue and cycle-specific antimetabolite) may be effective but is associated with more flares. In patients whose renal biopsies show ISN grade III or IV disease, early treatment with combinations of glucocorticoids and cyclophosphamide reduces progression to ESRD and death. Shorter-term studies with glucocorticoids plus mycophenolate mofetil (prospective randomized trials of 6 months, follow-up studies of 5 years) show that this regimen is similar to cyclophosphamide in achieving improvement. Comparisons are complicated by effects of race, since higher proportions of African Americans and Latin Americans respond to mycophenolate than to cyclophosphamide, whereas similar proportions of whites and Asians respond to each drug. Regarding toxicity, diarrhea is more common with mycophenolate mofetil; amenorrhea, leukopenia, and nausea are more common with high-dose cyclophosphamide. Importantly, rates of severe infections and death are similar in meta-analyses. Two different regimens of IV cyclophosphamide are available for induction therapy. For white patients with northern European backgrounds, low doses of cyclophosphamide (500 mg every 2 weeks for six total doses, followed by daily azathioprine or mycophenolate maintenance) are as effective as standard high doses, with less toxicity. Ten-year follow-up has shown no differences between the high-dose and low-dose groups (death or ESRD in 9–20% of patients in each group). It is not clear whether the data apply to U.S. populations, especially African Americans and Latinas. In general, it may be better to induce improvement in African-American or Hispanic patients with proliferative glomerulonephritis with mycophenolate mofetil (2–3 g daily) rather than cyclophosphamide, with the option to switch if no evidence of response is detectable after 2–6 months of treatment. For whites and Asians, induction with either mycophenolate mofetil or cyclophosphamide is acceptable. The presence of cellular or fibrotic crescents in glomeruli with proliferative glomerulonephritis, or rapidly progressive glomerulonephritis, indicates more severe disease and a worse prognosis. High-dose cyclophosphamide (500–1000 mg/m^2 body surface area given monthly IV for 6 months, followed by azathioprine or mycophenolate maintenance) is an acceptable approach for patients with severe nephritis. Cyclophosphamide and mycophenolate

responses begin 3–16 weeks after treatment is initiated, whereas glucocorticoid responses may begin within 24 h. The incidence of ovarian failure, a common effect of high-dose cyclophosphamide therapy (but probably not of low-dose therapy), can be reduced by treatment with a gonadotropin-releasing hormone agonist (e.g., leuprolide 3.75 mg intramuscularly) prior to each monthly cyclophosphamide dose. Recent studies have shown improved short-term responses with a combination of calcineurin inhibitors (tacrolimus, voclosporin) plus mycophenolate (MMF) plus glucocorticoids (GC) compared with MMF or cyclophosphamide with GC. Complete renal responses occurred in 41% on triple therapy at 52 weeks compared with 21% on double therapy. Including partial with complete renal responses, 70% on triple vs 50% on double therapy improved by 24 weeks. Calcineurin inhibitors are nephrotoxic; they should probably be discontinued after 6 months if no signs of improvement occur and used for no more than 12 months in most patients.

For maintenance therapy, mycophenolate and azathioprine probably are similar in efficacy and toxicity; both are safer than cyclophosphamide. In a multicenter international study, mycophenolate was superior to azathioprine in maintaining renal function and survival in patients who responded to induction therapy with either cyclophosphamide or mycophenolate. Patients with high serum creatinine levels (e.g., ≥265 μmol/L [≥3.0 mg/dL]) many months in duration and high chronicity scores on renal biopsy are not likely to respond to any of these therapies. The number of SLE flares is reduced by maintenance therapy with mycophenolate mofetil (1.5–2 g daily) or azathioprine (1–2.5 mg/kg per day). Mycophenolate, cyclophosphamide, methotrexate, and calcineurin inhibitors can cause fetal harm; patients should be off any of these for at least 3 months before attempting to conceive. Azathioprine can be used if necessary to control active SLE in patients who are pregnant. Patients treated with azathioprine may be prescreened for homozygous deficiency of the TMPT enzyme (which is required to metabolize the 6-mercaptopurine product of azathioprine) because they are at higher risk for bone marrow suppression.

Most SLE patients with membranous (INS class V) nephritis also have proliferative changes and should be treated for proliferative disease. However, some have pure membranous changes. Treatment for this group is less well defined. Some authorities do not recommend immunosuppression unless proteinuria is in the nephrotic range (although treatment with angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers is recommended). Prospective controlled trials suggest that alternate-day glucocorticoids plus cyclophosphamide or mycophenolate mofetil or cyclosporine or tacrolimus are all effective in the majority of patients in reducing proteinuria. It is more controversial whether any of these treatments preserve renal function over the long term.

Good improvement occurs in approximately 60% of lupus nephritis patients receiving either cyclophosphamide or mycophenolate at 1–2 years of follow-up. Addition of a calcineurin inhibitor improves response rates (70-80% in triple therapy vs 40-60% in double therapy) and increases time to flare. However, at least 50% of these individuals have flares of nephritis over the next 5 years, and re-treatment is required; such individuals are more likely to progress to ESRD. Long-term outcome of lupus nephritis to most interventions is better in whites than in African Americans. Small controlled trials (in Asia) of leflunomide, a relatively lymphocyte-specific pyrimidine antagonist licensed for use in rheumatoid arthritis, have suggested it can suppress disease activity in some SLE patients. Methotrexate (a folinic acid antagonist) may have a role in the treatment of arthritis and dermatitis but probably not in nephritis or other life-threatening disease. Most patients with SLE of any type should be treated with hydroxychloroquine since it prolongs survival and reduces overall damage. Patients with proteinuria >500 mg daily should receive angiotensin-converting enzyme inhibitors or angiotensin receptor blockers as they reduce the chance for ESRD.

Use of biologics directed against B cells for active SLE is under intense study. Anti-CD20 (rituximab), particularly in patients with SLE who are resistant to the more standard combination therapies discussed above, is widely used. Several open trials have shown efficacy in a majority of such patients, both for nephritis and for extrarenal lupus. However, prospective placebo-controlled randomized trials, one in renal and one in nonrenal SLE, did not show a difference between anti-CD20 and placebo when added to standard combination therapies. A monoclonal antibody anti-CD20 that depletes tissue B cells better than rituximab (obinutuzumab) has received fast track approval by the U.S. Food and Drug Administration (FDA) for potential approval in SLE, but data from phase 3 clinical trials have not yet been published. Belimumab was recently approved for treatment of lupus nephritis in the USA: when given along with mycophenolate plus glucocorticoids for two years it reduces renal damage significantly. Rituximab in combination with or followed by belimumab is also being studied in lupus nephritis. A fusion protein (telitacicept) that inactivates both BAFF and APRIL growth factors for B cells has been approved for fast-track review by the FDA; phase 3 clinical trials in SLE have not yet been reported.

SPECIAL CONDITIONS IN SLE THAT MAY REQUIRE ADDITIONAL OR DIFFERENT THERAPIES

Pregnancy and Lupus Fertility rates for men and women with SLE are probably normal. However, rate of fetal loss is increased (approximately two- to threefold) in women with SLE. Fetal demise is higher in mothers with high disease activity, antiphospholipid antibodies (especially the lupus anticoagulant), hypertension, and/or active nephritis. Suppression of disease activity can be achieved by administration of systemic glucocorticoids. A placental enzyme, 11-β-dehydrogenase 2, deactivates glucocorticoids; it is more effective in deactivating prednisone and prednisolone than the fluorinated glucocorticoids dexamethasone and betamethasone (fluorinated steroids should be avoided in pregnant patients). Adverse effects of prenatal glucocorticoid exposure (primarily the fluorinated steroid betamethasone) on offspring may include low birth weight, developmental abnormalities in the CNS, and predilection toward adult metabolic syndrome. Glucocorticoids are listed by the FDA as "fetal risk cannot be ruled out." Also in that category are hydroxychloroquine, belimumab, cyclosporine, in the "may cause fetal harm" category are rituximab, azathioprine, cyclophosphamide, tacrolimus, and voclosporin. In the "fetal risk has been demonstrated" or "avoid in pregnancy" are methotrexate and mycophenolate. Therefore, active SLE in pregnant women should be controlled with hydroxychloroquine and, if necessary, prednisone/prednisolone at the lowest effective doses for the shortest time required. Azathioprine may be added if these treatments do not suppress disease activity. It is likely that each of these glucocorticoids and immunosuppressive medications gets into breast milk, at least in low levels; patients should consider not breastfeeding if they need therapy for SLE. In SLE patients with antiphospholipid antibodies and prior fetal losses, treatment with heparin (usually low-molecular-weight) plus low-dose aspirin has been shown in prospective controlled trials to increase significantly the proportion of live births. Aspirin alone may be used, although most consider it less effective than heparin-plus-aspirin. Warfarin is teratogenic. Direct oral anticoagulants are usually avoided in pregnancy because safety and efficacy have not been established in pregnancy or APS. An additional potential problem for the fetus is the presence of antibodies to Ro, sometimes associated with neonatal lupus consisting of rash and/or congenital heart block with or without cardiomyopathy. The cardiac manifestations can be life-threatening; therefore, the presence of anti-Ro requires vigilant monitoring of fetal heart rates with prompt intervention (delivery if possible) if distress occurs. Hydroxychloroquine treatment of an anti-Ro-positive mother whose prior infant developed congenital heart block significantly reduces the chance that subsequent fetuses will develop heart block. Dexamethasone treatment of a mother in whom fetal first- or second-degree heart block is detected in utero sometimes prevents progression of heart block. Women with SLE usually tolerate pregnancy without disease flares. However, a small proportion develops severe flares requiring aggressive glucocorticoid therapy or early delivery.

Lupus and Antiphospholipid Syndrome Patients with SLE who have venous or arterial clotting and/or repeated fetal losses and at

least two positive tests for antiphospholipid antibodies have APS and should be managed with long-term anticoagulation (Chap. 357). With warfarin, a target international normalized ratio (INR) of 2.0–2.5 is recommended for patients with one episode of venous clotting; an INR of 3.0–3.5 is recommended for patients with recurring clots or arterial clotting, particularly in the CNS. Recommendations are based on both retrospective and prospective studies of posttreatment clotting events and adverse effects from anticoagulation. Direct oral anticoagulants are not effective and not recommended in APS.

Microvascular Thrombotic Crisis (Thrombotic Thrombocytopenic Purpura, Hemolytic-Uremic Syndrome) This syndrome of hemolysis, thrombocytopenia, and microvascular thrombosis in kidneys, brain, and other tissues carries a high mortality rate and occurs most commonly in young individuals with lupus nephritis. The most useful laboratory tests are identification of schistocytes on peripheral blood smears, elevated serum levels of lactate dehydrogenase, and low levels of ADAMS13 activity". Plasma exchange or extensive plasmapheresis is usually life-saving; most authorities recommend concomitant glucocorticoid therapy; there is no evidence that cytotoxic drugs are effective. Rituximab and eculizumab (an inhibitor of C5) have been used in refractory cases.

Lupus Dermatitis Patients with any form of lupus dermatitis should minimize exposure to ultraviolet light, using appropriate clothing and sunscreens with a sun protection factor of at least 30. Topical glucocorticoids and antimalarials (such as hydroxychloroquine) are effective in reducing lesion severity in most patients and are relatively safe. Methotrexate, azathioprine, mycophenolate, belimumab and anifrolumab each may be effective in some patients who need additional treatment. Systemic treatment with retinoic acid is a useful strategy in patients with inadequate improvement after these interventions on adverse effects are potentially severe (particularly fetal abnormalities), and there are stringent reporting requirements for its use in the United States. Extensive, pruritic, bullous, or ulcerating dermatitides usually improve promptly after institution of systemic glucocorticoids; tapering may be accompanied by flare of lesions, thus necessitating use of a second medication such as hydroxychloroquine, retinoids, or belimumab. Cytotoxic medications such as methotrexate, azathioprine, or mycophenolate mofetil may also be effective. In therapy-resistant lupus dermatitis there are reports of success with topical tacrolimus (caution must be exerted because of the possible increased risk for malignancies) or with systemic dapsone or thalidomide or the related lenalidomide (the extreme danger of fetal deformities from thalidomide requires permission from and supervision by the supplier; peripheral neuropathy is also common).

PREVENTIVE THERAPIES

Prevention of complications of SLE and its therapy include providing appropriate vaccinations (the administration of influenza and pneumococcal vaccines has been studied in patients with SLE; flare rates are similar to those receiving placebo) and suppressing recurrent urinary tract infections. In patients receiving glucocorticoids, the higher the daily dose, the lower is the immune response to vaccination; however, the great majority of patients achieve protective levels. Vaccination with attenuated live viruses is generally discouraged in patients who are immunosuppressed; however, a recent study of vaccination of a small number of SLE patient with Zostavax showed safety and efficacy. The availability of Shingrix (which does not contain live virus) should replace Zostavax. Patients receiving ≥20 mg of prednisone daily may be protected from pneumocystis infections with trimethoprim-sulfamethoxazole (Bactrim) or atovaquone (we prefer the latter because SLE patients are predisposed to allergic reactions to sulfa-containing medications) and from recurrent herpes simplex infections with acyclovir, with preventives withdrawn when the prednisone dose is decreased. Strategies to prevent osteoporosis should be initiated in most patients likely to require long-term glucocorticoid therapy and/or with other predisposing factors. Postmenopausal women can be partially protected from steroid-induced osteoporosis with calcium supplementation, vitamin D, and either bisphosphonates or denosumab. Safety of long-term use of these strategies in premenopausal women is not well established. Control of hypertension and appropriate prevention strategies for atherosclerosis, including monitoring and treatment of dyslipidemias, management of hyperglycemia, and management of obesity, are recommended. Statin therapies reduce all-cause deaths in SLE patients and should be considered in patients with elevated LDL or total cholesterol levels. Finally, the physician must keep in mind that some cancers are increased in SLE patients including non-Hodgkin lymphomas and cancers of thyroid, lung, liver, and vulvar/vaginal tissues.

EXPERIMENTAL THERAPIES

Studies of highly targeted experimental therapies for SLE are in progress. They include (1) depletion of B cells with obinituzumab; (2) inhibition of B cells by blocking more than one receptor for BAFF (telacicept); (3) elimination of plasma cells; (4) B-cell inhibition through inhibition of BTK, anti-CD20 therapies more depleting than rituximab, or a fusion protein that inhibits both BAFF and APRIL B-cell growth factors; (5) inhibition of B-/T-cell second signal coactivation with CTLA-Ig or anti-CD40L; (6) inhibition of innate immune activation via TLR7 or TLR7 and TLR9; (7) induction of regulatory T cells with peptides from immunoglobulins or autoantigens or with low doses of IL-2; (8) inhibition of T effector cells through CD6; (9) targeting lymphocyte migration by modulation of the S1P1 receptor; and (10) inhibition of lymphocyte activation by blockade of Jak/Stat.

A few studies have used vigorous untargeted immunosuppression with high-dose cyclophosphamide plus anti-T-cell strategies, with rescue by transplantation of autologous hematopoietic stem cells for the treatment of severe and refractory SLE. One U.S. report showed an estimated mortality rate over 5 years of 15% and sustained remission in 50%. Mesenchymal stem cell transplant studies are also underway in lupus. It is hoped that in the next edition of this text, we will be able to recommend more effective and less toxic approaches to treatment of SLE based on some of these strategies.

PATIENT OUTCOMES, PROGNOSIS, AND SURVIVAL

Survival in patients with SLE in the United States, Canada, Europe, and China is ~95% at 5 years, 90% at 10 years, and 78% at 20 years. In the United States, African Americans and Hispanic Americans with a mestizo heritage have a worse prognosis than whites, whereas Africans in Africa and Hispanic Americans with a Puerto Rican origin do not. The relative importance of gene mixtures and environmental differences accounting for ethnic differences is not known. Poor prognosis (~50% mortality in 10 years) in most series is associated with (at the time of diagnosis) high serum creatinine levels (>124 μmol/L [>1.4 mg/dL]), hypertension, nephrotic syndrome (24-h urine protein excretion >2.6 g), anemia (hemoglobin <124 g/L [<12.4 g/dL]), hypoalbuminemia, hypocomplementemia, antiphospholipid antibodies, male sex, ethnicity (African American, Hispanic with mestizo heritage), and low socioeconomic status. Data regarding outcomes in SLE patients with renal transplants show mixed results: some series show a twofold increase in graft rejection compared to patients with other causes of ESRD, whereas others show no differences. Overall patient survival is comparable (85% at 2 years). Lupus nephritis occurs in ~5% of transplanted kidneys. Disability in patients with SLE is common due primarily to chronic fatigue, arthritis, and pain, as well as renal disease. As many as 30–50% of patients may achieve low disease activity (defined as mild activity on hydroxychloroquine with or without low-dose glucocorticoids); <10% experience remissions (defined as no disease activity on no medications). The leading causes of death in the first decade of disease are systemic disease activity, renal failure, and infections; subsequently, thromboembolic events become increasingly frequent causes of mortality.

DRUG-INDUCED LUPUS

This is a syndrome of positive ANA associated with symptoms such as fever, malaise, arthritis or intense arthralgias/myalgias, serositis, and/or rash. The syndrome appears during therapy with certain medications and biologic agents, is predominant in whites, has less female predilection than SLE, rarely involves kidneys or brain, is rarely associated

with anti-dsDNA, is commonly associated with antibodies to histones, and usually resolves over several weeks after discontinuation of the offending medication. The list of substances that can induce lupus-like disease is long. Among the most frequent are the antiarrhythmics procainamide, disopyramide, and propafenone; the antihypertensive hydralazine; several angiotensin-converting enzyme inhibitors and beta blockers; the antithyroid propylthiouracil; the antipsychotics chlorpromazine and lithium; the anticonvulsants carbamazepine and phenytoin; the antibiotics isoniazid, minocycline, and nitrofurantoin (Macrodantin); the antirheumatic sulfasalazine; the diuretic hydrochlorothiazide; and the antihyperlipidemics lovastatin and simvastatin. Biologics that can cause drug-induced lupus (DIL) include inhibitors of IFNs and TNF. In DIL, ANA usually appears before symptoms; however, many of the medications mentioned above induce ANA in patients who never develop symptoms of drug-induced lupus. It is appropriate to test for ANA at the first hint of relevant symptoms and to use test results to help decide whether to withdraw the suspect agent.

357 Antiphospholipid Syndrome

Haralampos M. Moutsopoulos, Clio P. Mavragani

DEFINITIONS

Antiphospholipid syndrome (APS) is an autoantibody-mediated acquired thrombophilia characterized by recurrent arterial or venous thrombosis and/or pregnancy morbidity. It affects primarily females. APS may occur alone (primary) or in association with other autoimmune diseases, mainly systemic lupus erythematosus (SLE) (secondary). Catastrophic APS (CAPS) is a life-threatening rapidly progressive thromboembolic disease involving simultaneously three or more organs.

The major autoantibodies detected in patients' sera are directed against negatively charged phospholipids (PLs) and/or PL-binding plasma proteins such as β_2-glycoprotein I (β_2GPI) and prothrombin.

TABLE 357-1 Classification and Nomenclature of Antiphospholipid Antibodies

NAME	ASSAY FOR THEIR DETECTION	COMMENTS
Antibodies against cardiolipin (aCL)	Enzyme-linked immunosorbent assay (ELISA) using as antigen cardiolipin (CL), a negatively charged phospholipid	aCL from patients with APS recognize β_2GPI existing in the human serum as well as in bovine serum, which is used to block the nonspecific binding sites on the ELISA plate. CL simply stabilizes β_2GPI at high concentration on the polystyrene surface.
Antibodies against β_2GPI (anti-β_2GPI)	ELISA using as antigen affinity purified or recombinant β_2GPI in the absence of PL	Antibodies recognize β_2GPI bound in the absence of CL to an oxidized polystyrene surface, where oxygen atoms in the moieties C–O or C=O were introduced by γ-irradiation.
Lupus anticoagulant (LA)	Activated partial thromboplastin time (aPTT) Kaolin clotting time (KCT) Dilute Russel viper venom test (DRVVT)	Antibodies recognize β_2GPI or prothrombin (PT) and elongate aPTT, implying that they interfere with the generation of thrombin by prothrombin. Prolongation of the clotting times is an in vitro phenomenon, and LA induces thromboses in vivo.

Abbreviations: APL, antiphospholipid syndrome; β_2GPI, β_2-glycoprotein I; PL, phospholipid.

PLs are components of the cytoplasmic membrane of all living cells. The antibodies are directed against PLs, such as cardiolipin, phosphocholine, and phosphatidylserine. The plasma protein β_2GPI is a 43-kDa plasma apolipoprotein, which consists of 326 amino acids arranged in five domains (I through V). Domain V forms a positively charged patch, suitable to interact with negatively charged PLs. In plasma, β_2GPI has a circular conformation with domain V binding to and concealing the B-cell epitopes lying on domain I. The presence of anti–domain I IgG antibodies has been recently associated with increased thrombotic risk. Another group of antibodies termed *lupus anticoagulant* (LA) prolongs clotting times in vitro, which are not corrected by adding normal plasma **(Table 357-1)**. Patients with APS often possess antibodies recognizing *Treponema pallidum* PL/cholesterol complexes, detected by Venereal Disease Research Laboratory (VDRL) tests and characterized as biologic false-positive serologic tests for syphilis (BFP-STS). Since patients can present with features highly reminiscent of APS in the absence of classical anti-PL antibodies, the term *seronegative APS* has been coined. In patients with strong suspicion of seronegative APS, testing for antiphosphatidylserine/prothrombin antibodies may have a valuable diagnostic role.

EPIDEMIOLOGY

The incidence of APS is estimated to be ~5 cases per 100,000 persons per year. The prevalence of APS in the general population is estimated to be 40–50 per 100,000. Anti-PL antibodies occur in 1–5% of the general population. Their prevalence increases with age; however, it is questionable whether they are able to induce thrombotic events in elderly individuals. Moreover, although one-third of patients with SLE and other autoimmune diseases **(Chap. 356)** possess these antibodies, only 5–10% of them develop APS.

PATHOGENESIS

The initiating events for the induction of antibodies to PL-binding proteins seem to be infections, oxidative stress, and major physical stresses such as surgery or trauma in an appropriate genetic background, given the previously demonstrated associations with alleles within the HLA locus. These contributors seem to induce increased apoptosis of the vessel endothelial cells and subsequent exposure of PLs. The latter, bound with serum proteins such as β_2GPI or prothrombin, lead to neoantigen formation, which in turn triggers the induction of anti-PLs. The binding of anti-PLs to the disrupted endothelial cells leads to initiation of intravascular coagulation and thrombus formation. Complement

and neutrophil activation and, recently, an imbalance between type I and III interferons have been proposed as potential mechanisms of thrombotic events and APS-related obstetric complications.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

Clinical manifestations represent the consequences of venous or arterial thrombosis and/or pregnancy morbidity (Table 357-2). Venous thrombosis, superficial or deep, occurs primarily in the lower extremities, often leading to pulmonary emboli. Thrombosis of the pulmonary arteries leads to pulmonary hypertension, and thrombosis of the inferior vena cava to Budd-Chiari syndrome. Cerebral venous thrombosis presents with signs and symptoms of intracranial hypertension and retinal vein thrombosis. Arterial thrombosis affects more commonly the arteries of the brain and is manifested as migraines, cognitive dysfunction, transient ischemic attacks, stroke, and retinal artery occlusion. Arterial thrombosis of the extremities presents with ischemic leg ulcers, digital gangrene, and avascular bone necrosis, whereas thrombosis of other arteries leads to myocardial infarction, renal artery stenosis, glomerular lesions, and infarcts of spleen, pancreas, and adrenals.

Livedo reticularis consists of a mottled reticular vascular pattern that appears as a lace-like, purplish discoloration of the skin. It is probably caused by swelling of the venules due to obstruction of capillaries by thrombi. This clinical manifestation usually occurs together with vascular lesions in the central nervous system and with aseptic bone necrosis. Libman-Sacks endocarditis consists of very small vegetations, histologically characterized by organized platelet-fibrin microthrombi surrounded by growing fibroblasts and macrophages. Glomerular involvement is manifested with hypertension, mildly elevated serum creatinine levels, and proteinuria/hematuria. Histologically, in an acute phase, thrombotic microangiopathy is present in the glomerular capillaries. In a chronic phase, fibrous intima hyperplasia, fibrous and/or fibrocellular arteriolar occlusions, and focal cortical atrophy are present (Table 357-2). Pregnancy morbidity manifests with increased risk of recurrent miscarriages, intrauterine growth retardation, preeclampsia, eclampsia, and preterm birth. The major causes of these complications are due to infarctions of the placenta.

Premature atherosclerosis has been also recognized as a feature of APS. Musculoskeletal manifestations include, in addition to bone necrosis, arthralgia/arthritis, bone marrow necrosis, muscle infarction, nontraumatic fractures, and osteoporosis. Coombs-positive hemolytic anemia and thrombocytopenia are laboratory findings associated with APS.

TABLE 357-2 Clinical Features of Antiphospholipid Syndrome

MANIFESTATION	%
Venous Thrombosis and Related Consequences	
Deep-vein thrombosis	39
Livedo reticularis	24
Pulmonary embolism	14
Superficial thrombophlebitis	12
Thrombosis in various other sites	11
Arterial Thrombosis and Related Consequences	
Stroke	20
Cardiac valve thickening/dysfunction and/or Libman-Sacks vegetations	14
Transient ischemic attack	11
Myocardial ischemia (infarction or angina) and coronary bypass graft thrombosis	10
Leg ulcers and/or digital gangrene	9
Arterial thrombosis in the extremities	7
Retinal artery thrombosis/amaurosis fugax	7
Ischemia of visceral organs or avascular necrosis of bone	6
Multi-infarct dementia	3
Neurologic Manifestations of Uncertain Etiology	
Migraine	20
Epilepsy	7
Chorea	1
Cerebellar ataxia	1
Transverse myelopathy	0.5
Renal Manifestations Due to Various Reasons (Renal Artery/Renal Vein/Glomerular Thrombosis, Fibrous Intima Hyperplasia)	**3**
Musculoskeletal Manifestations	
Arthralgias	39
Arthritis	27
Obstetric Manifestations (Referred to the Number of Pregnancies)	
Preeclampsia	10
Eclampsia	4
Fetal Manifestations (Referred to the Number of Pregnancies)	
Early fetal loss (<10 weeks)	35
Late fetal loss (≥10 weeks)	17
Premature birth among the live births	11
Hematologic Manifestations	
Thrombocytopenia	30
Autoimmune hemolytic anemia	10

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of APS should be seriously considered in cases of thrombosis, cerebral vascular accidents in individuals <55 years of age, or pregnancy morbidity in the presence of livedo reticularis or thrombocytopenia. In these cases, anti-PL antibodies should be measured. The presence of at least one clinical and one laboratory criterion is compatible with the diagnosis, in the absence of other thrombophilia causes. Clinical criteria include (1) vascular thrombosis, defined as one or more clinical episodes of arterial, venous, or small vessel thrombosis in any tissue or organ; and (2) pregnancy morbidity, defined as (a) one or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation; (b) one or more premature births of a morphologically normal neonate before the 34th week of gestation because of eclampsia, severe preeclampsia, or placental insufficiency; or (c) three or more unexplained consecutive spontaneous abortions before the 10th week of gestation. Laboratory criteria include (1) LA, (2) anticardiolipin (aCL), and/or (3) anti-β_2GPI antibodies, at intermediate or high titers on two occasions 12 weeks apart.

Differential diagnosis is based on the exclusion of other inherited or acquired causes of thrombophilia (Chap. 116), Coombs-positive hemolytic anemia (Chap. 100), and thrombocytopenia (Chap. 115). Livedo reticularis with or without a painful ulceration on the lower extremities may be also a manifestation of disorders affecting (1) the vascular wall, such as atherosclerosis, polyarteritis nodosa, SLE, cryoglobulinemia, and lymphomas; or (2) the vascular lumen, such as myeloproliferative disorders, hypercholesterolemia, or other causes of thrombophilia.

TREATMENT

Antiphospholipid Syndrome

It has been increasingly appreciated that the risk of thrombotic and obstetric events is closely related to the underlying anti-PL profile. The latter depends on the type of autoantibodies (IgG high risk vs IgM low risk), the number of anti-PL antibodies (simultaneous presence of two or three classical autoantibodies denotes a higher risk profile vs a single antibody), their titer (moderate-high titer vs low), and the persistence of anti-PL positivity in repeated measurements.

Following the first thrombotic event, APS patients should be placed on vitamin K antagonists (VKAs) for life, aiming to achieve

an international normalized ratio (INR) ranging from 2.0 to 3.0 in case of an unprovoked venous thrombosis. For patients with arterial thrombosis, the corresponding INR target should be 3.0–4.0 or 2.0–3.0 along with low-dose aspirin (LDA, 75–100 mg daily), depending on the thrombotic/hemorrhagic patient profile. Administration of direct oral thrombin inhibitors recently has been shown to increase the risk of arterial events, especially in patients with triple positivity or previous arterial thrombosis. However, they could be considered with extreme caution in cases in which contraindications to VKAs or inability to achieve a target INR despite adherence to the treatment are present. In pregnant women with a history of obstetric APS, combination treatment with LDA and prophylactic dose of low-molecular-weight heparin (LMWH) is recommended, whereas in cases of thrombotic APS, LDA plus therapeutic LMWH dose should be administered. When recurrent obstetric complications occur despite standard treatment, increasing the LMWH dose (from prophylactic to therapeutic) or administering oral hydroxychloroquine 400 mg/d or IV immunoglobulin (IVIg) 400 mg/kg every day for 5 days are alternative options.

For asymptomatic individuals or SLE patients with a high-risk anti-PL profile and no evidence of a previous thrombotic event or pregnancy morbidity, prophylactic treatment with LDA is recommended. In nonpregnant women with a history of APS-related obstetric complications, independently of the presence of underlying SLE diagnosis, treatment with LDA seems to reduce the risk of a subsequent thrombotic event.

Patients with CAPS should be treated with combination therapy with glucocorticoids, heparin, and plasma exchange or IVIG together with appropriate management of triggering events such as infections. For refractory CAPS, B-cell depletion (e.g., with rituximab) or complement inhibition (e.g., with eculizumab) therapies are alternative options.

358 Rheumatoid Arthritis

Ankoor Shah, E. William St. Clair

INTRODUCTION

Rheumatoid arthritis (RA) is a chronic inflammatory disease of unknown etiology characterized by a symmetric polyarthritis and is the most common form of chronic inflammatory arthritis. Since persistently active RA often results in articular cartilage and bone destruction and functional disability, it is vital to diagnose and treat this disease early and aggressively before damage ensues. RA, a systemic disease, may also lead to a variety of extraarticular manifestations, including fatigue, subcutaneous nodules, lung involvement, pericarditis, peripheral neuropathy, vasculitis, and hematologic abnormalities, which must be managed accordingly.

Insights gained by a wealth of basic and clinical research over the past two decades have revolutionized the contemporary paradigms for the diagnosis and management of RA. Testing for serum antibodies to anti-citrullinated protein antibodies (ACPA) and rheumatoid factor continues to be valuable in the diagnostic evaluation of patients with suspected RA, and these antibodies serve as biomarkers of prognostic significance. Advances in imaging modalities assist clinical decision-making by improving the detection of joint inflammation and monitoring the progression of damage. The science of RA has taken major leaps forward by illuminating new disease-related genes, environmental interactions, and the molecular components and pathways of disease pathogenesis in even more detail. The relative contribution of these cellular and inflammatory mediators in disease pathogenesis has been further brought to light by the observed benefits of an expanded pipeline of biologic and targeted synthetic disease-modifying therapies. Despite this progress, incomplete understanding of the initiating events of RA and the factors perpetuating the chronic inflammatory response remains a barrier to its cure and prevention.

The past 20 years have witnessed a remarkable improvement in the outcomes of RA. The crippling arthritis of years past is encountered much less frequently today. Much of this progress can be traced to the expanded therapeutic armamentarium and the adoption of early treatment intervention. The shift in treatment strategy dictates a new mindset for primary care practitioners—namely, one that demands early referral of patients with inflammatory arthritis to a rheumatologist for prompt diagnosis and initiation of therapy. Only then will patients achieve their best outcomes.

CLINICAL FEATURES

The incidence of RA increases between 25 and 55 years of age, after which it plateaus until the age of 75 and then decreases. The presenting symptoms of RA typically result from inflammation of the joints, tendons, and bursae. Patients often complain of early morning joint stiffness lasting >1 hour that eases with physical activity. The earliest involved joints are typically the small joints of the hands and feet. The initial pattern of joint involvement may be monoarticular, oligoarticular (≤4 joints), or polyarticular (>5 joints), usually in a symmetric distribution. Some patients with inflammatory arthritis will present with too few affected joints to be classified as having RA—so-called undifferentiated inflammatory arthritis. Those with an undifferentiated arthritis who are most likely to be diagnosed later with RA have a higher number of tender and swollen joints, test positive for serum rheumatoid factor (RF) or ACPA, and have higher scores for physical disability.

Once the disease process of RA is established, the wrists and metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints stand out as the most frequently involved joints **(Fig. 358-1)**. Distal

FIGURE 358-1 Metacarpophalangeal joint swelling and subluxation. *(RP Usatine, MA Smith, EJ Mayeaux: The Color Atlas and Synopsis of Family Medicine, 3rd ed. New York, McGraw Hill, 2019; Fig. 97.5.)*

interphalangeal (DIP) joint involvement may occur in RA, but it usually is a manifestation of coexistent osteoarthritis. Flexor tendon tenosynovitis is a frequent hallmark of RA and leads to decreased range of motion, reduced grip strength, and "trigger" fingers. Flexor tendon involvement may also lead to tendon rupture, with the flexor pollicis longest the most common flexor tendon to be affected by RA. Progressive destruction of the joints and soft tissues may lead to chronic, irreversible deformities. Ulnar deviation results from subluxation of the MCP joints, with subluxation, or partial dislocation, of the proximal phalanx to the volar side of the hand. Hyperextension of the PIP joint with flexion of the DIP joint ("swan-neck deformity"), flexion of the PIP joint with hyperextension of the DIP joint ("boutonnière deformity"), and subluxation of the first MCP joint with hyperextension of the first interphalangeal (IP) joint ("Z-line deformity") also may result from damage to the tendons, joint capsule, and other soft tissues in these small joints. Inflammation about the ulnar styloid and tenosynovitis of the extensor carpi ulnaris may cause subluxation of the distal ulna, resulting in a "piano-key movement" of the ulnar styloid. Although metatarsophalangeal (MTP) joint involvement in the feet is an early feature of disease, chronic inflammation of the ankle and midtarsal regions usually comes later and may lead to pes planovalgus ("flat feet"). Large joints, including the knees and shoulders, are often affected in established disease, although these joints may remain asymptomatic for many years after onset.

Atlantoaxial involvement of the cervical spine is clinically noteworthy because of its potential to cause compressive myelopathy and neurologic dysfunction. Neurologic manifestations are rarely a presenting sign or symptom of atlantoaxial disease, but they may evolve over time with progressive instability of C1 on C2. The prevalence of atlantoaxial subluxation has been declining in recent years and occurs now in <10% of patients. Unlike the spondyloarthritides **(Chap. 362)**, RA rarely affects the thoracic and lumbar spine.

Extraarticular manifestations may develop during the clinical course of RA in up to 40% of patients, even prior to the onset of arthritis **(Fig. 358-2)**. Patients most likely to develop extraarticular disease have a history of cigarette smoking, have early onset of significant physical disability, and test positive for serum RF or ACPA. Subcutaneous nodules, secondary Sjögren's syndrome, interstitial lung disease (ILD), pulmonary nodules, and anemia are among the most frequently observed extraarticular manifestations. Recent studies have shown a decrease in the incidence and severity of at least some extraarticular manifestations, particularly Felty's syndrome and vasculitis.

The most common systemic and extraarticular features of RA are described in more detail in the sections below.

CONSTITUTIONAL

These signs and symptoms include weight loss, fever, fatigue, malaise, depression, and in the most severe cases, cachexia; they generally reflect a high degree of inflammation and may even precede the onset of joint symptoms. In general, the presence of a fever of >38.3°C (101°F) at any time during the clinical course should raise suspicion of systemic vasculitis (see below) or infection.

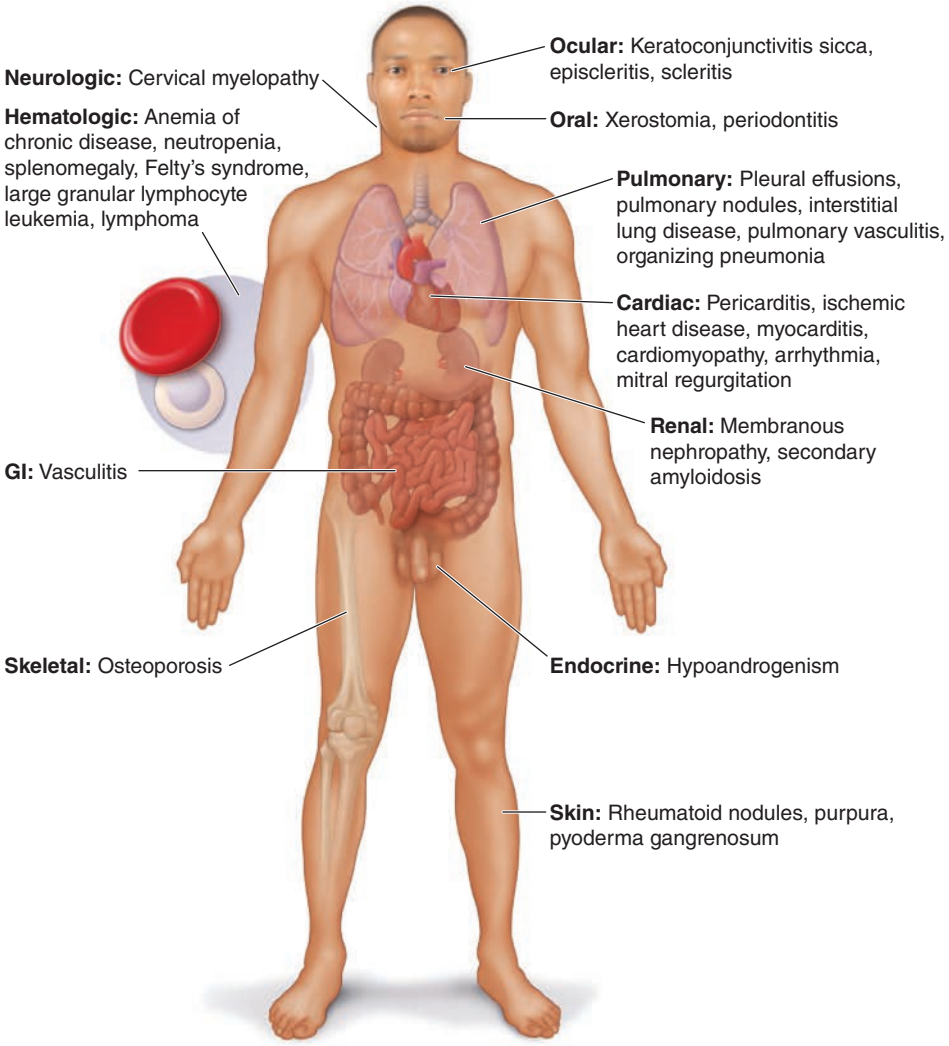

FIGURE 358-2 Extraarticular manifestations of rheumatoid arthritis.

NODULES

Subcutaneous nodules have been reported to occur in 30–40% of patients and more commonly in those with the highest levels of disease activity, the disease-related shared epitope (SE) (see below), a positive test for serum RF, and radiographic evidence of joint erosions. However, more recent cohort studies suggest a declining prevalence of subcutaneous nodules, perhaps related to early and more aggressive disease-modifying therapy. When palpated, the nodules are generally firm; nontender; and adherent to periosteum, tendons, or bursae; they develop in areas of the skeleton subject to repeated trauma or irritation such as the forearm, sacral prominences, and Achilles tendon. They may also occur in the lungs, pleura, pericardium, and peritoneum. Nodules are typically benign, although they can be associated with infection, ulceration, and gangrene. Accelerated growth of smaller nodules may occur in up to 10% of patients taking long-term methotrexate, although the mechanisms behind this phenomenon is unclear.

SJÖGREN'S SYNDROME

Secondary Sjögren's syndrome **(Chap. 361)** is defined by the presence of either keratoconjunctivitis sicca (dry eyes) or xerostomia (dry mouth) in association with another connective tissue disease, such as RA. Approximately 10% of patients with RA have secondary Sjögren's syndrome.

PULMONARY

Pleuritis, the most common pulmonary manifestation of RA, may produce pleuritic chest pain and dyspnea, as well as a pleural friction rub and effusion. Pleural effusions tend to be exudative with increased numbers of monocytes and neutrophils. ILD may also occur in patients with RA and is heralded by symptoms of dry cough and progressive shortness of breath. ILD can be associated with cigarette smoking and is generally found in patients with higher disease activity, although it may be diagnosed in up to 3.5% of patients prior to the onset of joint symptoms. Recent studies have shown the overall prevalence of ILD in RA to be as high as 12%. Diagnosis is readily made by high-resolution chest CT scan, which shows infiltrative opacification, or ground-glass opacities, in the periphery of both lungs. Usual interstitial pneumonia (UIP) and nonspecific interstitial pneumonia (NSIP) are the main histologic and radiologic patterns of ILD. UIP causes progressive scarring of the lungs that, on chest CT scan, produces honeycomb changes in the periphery and lower portions of the lungs. In contrast, the most common radiographic changes in NSIP are relatively symmetric and bilateral ground-glass opacities with associated fine reticulations, with volume loss and traction bronchiectasis. In both cases, pulmonary function testing shows a restrictive pattern (e.g., reduced total lung capacity) with a reduced diffusing capacity for carbon monoxide (D_{LCO}). The presence of ILD confers a poor prognosis. The prognosis of ILD in RA, however, is not quite as poor as that of idiopathic pulmonary fibrosis (e.g., usual interstitial pneumonitis) and responds better to immunosuppressive therapy **(Chap. 293)**. Pulmonary nodules are also common in patients with RA and may be solitary or multiple. Caplan's syndrome is a rare subset of pulmonary nodulosis characterized by the development of nodules and pneumoconiosis following silica exposure. Respiratory bronchiolitis and bronchiectasis are pulmonary disorders less commonly associated with RA.

CARDIAC

The most frequent site of cardiac involvement in RA is the pericardium. However, clinical manifestations of pericarditis occur in <10% of patients with RA despite the fact that pericardial involvement is detectable in nearly one-half of cases by echocardiogram or autopsy studies. Up to 20% of patients with RA may have asymptomatic pericardial effusions on echocardiography. Cardiomyopathy, another clinically important manifestation of RA, may result from necrotizing or granulomatous myocarditis, coronary artery disease, or diastolic dysfunction. This involvement too may be subclinical and only identified by echocardiography or cardiac MRI. Rarely, the heart muscle may contain rheumatoid nodules or be infiltrated with amyloid. Mitral regurgitation is the most common valvular abnormality in RA, occurring at a higher frequency than in the general population.

VASCULITIS

Rheumatoid vasculitis **(Chap. 363)** typically occurs in patients with long-standing disease, a positive test for serum RF or anti–cyclic citrullinated peptide (CCP) antibodies, and hypocomplementemia. The overall incidence has decreased significantly in the past decade to <1% of patients. The cutaneous signs vary and include petechiae, purpura, digital infarcts, gangrene, livedo reticularis, and in severe cases large, painful lower extremity ulcerations. Vasculitic ulcers, which may be difficult to distinguish from those caused by venous insufficiency, may be treated successfully with immunosuppressive agents (requiring cytotoxic treatment in severe cases) as well as skin grafting. Sensorimotor polyneuropathies, such as mononeuritis multiplex, may occur in association with systemic rheumatoid vasculitis and usually clinically present with a new onset of numbness, tingling, or focal muscle weakness depending on its severity.

HEMATOLOGIC

A normochromic, normocytic anemia often develops in patients with RA and is the most common hematologic abnormality. The degree of anemia parallels the degree of inflammation, correlating with the levels of serum C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR). Platelet counts may also be elevated in RA as an acute-phase reactant. Immune-mediated thrombocytopenia is rare in this disease.

Felty's syndrome is defined by the clinical triad of neutropenia, splenomegaly, and nodular RA and is seen in <1% of patients, although its incidence appears to be declining in the face of more aggressive treatment of the joint disease. It typically occurs in the late stages of severe RA and is more common in whites than other racial groups. T-cell large granular lymphocyte leukemia (T-LGL) may have a similar clinical presentation and often occurs in association with RA. T-LGL is characterized by a chronic, indolent clonal growth of LGL cells, leading to neutropenia and splenomegaly. As opposed to Felty's syndrome, T-LGL may develop early in the course of RA. Leukopenia apart from these disorders is uncommon and most often a side effect of drug therapy.

LYMPHOMA

Large cohort studies have shown a two- to fourfold increased risk of lymphoma in RA patients compared with the general population. The most common histopathologic type of lymphoma is a diffuse large B-cell lymphoma. The risk of developing lymphoma increases if the patient has high levels of disease activity or Felty's syndrome.

ASSOCIATED CONDITIONS

In addition to extraarticular manifestations, several conditions associated with RA contribute to disease morbidity and mortality rates. They are worthy of mention because they affect chronic disease management.

Cardiovascular Disease The most common cause of death in patients with RA is cardiovascular disease. The incidence of coronary artery disease and carotid atherosclerosis is higher in RA patients than in the general population even when controlling for traditional cardiac risk factors, such as hypertension, obesity, hypercholesterolemia, diabetes, and cigarette smoking. Furthermore, congestive heart failure (including both systolic and diastolic dysfunction) occurs at an approximately twofold higher rate in RA than in the general population. The presence of elevated serum inflammatory markers appears to confer an increased risk of cardiovascular disease in this disease population.

Osteoporosis Osteoporosis is more common in patients with RA than an age- and sex-matched population, with an incidence rate of nearly double that of the healthy population and a prevalence of approximately one-third in postmenopausal women with RA. There is also an increased risk of fragility fracture, with a greater risk among women. The inflammatory milieu of the joint probably spills over into the rest of the body and promotes generalized bone loss by activating osteoclasts. Both trabecular and cortical bone are affected by the

inflammatory response, with cortical sites more susceptible to bone loss. Chronic use of glucocorticoids and disability-related immobility also contribute to osteoporosis. Hip fractures are more likely to occur in patients with RA and are significant predictors of increased disability and mortality rate in this disease.

EPIDEMIOLOGY

RA affects ~0.5–1% of the adult population worldwide. There is evidence that the overall incidence of RA has been decreasing in recent decades, whereas the prevalence has remained the same because individuals with RA are living longer. The incidence and prevalence of RA vary based on geographic location, both globally and among certain ethnic groups within a country **(Fig. 358-3)**. For example, the Native American Yakima, Pima, and Chippewa tribes of North America have reported prevalence rates in some studies of nearly 7%. In contrast, many population studies from Africa and Asia show lower prevalence rates for RA in the range of 0.2–0.4%.

Like many other autoimmune diseases, RA occurs more commonly in females than in males, with a 2–3:1 ratio. Interestingly, studies of RA from some of the Latin American and African countries show an even greater predominance of disease in females compared to males, with ratios of 6–8:1. Given this preponderance of females, various theories have been proposed to explain the possible role of estrogen in disease pathogenesis. Broadly speaking, most of the theories center on the role of estrogens and androgens in enhancing and suppressing the immune response, respectively. However, estrogens have both stimulatory and inhibitory effects on the immune system, and the hormonal mechanisms, if any, influencing the development of RA are unknown

GENETIC CONSIDERATIONS

It has been recognized for >30 years that genetic factors contribute to the occurrence of RA as well as to its severity. The likelihood that a first-degree relative of a patient will share the diagnosis of RA is 2–10 times greater than in the general population. There remains, however, some uncertainty in the extent to which genetics plays a role in the causative mechanisms of RA. Heritability estimates range from 40 to 50% and are approximately the same for autoantibody-positive and -negative individuals. The estimate of genetic influence may vary across studies due to gene–environment interactions.

The alleles known to confer the greatest risk of RA are located within the major histocompatibility complex (MHC) and, in particular, MHC class II molecules. MHC class II molecules are typically expressed on antigen-presenting cells and are comprised of α and β chains. Most, but probably not all, of this risk is associated with allelic variation in the HLA-DRB1 gene, which encodes the MHC II β-chain molecule. The disease-associated HLA-DRB1 alleles share an amino acid sequence at positions 70–74 in the third hypervariable regions of the HLA-DR β-chain, termed the *shared epitope*. These amino acids are located in the antigen-binding grove with the hypervariable regions of the HLA-DRβ1 molecule. Hypervariable regions within DR molecules are particularly important for determining antigen recognition and binding of the MHC-peptide complex to the T-cell receptor (TCR). Peptides derived from posttranslationally modified proteins (via citrullination, acetylation, or carbamylation, for example) may bind with greater avidity to the shared epitope, providing a potential mechanism for increased disease risk at a molecular level.

Carriership of the SE alleles is associated with production of anti-ACPA and worse disease outcomes. Some of these HLA-DRB1 alleles bestow a high risk of disease (*0401), whereas others confer a more moderate risk (*0101, 0404, 1001, and 0901). Over 90% of patients with RA express at least one of these variants. Interestingly, HLA-DRB1*1301 and to a lesser extent HLA-DRB1*1302 confer protection from ACPA-positive RA.

Additionally, there is geographic variation in disease susceptibility and the identity of the HLA-DRB1 risk alleles. In Greece, for example, where RA tends to be milder than in western European countries, RA susceptibility has been associated with the *0101 SE allele. By comparison, the *0401 or *0404 alleles are found in ~50–70% of northern Europeans and are the predominant risk alleles in this group. The most common disease susceptibility SE alleles in Asians, namely the Japanese, Koreans, and Chinese, are *0405 and *0901. Lastly, disease susceptibility of Native American populations such as the Pima and Tlingit Indians, where the prevalence of RA can be as high as 7%, is associated with the SE allele *1042. The risk of RA conferred by these SE alleles is less in African and Hispanic Americans than in individuals of European ancestry.

Genome-wide association studies (GWAS) have made possible the identification of several non-MHC-related genes that contribute to RA susceptibility. GWAS are based on the detection of single nucleotide polymorphisms (SNPs), which allow for examination of the genetic architecture of complex diseases such as RA. There are ~10 million common SNPs within a human genome consisting of 3 billion base pairs. As a rule, GWAS identify only common variants, namely, those with a frequency of >5% in the general population.

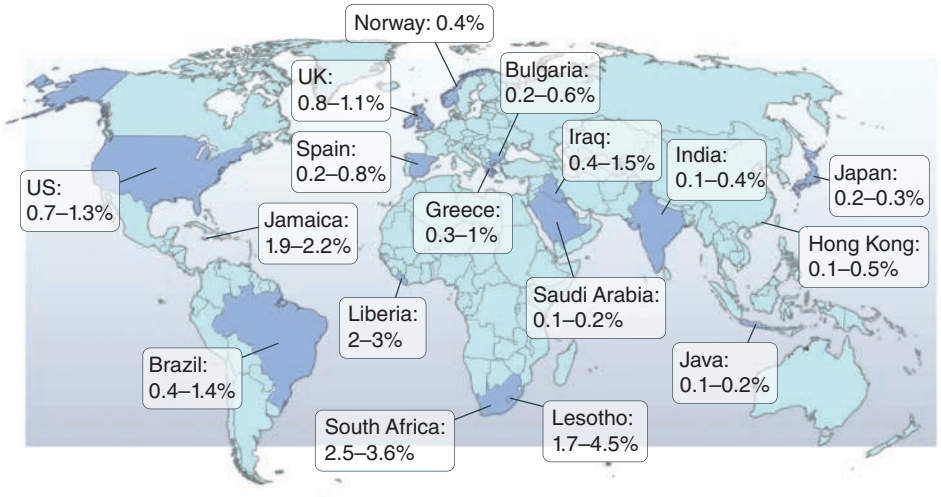

FIGURE 358-3 Global prevalence rates of rheumatoid arthritis (RA) with genetic associations. Listed are the major genetic alleles associated with RA. Although human leukocyte antigen (HLA)-DRB1 mutations are found globally, some alleles have been associated with RA in only certain ethnic groups.

Overall, several themes have emerged from GWAS in RA. First, among the >100 non-MHC loci identified as risk alleles for RA, they individually have only a modest effect on risk; they also contribute to the risk for developing other autoimmune diseases, such as type 1 diabetes mellitus, systemic lupus erythematosus, and multiple sclerosis. Second, although most of the non-HLA associations are described in patients with ACPA-positive disease, there are several risk loci that are unique to ACPA-negative disease. Third, risk alleles vary among ethnic groups. And fourth, the risk loci mostly reside in genes encoding proteins involved in the regulation of the immune response. However, the risk alleles identified by GWAS only account at present for ~5% of the genetic risk, suggesting that rare variants or other classes of DNA variants, such as variants in copy number, may be yet found that significantly contribute to the overall risk model.

Among the best examples of the non-MHC genes contributing to the risk of RA is the gene encoding protein tyrosine phosphatase non-receptor 22 (*PTPN22*). This gene varies in frequency among patients from different parts of Europe (e.g., 3–10%) but is absent in patients of East Asian ancestry. *PTPN22* encodes lymphoid tyrosine phosphatase, a protein that regulates T- and B-cell function. Inheritance of the risk allele for *PTPN22* produces a gain-of-function in the protein that is hypothesized to result in the abnormal thymic selection of autoreactive T and B cells and appears to be associated exclusively with ACPA-positive disease. The peptidyl arginine deiminase type IV (*PADI4*) gene is another risk allele that encodes an enzyme involved in the conversion of arginine to citrulline and is postulated to play a role in the development of antibodies to citrullinated antigens. A polymorphism in *PADI4* has been associated with a twofold increase in the risk of RA, primarily in those of East Asian descent. Recently, polymorphisms in apolipoprotein M (*APOM*) have been demonstrated in an East Asian population to confer an increased risk for RA as well as risk for dyslipidemia, independent of RA disease activity.

In addition to *PTPN22*, other genes associated with B-cell function and/or antigen presentation such as *BTLA* (B- and T-lymphocyte attenuator), Fc receptors, and CD40 have been identified. Signal transduction genes and pathways that regulate immune function (e.g., *TRAF1-C5* and *STAT4*), cell migration (*ELMO1*) and fetal development (*LBH*) have also been discovered to be linked to RA. Other risk alleles affect cytokine signaling, such as tumor necrosis factor (TNF) promoter polymorphisms that can potentially modulate TNF gene expression and an interleukin (IL) 6 receptor polymorphism that is functionally implicated in the strength of IL-6 signaling. Thus, the genetic clues implicate both adaptive and innate immune mechanisms in disease pathogenesis.

Epigenetics is the study of heritable traits that affect gene expression but do not modify DNA sequence. It may provide a link between environmental exposure and predisposition to disease. Epigenetic mechanisms are theoretically involved in three important aspects of RA: contribution to disease etiology, perpetuation of chronic inflammatory responses, and disease severity. The best-studied epigenetic mechanisms are those regulating posttranslational histone modifications and DNA methylation. DNA methylation patterns have been shown to differ between RA patients and healthy controls, as well as from patients with osteoarthritis. MicroRNAs, which are noncoding RNAs that function as posttranscriptional regulators of gene expression, represent an additional epigenetic mechanism that may potentially influence cellular responses. Many microRNAs have been identified as contributing to the activated phenotype of synovial fibroblasts, such as miR146a or miR155.

ENVIRONMENTAL FACTORS

In addition to genetic predisposition, a host of environmental factors have been implicated in the pathogenesis of RA. The most reproducible of these environmental links is cigarette smoking. Numerous cohort and case-control studies have demonstrated that smoking confers a relative risk for developing RA of 1.5–3.5 times. Smoking-related risk interacts in a synergistic manner with MHC risk alleles. The classic shared epitope alleles alone modestly increase the likelihood of developing RA by four- to sixfold; however, this risk increases to 20- to 40-fold when combined with smoking. In particular, women who smoke cigarettes have a nearly 2.5 times greater risk of RA, a risk that persists even 15 years after smoking cessation. A twin who smokes will have a significantly higher risk for RA than his or her monozygotic co-twin, theoretically with the same genetic risk, who does not smoke. Interestingly, the risk from smoking is almost exclusively related to RF and ACPA-positive disease. However, it has not been shown that smoking cessation, while having many health benefits, improves disease activity. Inhalant-related occupations and silica inhalants also may increase RA risk. These observations have led to the theory that lung disease may play a critical early role in the initial development of autoreactive immune cells, as well as to the known occurrence of autoantibodies more than a decade prior to the clinical development of joint disease.

Researchers began to aggressively seek an infectious etiology for RA after the discovery in 1931 that sera from patients with this disease could agglutinate strains of streptococci. Certain viruses such as Epstein-Barr virus (EBV) have garnered the most interest over the past 30 years given their ubiquity, ability to persist for many years in the host, and frequent association with arthritic complaints. For example, titers of IgG antibodies against EBV antigens in the peripheral blood and saliva are significantly higher in patients with RA than the general population. EBV DNA has also been found in synovial fluid and synovial cells of RA patients. Because the evidence for these links is largely circumstantial, it has not been possible to directly implicate infection as a causative factor in RA.

An attractive hypothesis is that microbial dysbiosis of the oral or gut microbiome may predispose to the development of RA. Recent studies suggest that periodontitis in the oral cavity may play a role in disease mechanisms. Multiple studies provide evidence for a link between ACPA-positive RA and cigarette smoking, periodontal disease, and the oral microbiome, specifically *Porphyromonas gingivalis*. It has been hypothesized that the immune response to *P. gingivalis* may trigger the development of RA and that induction of ACPA results from citrullination of arginine residues in human tissues by the bacterial enzyme peptidyl arginine deiminase (PAD). Interestingly, *P. gingivalis* is the only oral bacterial species known to harbor this enzyme. Some studies have shown a relationship between circulating antibodies to *P. gingivalis* and RA, as well as these antibodies and first-degree relatives at risk for this disease. However, it remains unproven whether the observed dysbiosis in the oral cavity precedes the development of disease, and results from other studies argue against a causal link between periodontitis and the development of RA.

There are also limited data suggesting a role for the gut microbiome in the etiology of RA. Some studies have found that the gut microbiome is different in patients with early RA compared with controls. In particular, *Prevotella copri* was reported to be enriched in early untreated RA as well as an "at-risk" population. On the other hand, a common dysbiotic signature does not seem to predominate in patients with RA, and evidence is lacking for direct immune-modulating mechanisms.

PATHOLOGY

RA affects the synovial tissue primarily of the diarthrodial joints and underlying cartilage and bone. The synovial membrane, which covers most articular surfaces, tendon sheaths, and bursae, normally is a thin layer of connective tissue. In joints, it faces the bone and cartilage, bridging the opposing bony surfaces and inserting at periosteal regions close to the articular cartilage. It consists primarily of two cell types—type A synoviocytes (macrophage-derived) and type B synoviocytes (fibroblast-derived). The synovial fibroblasts are the most abundant and produce the structural components of joints, including collagen, fibronectin, and laminin, as well as other extracellular constituents of the synovial matrix. The sublining layer consists of blood vessels and a sparse population of mononuclear cells within a loose network of connective tissue. Synovial fluid, an ultrafiltrate of blood, diffuses through the subsynovial lining tissue across the synovial membrane and into the joint cavity. Its main constituents are hyaluronan and lubricin. Hyaluronan is a glycosaminoglycan that contributes to the

viscous nature of synovial fluid, which, along with lubricin, lubricates the surface of the articular cartilage.

The pathologic hallmarks of RA are synovial inflammation and proliferation, focal bone erosions, and thinning of articular cartilage. Chronic inflammation leads to synovial lining hyperplasia and the formation of pannus, a thickened cellular membrane containing multiple layers of fibroblast-like synoviocytes and granulation-reactive fibrovascular tissue that invades the underlying cartilage and bone. The inflammatory infiltrate is made up of no less than six cell types: T cells, B cells, plasma cells, dendritic cells, mast cells, and, to a lesser extent, granulocytes. The T cells compose 30–50% of the infiltrate, with the other cells accounting for the remainder. The topographical organization of these cells is complex and may vary among individuals with RA. Most often, the lymphocytes are diffusely organized among the tissue resident cells; however, in some cases, the B cells, T cells, and dendritic cells may form higher levels of organization, such as lymphoid follicles and germinal center–like structures. Growth factors secreted by synovial fibroblasts and macrophages promote the formation of new blood vessels in the synovial sublining that supply the increasing demands for oxygenation and nutrition required by the infiltrating leukocytes and expanding synovial tissue.

The structural damage to the mineralized cartilage and subchondral bone is mediated by the osteoclast. Osteoclasts are multinucleated giant cells that can be identified by their expression of CD68, tartrate-resistant acid phosphatase, cathepsin K, and the calcitonin receptor. They appear at the pannus-bone interface where they eventually form resorption lacunae. These lesions typically localize where the synovial membrane inserts into the periosteal surface at the edges of bones close to the rim of articular cartilage and at the attachment sites of ligaments and tendon sheaths. This process most likely explains why bone erosions usually develop at the radial sites of the MCP joints juxtaposed to the insertion sites of the tendons, collateral ligaments, and synovial membrane. Another form of bone loss is periarticular osteopenia that occurs in joints with active inflammation. It is associated with substantial thinning of the bony trabeculae along the metaphyses of bones, and likely results from inflammation of the bone marrow cavity. These lesions can be visualized on MRI scans, where they appear as signal alterations in the bone marrow adjacent to inflamed joints. Their signal characteristics show they are water-rich with a low-fat content and are consistent with highly vascularized inflammatory tissue. These bone marrow lesions are often the forerunner of bone erosions.

The cortical bone layer that separates the bone marrow from the invading pannus is relatively thin and susceptible to penetration by the inflamed synovium. The bone marrow lesions seen on MRI scans are associated with an endosteal bone response characterized by the accumulation of osteoblasts and deposition of osteoid. Finally, generalized osteoporosis, which results in the thinning of trabecular bone throughout the body, is a third form of bone loss found in patients with RA.

Articular cartilage is an avascular tissue comprised of a specialized matrix of collagens, proteoglycans, and other proteins. It is organized in four distinct regions (superficial, middle, deep, and calcified cartilage zones)—chondrocytes constitute the unique cellular component in these layers. Originally, cartilage was considered to be an inert tissue, but it is now known to be a highly responsive tissue that reacts to inflammatory mediators and mechanical factors, which in turn, alter the balance between cartilage anabolism and catabolism. In RA, the initial areas of cartilage degradation are juxtaposed to the synovial pannus. The cartilage matrix is characterized by a generalized loss of proteoglycan, most evident in the superficial zones adjacent to the synovial fluid. Degradation of cartilage may also take place in the perichondrocytic zone and in regions adjacent to the subchondral bone.

PATHOGENESIS

The pathogenic mechanisms of synovial inflammation are likely to result from a complex interplay of genetic, environmental, and immunologic factors that produces dysregulation of the immune system and a breakdown in self-tolerance **(Fig. 358-4)**. Precisely what triggers these initiating events and what genetic and environmental factors disrupt the immune system remain a mystery. However, a detailed molecular picture is emerging of the mechanisms underlying the chronic inflammatory response and the destruction of the articular cartilage and bone.

In RA, the preclinical stage appears to be characterized by a breakdown in self-tolerance. This idea is supported by the finding that autoantibodies, such as RF and ACPA, may be found in sera from patients many years before onset of clinical disease. However, the antigenic targets of ACPA and RF are not restricted to the joint, and their role in disease pathogenesis remains speculative. ACPA are directed against deaminated peptides, which result from posttranslational modification by the enzyme PADI4. They recognize citrulline-containing regions of several different matrix proteins, including filaggrin, keratin, fibrinogen, and vimentin, and are present at higher levels in the joint fluid compared to the serum. Other autoantibodies have been found in a minority of patients with RA, but they also occur in the setting of other types of arthritis. They bind to a diverse array of autoantigens, including type II collagen, human cartilage gp-39, aggrecan, calpastatin, immunoglobulin binding protein (BiP), and glucose-6-phosphate isomerase.

In theory, environmental stimulants may synergize with other factors to bring about inflammation in RA. People who smoke display higher citrullination of proteins in bronchoalveolar fluid than those who do not smoke. Thus, it has been speculated that long-term exposure to tobacco smoke might induce citrullination of cellular proteins via increased PADI expression in the lung and generate a neoepitope capable of inducing self-reactivity, which in turns, leads to formation of immune complexes that trigger joint inflammation.

How might microbes or their products be involved in the initiating events of RA? The immune system is alerted to the presence of microbial infections through the binding of pathogen-associated molecular patterns (PAMPs) to Toll-like receptors (TLRs). There are 10 TLRs in humans that recognize a variety of microbial products, including bacterial cell-surface lipopolysaccharides and heat-shock proteins (TLR4), lipoproteins (TLR2), double-strand RNA viruses (TLR3), and unmethylated CpG DNA from bacteria (TLR9). TLR2, 3, and 4 are abundantly expressed by synovial fibroblasts in early RA and, when bound by their ligands, upregulate production of proinflammatory cytokines. Although TLR ligands may theoretically amplify inflammatory pathways in RA, their specific role in disease pathogenesis remains uncertain.

The pathogenesis of RA is built upon the concept that self-reactive T cells drive the chronic inflammatory response. In theory, self-reactive T cells might arise in RA from abnormal central (thymic) selection or intrinsic defects lowering the threshold in the periphery for T-cell activation. Either mechanism might result in abnormal expansion of the self-reactive T-cell repertoire and a breakdown in T-cell tolerance. The support for these theories comes mainly from studies of arthritis in mouse models. It has not been shown that patients with RA have abnormal thymic selection of T cells or defective apoptotic pathways regulating cell death. At least some antigen stimulation inside the joint seems likely, owing to the fact that T cells in the synovium express a cell-surface phenotype indicating prior antigen exposure and show evidence of clonal expansion. Of interest, peripheral blood T cells from patients with RA have been shown to display a fingerprint of premature aging that mostly affects inexperienced naïve T cells. In these studies, the most glaring findings have been the loss of telomeric sequences and a decrease in the thymic output of new T cells. Although intriguing, it is not clear how generalized T-cell abnormalities might provoke a systemic disease with a predominance of synovitis.

There is substantial evidence of a role for CD4+ T cells in the pathogenesis of RA. First, the co-receptor CD4 on the surface of T cells binds to invariant sites on MHC class II molecules, stabilizing the MHC-peptide–T-cell receptor complex during T-cell activation. Because the SE on MHC class II molecules is a risk factor for RA, it follows that CD4+ T-cell activation may play a role in the pathogenesis of this disease. Second, CD4+ memory T cells are enriched in the synovial tissue from patients with RA and can be implicated through "guilt by association." Third, CD4+ T cells have been shown to be important in the initiation of arthritis in animal models. Fourth, some, but not all,

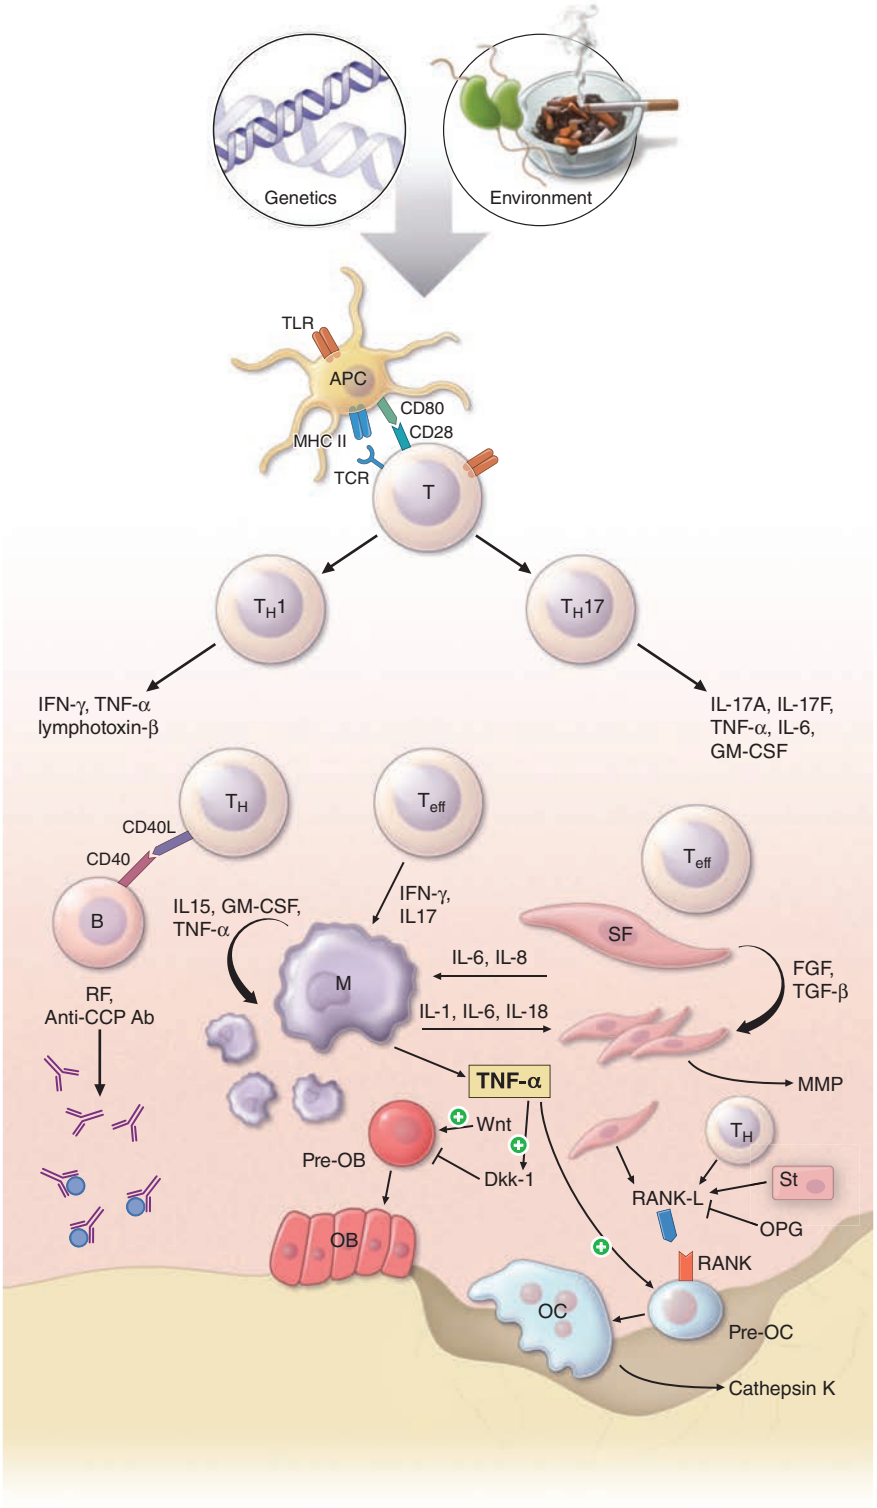

FIGURE 358-4 Pathophysiologic mechanisms of inflammation and joint destruction. Genetic predisposition along with environmental factors may trigger the development of rheumatoid arthritis (RA), with subsequent synovial T-cell activation. CD4+ T cells become activated by antigen-presenting cells (APCs) through interactions between the T-cell receptor and class II MHC-peptide antigen (signal 1) with co-stimulation through the CD28-CD80/86 pathway, as well as other pathways (signal 2). In theory, ligands binding Toll-like receptors (TLRs) may further stimulate activation of APCs inside the joint. Synovial CD4+ T cells differentiate into T_H1 and T_H17 cells, each with their distinctive cytokine profile. CD4+ T_H cells in turn activate B cells, some of which are destined to differentiate into autoantibody-producing plasma cells. Immune complexes, possibly comprised of rheumatoid factors (RFs) and anti–cyclic citrullinated peptides (CCP) antibodies, may form inside the joint, activating the complement pathway and amplifying inflammation. T effector cells stimulate synovial macrophages (M) and fibroblasts (SF) to secrete proinflammatory mediators, among which is tumor necrosis factor α (TNF-α). TNF-α upregulates adhesion molecules on endothelial cells, promoting leukocyte influx into the joint. It also stimulates the production of other inflammatory mediators, such as interleukin 1 (IL-1), IL-6, and granulocyte-macrophage colony-stimulating factor (GM-CSF). TNF-α has a critically important function in regulating the balance between bone destruction and formation. It upregulates the expression of dickkopf-1 (DKK-1), which can then internalize Wnt receptors on osteoblast precursors. Wnt is a soluble mediator that promotes osteoblastogenesis and bone formation. In RA, bone formation is inhibited through the Wnt pathway, presumably due to the action of elevated levels of DKK-1. In addition to inhibiting bone formation, TNF-α stimulates osteoclastogenesis. However, it is not sufficient by itself to induce the differentiation of osteoclast precursors (Pre-OC) into activated osteoclasts capable of eroding bone. Osteoclast differentiation requires the presence of macrophage colony-stimulating factor (M-CSF) and receptor activator of nuclear factor-κB (RANK) ligand (RANKL), which binds to RANK on the surface of Pre-OC. Inside the joint, RANKL is mainly derived from stromal cells, synovial fibroblasts, and T cells. Osteoprotegerin (OPG) acts as a decoy receptor for RANKL, thereby inhibiting osteoclastogenesis and bone loss. FGF, fibroblast growth factor; IFN, interferon; MMP, matrix metalloproteinase; TGF, transforming growth factor.

T cell–directed therapies have shown clinical efficacy in this disease. Taken together, these lines of evidence suggest that CD4+ T cells play an important role in orchestrating the chronic inflammatory response in RA. However, other cell types, such as CD8+ T cells, natural killer (NK) cells, and B cells are present in synovial tissue and may also influence pathogenic responses.

In the rheumatoid joint, by mechanisms of cell-cell contact and release of soluble mediators, activated T cells stimulate macrophages and fibroblast-like synoviocytes to generate proinflammatory mediators and proteases that drive the synovial inflammatory response and destroy the cartilage and bone. CD4+ T-cell activation is dependent on two signals: (1) T-cell receptor binding to peptide-MHC on antigen-presenting cells; and (2) CD28 binding to CD80/86 on antigen-presenting cells. This interaction then leads to downstream signals that differentiate CD4+ T cells into effector and memory cell populations, as well as activate CD8+ T cells. Certain subsets of CD4+ T cells, called T helper cells, enable B cells to differentiate into antibody-secreting cells. An earlier T cell–centric model for the pathogenesis of RA was based on a T_H1-driven paradigm, which came from studies indicating that CD4+ T helper (T_H) cells differentiated into T_H1 and T_H2 subsets, each with their distinctive cytokine profiles. T_H1 cells were found to mainly produce interferon γ (IFN-γ), lymphotoxin β, and TNF-α, whereas T_H2 cells predominately secreted IL-4, IL-5, IL-6, IL-10, and IL-13. In humans, naïve T cells may be induced to differentiate into T_H17 cells by exposure to transforming growth factor β (TGF-β), IL-1, IL-6, and IL-23. Upon activation, T_H17 cells secrete a variety of proinflammatory mediators such as IL-17, IL-21, IL-22, TNF-α, IL-26, IL-6, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Substantial evidence now exists from studies in both animal models and humans that IL-17 plays an important role not only in promoting joint inflammation but also in destroying cartilage and subchondral bone. However, in a phase 2 clinical trial, treatment with secukinumab, an anti-IL-17 receptor antibody, failed to produce significant clinical benefit in patients with RA.

The immune system has evolved mechanisms to counterbalance the potential harmful immune-mediated inflammatory responses provoked by infectious agents and other triggers. Among these negative regulators are regulatory T (Treg) cells, which are produced in the thymus and induced in the periphery to suppress immune-mediated inflammation. They are characterized by the surface expression of CD25 and the expression of the transcription factor forkhead box P3 (FOXP3) and the absence of CD127, the IL-7 receptor. Tregs orchestrate dominant tolerance through contact with other immune cells and secretion of inhibitory cytokines, such as TGF-β, IL-10, and IL-35. They are heterogeneous and capable of suppressing distinct classes (T_H1, T_H2, T_H17) of the immune response. In RA, the data that Treg numbers and suppressive capacity are deficient compared with normal healthy controls are contradictory and inconclusive. Some experimental evidence suggests that Treg suppressive activity is lost due to dysfunctional expression of cytotoxic T lymphocyte antigen 4 (CTLA-4). The nature of Treg defects in RA and their role in disease mechanisms remain unclear.

Cytokines, chemokines, antibodies, and endogenous danger signals bind to receptors on the surface of immune cells and stimulate a cascade of intracellular signaling events that can amplify the inflammatory response. Signaling molecules and their binding partners in these pathways are the target of small-molecule drugs designed to interfere with signal transduction and, in turn, block these reinforcing inflammatory loops. Examples of signaling molecules in these critical inflammatory pathways include Janus kinase (JAK)/signal transducers and activators of transcription (STAT), spleen tyrosine kinase (Syk), mitogen-activated protein kinases (MAPKs), and nuclear factor-κB (NF-κB). These pathways exhibit significant crosstalk and are found in many cell types. Some signal transducers, such as the JAKs, are expressed in hematopoietic cells and play an important role in the inflammatory response in RA.

Activated, autoreactive B cells are also important players in the chronic inflammatory response. B cells give rise to plasma cells, which in turn, produce antibodies, including RF and ACPA. RFs may form large immune complexes inside the joint that contribute to the pathogenic process by fixing complement and promoting the release of proinflammatory cytokines and chemokines. In mouse models of arthritis, RF-containing immune complexes and ACPA-containing immune complexes synergize with other mechanisms to exacerbate the synovial inflammatory response.

RA is often considered to be a macrophage-driven disease because this cell type is the predominant source of proinflammatory cytokines inside the joint. Key proinflammatory cytokines released by synovial macrophages include TNF-α, IL-1, IL-6, IL-12, IL-15, IL-18, and IL-23. Synovial fibroblasts, the other major cell type in this microenvironment, produce the cytokines IL-1 and IL-6 as well as TNF-α. TNF-α is a pivotal cytokine in the pathobiology of synovial inflammation. It upregulates adhesion molecules on endothelial cells, promoting the influx of leukocytes into the synovial microenvironment; activates synovial fibroblasts; stimulates angiogenesis; promotes pain receptor sensitizing pathways; and drives osteoclastogenesis. Fibroblasts secrete matrix metalloproteinases (MMPs) as well as other proteases that are chiefly responsible for the breakdown of articular cartilage; they also promote inflammation and synovial proliferation by secreting cytokines such as IL-6, IL-1, IL-18, and GM-CSF, chemokines, and vascular endothelial growth factor.

Osteoclast activation at the site of the pannus is closely tied to the presence of focal bone erosion. Receptor activator of nuclear factor-κB ligand (RANKL) is expressed by stromal cells, synovial fibroblasts, and T cells. Upon binding to its receptor RANK on osteoclast progenitors, RANKL stimulates osteoclast differentiation and bone resorption. RANKL activity is regulated by osteoprotegerin (OPG), a decoy receptor of RANKL that blocks osteoclast formation. Monocytic cells in the synovium serve as the precursors of osteoclasts and, when exposed to macrophage colony-stimulating factor (M-CSF) and RANKL, fuse to form polykaryons termed *preosteoclasts*. These precursor cells undergo further differentiation into osteoclasts with the characteristic ruffled membrane. Cytokines such as TNF-α, IL-1, IL-6, and IL-17 increase the expression of RANKL in the joint and thus promote osteoclastogenesis. Osteoclasts also secrete cathepsin K, a cysteine protease that degrades the bone matrix by cleaving collagen and contributes to generalized bone loss and osteoporosis.

Increased bone loss is only part of the story in RA, as decreased bone formation plays a crucial role in bone remodeling at sites of inflammation. Recent evidence shows that inflammation suppresses bone formation. TNF-α plays a key role in actively suppressing bone formation by enhancing the expression of dickkopf-1 (DKK-1). DKK-1 is an important inhibitor of the Wnt pathway, which acts to promote osteoblast differentiation and bone formation. The Wnt system is a family of soluble glycoproteins that binds to cell-surface receptors known as frizzled (fz) and low-density lipoprotein (LDL) receptor–related proteins (LRPs) and promotes cell growth. In animal models, increased levels of DKK-1 are associated with decreased bone formation, whereas inhibition of DKK-1 protects against structural damage in the joint. Wnt proteins also induce the formation of OPG and thereby shut down bone resorption, emphasizing their key role in tightly regulating the balance between bone resorption and formation.

DIAGNOSIS

The clinical diagnosis of RA is largely based on signs and symptoms of a chronic inflammatory arthritis, with laboratory and radiographic results providing important corroborating information. In 2010, a collaborative effort between the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) revised the 1987 ACR classification criteria for RA in an effort to improve early diagnosis with the goal of identifying patients who would benefit from early introduction of disease-modifying therapy **(Table 358-1)**. Application of the newly revised criteria yields a score of 0–10, with a score of ≥6 fulfilling the requirements for definite RA. The new classification criteria differ in several ways from the older criteria set. Early clinical classifications for RA required symptoms to be present for >6 weeks. There are several conditions, including virus-related syndromes, that can cause a polyarthritis mimicking

TABLE 358-1 Classification Criteria for Rheumatoid Arthritis

		SCORE
Joint involvement	1 large joint (shoulder, elbow, hip, knee, ankle)	0
	2–10 large joints	1
	1–3 small joints (MCP, PIP, thumb IP, MTP, wrists)	2
	4–10 small joints	3
	>10 joints (at least 1 small joint)	5
Serology	Negative RF and negative ACPA	0
	Low-positive RF or low-positive anti-CCP antibodies (≤3 times ULN)	2
	High-positive RF or high-positive anti-CCP antibodies (>3 times ULN)	3
Acute-phase reactants	Normal CRP and normal ESR	0
	Abnormal CRP or abnormal ESR	1
Duration of symptoms	<6 weeks	0
	≥6 weeks	1

Note: These criteria are aimed at classification of newly presenting patients who have at least one joint with definite clinical synovitis that is not better explained by another disease. A score of ≥6 fulfills requirements for definite RA.

Abbreviations: ACPA, anti-citrullinated peptide antibodies; CCP, cyclic citrullinated peptides; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; IP, interphalangeal joint; MCP, metacarpophalangeal joint; MTP, metatarsophalangeal joint; PIP, proximal interphalangeal joint; RF, rheumatoid factor; ULN, upper limit of normal.

RA and stimulate the transient production of RF. Such conditions usually last only 2–3 weeks. The newer criteria, however, do not mandate symptoms be present for >6 weeks. The new criteria also include as an item a positive test for serum ACPA, which carries greater specificity for the diagnosis of RA than a positive test for RF. The newer classification criteria also do not take into account whether the patient has rheumatoid nodules or radiographic joint damage because these findings occur rarely in early RA. It is important to emphasize that the 2010 ACR-EULAR criteria are "classification criteria" as opposed to "diagnostic criteria" and serve to distinguish patients at the onset of disease who have a high likelihood of evolution to chronic disease with persistent synovitis and joint damage. The presence of radiographic joint erosions or subcutaneous nodules may inform the diagnosis in the later stages of the disease. About three-fourths of patients with the clinical and radiographic features of RA test positive for RF and/or ACPA (seropositive), while the remaining one-fourth of patients with RA test negative for RF and/or ACPA (seronegative).

The differential diagnosis for RA includes all types of acute and chronic inflammatory arthritides, many of which may be differentiated from RA based on the clinical course, pattern of joint involvement, and the presence of disease in other organ systems. Patients with primary Sjögren's syndrome whose predominate clinical manifestations are dry eyes and dry mouth often also have symptoms of polyarthralgia and may show a mild inflammatory synovitis similar to RA. Moreover, 50% of patients with primary Sjögren's syndrome test positive for RF and therefore, may be confused with early RA. Spondyloarthropathies such as psoriatic arthritis or enteropathy-associated arthritis may present similarly to RA. However, they may be distinguished by the presence of sacroiliitis and other enthesopathic features and are generally accompanied by signs of psoriasis or inflammatory bowel disease, respectively. In elderly patients, seronegative RA may be difficult at times to distinguish from polymyalgia rheumatica (PMR). While PMR has been associated in a minority with distal limb involvement, RA may be distinguished by predominant involvement of the wrists/hands and ankles/feet in most cases. Similarly, the relatively rare condition called remitting seronegative symmetrical synovitis with pitting edema (the so-called RS3PE syndrome) and paraneoplastic syndromes may also be confused with early RA. RS3PE is typically characterized by prominent distal limb pitting edema, which is unusual in RA, and particular responsive to treatment with low doses of prednisone. Chronic tophaceous gout may mimic severe RA in some cases, and tophi may be confused with rheumatoid nodules. Hepatitis C–related arthropathy often involves the small joints of the hands and is associated with a positive RF in about half the cases, but generally not ACPA.

LABORATORY FEATURES

Patients with systemic inflammatory diseases such as RA will often present with elevated nonspecific inflammatory markers such as an ESR or CRP. Detection of serum RF and anti-CCP antibodies is important in differentiating RA from other polyarticular diseases, although RF lacks diagnostic specificity and may be found in association with other chronic inflammatory diseases in which arthritis figures in the clinical manifestations.

IgM, IgG, and IgA isotypes of RF occur in sera from patients with RA, although the IgM isotype is the one most frequently measured by commercial laboratories. Serum IgM RF has been found in 75% of patients with RA; therefore, a negative result does not exclude the presence of this disease. It is also found in other connective tissue diseases, such as primary Sjögren's syndrome, systemic lupus erythematosus, and type II mixed essential cryoglobulinemia, as well as chronic infections such as subacute bacterial endocarditis and hepatitis B and C. Serum RF may also be detected in 1–5% of the healthy population.

The presence of serum anti-CCP antibodies has about the same sensitivity as serum RF for the diagnosis of RA. However, its diagnostic specificity approaches 95%, so a positive test for anti-CCP antibodies in the setting of an early inflammatory arthritis is useful for distinguishing RA from other forms of arthritis. There is some incremental value in testing for the presence of both RF and anti-CCP, as some patients with RA are positive for RF but negative for anti-CCP and vice versa. The presence of RF or anti-CCP antibodies also has prognostic significance, with anti-CCP antibodies showing the most value for predicting worse outcomes.

Patients with RA may also have other antibodies associated with autoimmune disease. Approximately 30% of patients with RA test positive for antinuclear antibodies (ANAs), and some sera from some patients contain antineutrophil cytoplasmic antibodies (ANCAs; particularly p-ANCAs). However, patients with RA would not be expected to test positive for anti-MPO or anti-PR3 antibodies.

SYNOVIAL FLUID ANALYSIS

Typically, the cellular composition of synovial fluid from patients with RA reflects an acute inflammatory state. Synovial fluid white blood cell (WBC) counts can vary widely but generally range between 5000 and 50,000 WBC/μL, compared with <2000 WBC/μL for a noninflammatory condition such as osteoarthritis. In contrast to the synovial tissue, the overwhelming cell type in the synovial fluid is the neutrophil. Clinically, the analysis of synovial fluid is most useful for confirming an inflammatory arthritis (as opposed to osteoarthritis), while at the same time excluding infection or a crystal-induced arthritis such as gout or pseudogout (Chap. 372).

JOINT IMAGING

Joint imaging is a valuable tool not only for diagnosing RA but also for tracking progression of any joint damage. Plain x-ray is the most common imaging modality, but it is limited to visualization of the bony structures and inferences about the state of the articular cartilage based on the amount of joint space narrowing. MRI and ultrasound techniques offer the added value of detecting changes in the soft tissues such as synovitis, tenosynovitis, and effusions, as well as providing greater sensitivity for identifying bony abnormalities. Plain radiographs are usually relied upon in clinical practice for the purpose of diagnosis and monitoring of affected joints. However, in selected cases, MRI and ultrasound can provide additional diagnostic information that may guide clinical decision making. Musculoskeletal ultrasound with power Doppler is increasingly used in rheumatology clinical practice for detecting synovitis and bone erosion.

Plain Radiography Classically in RA, the initial radiographic finding is periarticular osteopenia. Practically speaking, however, this finding is difficult to appreciate on plain films and on the newer digitalized x-rays. Other findings on plain radiographs include soft tissue swelling, symmetric joint space loss, and subchondral erosions,

FIGURE 358-5 X-ray demonstrating joint space loss and erosions of carpi, metacarpophalangeal and proximal interphlangeal joints. *(K Kgoebane et al: The role of imaging in rheumatoid arthritis. SA Journal of Radiology. S Afr J Radiology (Online) 22 (1), 2018.)*

most frequently in the wrists and hands (MCPs and PIPs) and the feet (MTPs). In the feet, the lateral aspect of the fifth MTP is often targeted first, but other MTP joints may be involved at the same time. X-ray imaging of advanced RA may reveal signs of severe destruction, including joint subluxation and collapse **(Fig. 358-5)**.

MRI MRI offers the greatest sensitivity for detecting synovitis and joint effusions, as well as early bone and bone marrow changes. These soft tissue abnormalities often occur before osseous changes are noted on x-ray. Presence of bone marrow edema has been recognized to be an early sign of inflammatory joint disease and can predict the subsequent development of erosions on plain radiographs as well as MRI scans. Cost and availability of MRI are the main factors limiting its routine clinical use.

Ultrasound Ultrasound, including power color Doppler, can detect more erosions than plain radiography, especially in easily accessible joints. It can also reliably detect synovitis, including increased joint vascularity indicative of inflammation. The usefulness of ultrasound is dependent on the experience of the sonographer; however, it does offer the advantages of portability, lack of radiation, and low expense relative to MRI, factors that make it attractive as a clinical tool **(Fig. 358-6)**.

CLINICAL COURSE

The natural history of RA is complex and affected by a number of factors including age of onset, gender, genotype, phenotype (i.e., extraarticular manifestations or variants of RA), and comorbid conditions, which make for a truly heterogeneous disease. There is no simple way to predict the clinical course. It is important to realize that as many as 10% of patients with inflammatory arthritis fulfilling ACR classification criteria for RA will undergo a spontaneous remission within 6 months (particularly seronegative patients). However, the vast majority of patients will exhibit a pattern of persistent and progressive disease activity that waxes and wanes in intensity over time. A minority of patients will show intermittent and recurrent explosive attacks of inflammatory arthritis interspersed with periods of disease quiescence. Finally, an aggressive form of RA may occur in an unfortunate few with inexorable progression of severe erosive joint disease, although this highly destructive course is less common in the modern treatment era.

Disability, as measured by the Health Assessment Questionnaire (HAQ), shows gradual worsening of disability over time in the face of poorly controlled disease activity and disease progression. Disability may result from both a disease activity–related component that is potentially reversible with therapy and a joint damage–related component owing to the cumulative and largely irreversible effects of soft tissue, cartilage, and bone breakdown. Early in the course of disease, the extent of joint inflammation is the primary determinant of disability, while in the later stages of disease, the amount of joint damage is the dominant contributing factor. Previous studies have shown that more than one-half of patients with RA are unable to work 10 years after the onset of their disease; however, increased employability and less work absenteeism have been reported recently with the use of newer therapies and earlier treatment intervention.

The overall mortality rate in RA is two times greater than the general population, with ischemic heart disease being the most common cause of death followed by infection. Median life expectancy is shortened by an average of 7 years for men and 3 years for women compared with control populations. Patients at higher risk for shortened survival are those with systemic extraarticular involvement, low functional capacity, low socioeconomic status, low education, and chronic prednisone use.

TREATMENT

Rheumatoid Arthritis

The amount of clinical disease activity in patients with RA reflects the overall burden of inflammation and is the variable that most influences treatment decisions. Joint inflammation is the main driver of joint damage and is the most important cause of functional disability in the early stages of disease. Several composite indices have been developed to assess clinical disease activity. The ACR 20, 50, and 70 improvement criteria (which correspond to a 20, 50, and 70% improvement, respectively, in joint counts, physician/

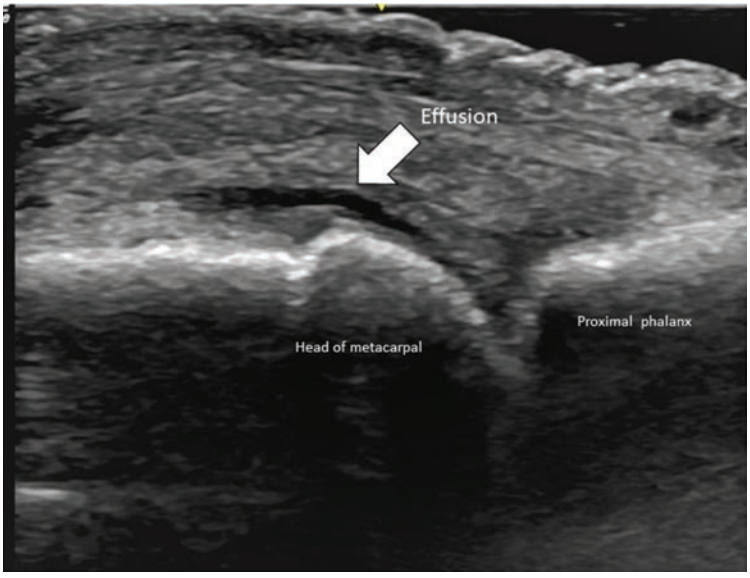

FIGURE 358-6 Ultrasound demonstrating an effusion (*arrow*) within the metacarpophalangeal joint. *(Courtesy of Dr. Ryan Jessee.)*

patient assessment of disease severity, pain scale, serum levels of acute-phase reactants [ESR or CRP], and a functional assessment of disability using a self-administered patient questionnaire) are a composite index with a dichotomous response variable. The ACR improvement criteria are commonly used in clinical trials as an endpoint for comparing the proportion of responders between treatment groups. In contrast, the Disease Activity Score (DAS), Simplified Disease Activity Index (SDAI), the Clinical Disease Activity Index (CDAI), and the Routine Assessment of Patient Index Data 3 (RAPID3) are continuous measures of disease activity that are used in clinical practice for tracking disease status and documenting treatment response.

Several developments during the past two decades have changed the therapeutic landscape in RA. They include (1) the emergence of methotrexate as the disease-modifying antirheumatic drug (DMARD) of first choice for the treatment of early RA; (2) the development of novel highly efficacious biologicals that can be used alone or in combination with methotrexate; and (3) the proven superiority of combination DMARD regimens over methotrexate alone. The medications used for the treatment of RA may be divided into broad categories: nonsteroidal anti-inflammatory drugs (NSAIDs); glucocorticoids, such as prednisone and methylprednisolone; conventional DMARDs; and biologic DMARDs **(Table 358-2)**. Although disease for some patients with RA is managed adequately with a single DMARD, such as methotrexate, it demands in most cases the use of a combination DMARD regimen that may vary in its components over the treatment course depending on fluctuations in disease activity and emergence of drug-related toxicities and comorbidities.

NSAIDS

NSAIDs were formerly viewed as the core of RA therapy, but they are now considered to be adjunctive agents for management of symptoms uncontrolled by other measures. NSAIDs exhibit both analgesic and anti-inflammatory properties. The anti-inflammatory effects of NSAIDs derive from their ability to nonselectively inhibit cyclooxygenase (COX)-1 and COX-2. Although the results of clinical trials suggest that NSAIDs are roughly equivalent in their efficacy, experience suggests that some individuals may preferentially respond to a particular NSAID. Chronic use should be minimized due to the possibility of side effects, including gastritis and peptic ulcer disease as well as impairment of renal function.

GLUCOCORTICOIDS

Glucocorticoids may serve in several ways to control disease activity in RA. First, they may be administered in low to moderate doses to achieve rapid disease control before the onset of fully effective DMARD therapy, which often takes several weeks or even months. Second, a 1- to 2-week burst of glucocorticoids may be prescribed for the management of acute disease flares, with dose and duration guided by the severity of the exacerbation. Chronic administration of low doses (5–10 mg/d) of prednisone (or its equivalent) may also be warranted to control disease activity in patients with an inadequate response to DMARD therapy. As much as possible, chronic glucocorticoid therapy should be avoided in favor of finding an effective DMARD that adequately controls the disease. Best practices minimize chronic use of low-dose prednisone therapy owing to the risk of osteoporosis and other long-term complications; however, the use of chronic prednisone therapy is unavoidable in some cases. High-dose glucocorticoids may be necessary for the treatment of severe extraarticular manifestations of RA, such as ILD. Finally, if a patient exhibits one or a few actively inflamed joints, the clinician may consider intraarticular injection of an intermediate-acting glucocorticoid such as triamcinolone acetonide. This approach may allow for rapid control of inflammation in a limited number of affected joints. Caution must be exercised to appropriately exclude joint infection as it often mimics an RA flare.

Osteoporosis ranks as an important long-term complication of chronic prednisone use. Based on a patient's risk factors, including total prednisone dosage, length of treatment, gender, race, and bone density, treatment with a bisphosphonate may be appropriate for primary prevention of glucocorticoid-induced osteoporosis. Other agents, including teriparatide and denosumab, have been approved for the treatment of osteoporosis and may be indicated in certain cases. Although prednisone use is known to increase the risk of peptic ulcer disease, especially with concomitant NSAID use, no evidence-based guidelines have been published regarding the use of gastrointestinal ulcer prophylaxis in this situation.

DMARDS

DMARDs are so named because of their ability to slow or prevent structural progression of RA. The conventional DMARDs include hydroxychloroquine, sulfasalazine, methotrexate, and leflunomide; they exhibit a delayed onset of action of ~6–12 weeks. Methotrexate is the DMARD of choice for the treatment of RA and is the anchor drug for most combination therapies. It was approved for the treatment of RA in 1988 and remains the benchmark for the efficacy and safety of new disease-modifying therapies. At the dosages used for the treatment of RA, methotrexate has been shown to stimulate adenosine release from cells, producing an anti-inflammatory effect. Methotrexate is administered weekly by the oral or subcutaneous route. Folic acid is taken as co-therapy to mitigate some of methotrexate's side effects. The clinical efficacy of leflunomide, an inhibitor of pyrimidine synthesis, appears similar to that of methotrexate; it has been shown in well-designed trials to be effective for the treatment of RA as monotherapy or in combination with methotrexate and other DMARDs.

Although similar to the other DMARDs in its slow onset of action, hydroxychloroquine has not been shown to delay radiographic progression of disease and thus is not considered to be a true DMARD. In clinical practice, hydroxychloroquine is generally used for treatment of early, mild disease or as adjunctive therapy in combination with other DMARDs. It is a prescribed at a dosage of 5 mg/kg of body weight or less to decrease the risk of retinal toxicity. Sulfasalazine is used in a similar manner and has been shown in randomized, controlled trials to reduce radiographic progression of disease. Minocycline, gold salts, penicillamine, azathioprine, and cyclosporine have all been used for the treatment of RA with varying degrees of success; however, they are used sparingly now due to their inconsistent clinical efficacy or unfavorable toxicity profile.

BIOLOGICALS

Biologic DMARDs have revolutionized the treatment of RA over the past decade (Table 358-2). They are protein therapeutics designed mostly to target cytokines and cell-surface molecules. The TNF inhibitors were the first biologicals approved for the treatment of RA. Anakinra, an IL-1 receptor antagonist, was approved shortly thereafter; however, its benefits have proved to be relatively modest compared with the other biologicals, and therefore, this biological is rarely used for the treatment of RA with the availability of other more effective agents. Abatacept, rituximab, and tocilizumab are the newest members of this class.

Anti-TNF Agents The development of TNF inhibitors was originally spurred by the experimental finding that TNF-α is a critical upstream mediator of joint inflammation. Currently, five agents that inhibit TNF-α are approved for the treatment of RA. There are three different anti-TNF monoclonal antibodies. Infliximab is a chimeric (part mouse and human) monoclonal antibody, whereas adalimumab and golimumab are humanized monoclonal antibodies. Certolizumab pegol is a pegylated Fab′ fragment of a humanized monoclonal antibody to TNF-α. Lastly, etanercept is a soluble fusion protein comprising the TNF receptor 2 in covalent linkage with the Fc portion of IgG1. All of the TNF inhibitors have been shown in randomized controlled clinical trials to reduce the signs and symptoms of RA, slow radiographic progression of joint damage, and improve physical function and quality of life. Anti-TNF drugs are typically used in combination with background methotrexate therapy. This combination regimen, which affords

TABLE 358-2 DMARDs Used for the Treatment of Rheumatoid Arthritis

DRUG	DOSAGE	SERIOUS TOXICITIES	OTHER COMMON SIDE EFFECTS	INITIAL EVALUATION	MONITORING
Hydroxychloroquine	200–400 mg/d orally (≤5 mg/kg)	Irreversible retinal damage Cardiotoxicity Blood dyscrasia	Nausea Diarrhea Headache Rash	Eye examination if >40 years old or prior ocular disease	Optical coherence tomography and visual field testing every 12 months
Sulfasalazine	Initial: 500 mg orally twice daily Maintenance: 1000–1500 mg twice daily	Granulocytopenia Hemolytic anemia (with G6PD deficiency)	Nausea Diarrhea Headache	CBC, LFTs G6PD level	CBC every 2–4 weeks for first 3 months, then every 3 months
Methotrexate	10–25 mg/week orally or SQ Folic acid 1 mg/d to reduce toxicities	Hepatotoxicity Myelosuppression Infection Interstitial pneumonitis Pregnancy category X	Nausea Diarrhea Stomatitis/mouth ulcers Alopecia Fatigue	CBC, LFTs Viral hepatitis panel[a] Chest x-ray	CBC, creatinine, LFTs every 2–3 months
Leflunomide	10–20 mg/d	Hepatotoxicity Myelosuppression Infection Pregnancy category X	Alopecia Diarrhea	CBC, LFTs Viral hepatitis panel[a]	CBC, creatinine, LFTs every 2–3 months
TNF-α inhibitors	Infliximab: 3 mg/kg IV at weeks 0, 2, 6, then every 8 weeks. May increase dose up to 10 mg/kg every 4 weeks	↑ Risk bacterial, fungal infections Reactivation of latent TB ↑ Lymphoma risk (controversial) Drug-induced lupus Neurologic deficits	Infusion reaction ↑ LFTs	Tuberculosis screening[b]	LFTs periodically
	Etanercept: 50 mg SQ weekly, or 25 mg SQ biweekly	As above	Injection site reaction	Tuberculosis screening	Monitor for injection site reactions
	Adalimumab: 40 mg SQ every other week	As above	Injection site reaction	Tuberculosis screening	Monitor for injection site reactions
	Golimumab: 50 mg SQ monthly	As above	Injection site reaction	Tuberculosis screening	Monitor for injection site reactions
	Certolizumab: 400 mg SQ weeks 0, 2, 4, then 200 mg every other week	As above	Injection site reaction	Tuberculosis screening	Monitor for injection site reactions
Abatacept	Weight based: <60 kg: 500 mg 60–100 kg: 750 mg >100 kg: 1000 mg IV dose at weeks 0, 2, and 4, and then every 4 weeks OR 125 mg SQ weekly	↑ Risk bacterial, viral infections	Headache Nausea	Tuberculosis screening	Monitor for infusion reactions
Anakinra	100 mg SQ daily	↑ Risk bacterial, viral infections Reactivation of latent TB Neutropenia	Injection site reaction Headache	Tuberculosis screening CBC with differential	CBC every month for 3 months, then every 4 months for 1 year Monitor for injection site reactions
Rituximab	1000 mg IV × 2, days 0 and 14 May repeat course every 24 weeks or more Premedicate with methyl-prednisolone 100 mg to decrease infusion reaction	↑ Risk bacterial, viral infections Infusion reaction Cytopenia Hepatitis B reactivation	Rash Fever	CBC Viral hepatitis panel[a]	CBC at regular intervals
Interleukin-6 inhibitors	Tocilizumab: 4–8 mg/kg IV monthly OR 162 mg SQ every other week (<100 kg weight) 162 mg SQ every week (≥100 kg weight) Sarilumab: 200 mg SQ every other week	Risk of infection Infusion reaction LFT elevation Dyslipidemia Cytopenias		Tuberculosis screening	CBC and LFTs at regular intervals

TABLE 358-2 DMARDs Used for the Treatment of Rheumatoid Arthritis (Continued)

DRUG	DOSAGE	SERIOUS TOXICITIES	OTHER COMMON SIDE EFFECTS	INITIAL EVALUATION	MONITORING
JAK inhibitors	Tofacitinib: 5 mg orally twice daily OR 11 mg orally daily Upadacitinib: 15 mg orally daily Baricitinib: 2 mg orally daily	Risk of infection LFT elevation Dyslipidemia Neutropenia Thrombosis	Upper respiratory tract infections Diarrhea Headache Nasopharyngitis	Tuberculosis screening	CBC, LFTs, and lipids at regular intervals

[a]Viral hepatitis panel: hepatitis B surface antigen, hepatitis C viral antibody. [b]Tuberculosis screening can be performed using a Mantoux tuberculin skin test or blood interferon-gamma release assay.

Abbreviations: CBC, complete blood count; DMARDs, disease-modifying antirheumatic drugs; G6PD, glucose-6-phosphate dehydrogenase; IV, intravenous; LFTs, liver function tests; JAK, Janus kinase; SQ, subcutaneous; TB, tuberculosis.

maximal benefit in many cases, is often the next step for treatment of patients with an inadequate response to methotrexate therapy. Etanercept, adalimumab, certolizumab pegol, and golimumab have also been approved for use as monotherapy.

Anti-TNF agents should be avoided in patients with active infection or a history of hypersensitivity to these agents and are contraindicated in patients with chronic hepatitis B infection or class III/IV congestive heart failure. The major concern is the increased risk for infection, including serious bacterial infections, opportunistic fungal infection, and reactivation of latent tuberculosis. For this reason, all patients are screened for latent tuberculosis according to national guidelines prior to starting anti-TNF therapy (Chap. 178). In the United States, patients have historically been skin tested for tuberculosis using an intradermal injection of purified protein derivative (PPD); individuals with skin reactions of >5 mm are presumed to have had previous exposure to tuberculosis and are evaluated for active disease and treated accordingly. Use of an IFN-γ release assay may also be appropriate for screening as some data suggest a lower rate of false-negative and false-positive tests with an IFN-γ release assay compared with skin testing with PPD in patients treated with corticosteroids. While a combination of PPD skin test and IFN-γ release assay may offer the highest sensitivity for screening purposes, no consensus guidelines exist.

Anakinra Anakinra is the recombinant form of the naturally occurring IL-1 receptor antagonist. Although anakinra has seen limited use for the treatment of RA, it has enjoyed a resurgence of late as an effective therapy of systemic juvenile-onset inflammatory arthritis and adult Still's disease and some rare inherited syndromes dependent on IL-1 production, including neonatal-onset inflammatory disease, Muckle-Wells syndrome, familial cold urticaria, and macrophage activation syndrome.

Abatacept Abatacept is a soluble fusion protein consisting of the extracellular domain of human CTLA-4 linked to the modified portion of human IgG. It inhibits the co-stimulation of T cells by blocking CD28-CD80/86 interactions and may also inhibit the function of antigen-presenting cells by reverse signaling through CD80 and CD86. Abatacept has been shown in clinical trials to reduce disease activity, slow radiographic progression of damage, and improve functional disability. Many patients receive abatacept in combination with a conventional DMARD. Abatacept therapy has been associated with an increased risk of infection.

Rituximab Rituximab is a chimeric monoclonal antibody directed against CD20, a cell-surface molecule expressed by most mature B lymphocytes. It works by depleting B cells, which in turn, leads to a reduction in the inflammatory response by unknown mechanisms. These mechanisms may include a reduction in autoantibodies, inhibition of T-cell activation, and alteration of cytokine production. Rituximab has been approved for the treatment of refractory RA (failure of treatment with a TNF-α inhibitor) in combination with methotrexate and has been shown to be more effective for patients with seropositive than seronegative disease. Rituximab therapy has been associated with mild to moderate infusion reactions as well as an increased risk of infection. Notably, there have been rare isolated reports of a potentially lethal brain disorder, progressive multifocal leukoencephalopathy (PML), in association with rituximab therapy, although the absolute risk of this complication appears to be very low in patients with RA. Most of these cases have occurred on a background of previous or current exposure to other potent immunosuppressive drugs.

Anti-IL-6 Agents IL-6 is a proinflammatory cytokine implicated in the pathogenesis of RA, with effects on both joint inflammation and damage. IL-6 binding to its receptor activates intracellular signaling pathways that affect the acute-phase response, cytokine production, and osteoclast activation. Tocilizumab and sarilumab are both monoclonal antibodies directed against the membrane and soluble forms of the IL-6 receptor. Clinical trials attest to the clinical efficacy of these therapies for RA, both as monotherapy and in combination with methotrexate and other DMARDs. Anti-IL-6 receptor agents have been associated with an increased risk of infection, neutropenia, and thrombocytopenia; the hematologic abnormalities appear to be reversible upon stopping the drug. In addition, this agent has been shown to increase LDL cholesterol. However, it is not known if this effect on lipid levels increases the risk for development of atherosclerotic disease.

TARGETED SYNTHETIC DMARDs

Because some patients do not adequately respond to conventional DMARDs or biologic therapy, other therapeutic targets have been investigated to fill this gap. Recently, drug development in RA has focused attention on the intracellular signaling pathways that transduce the positive signals of cytokines and other inflammatory mediators binding to their cell-surface receptors that create the positive feedback loops in the immune response. These targeted synthetic DMARDs aim to provide the same efficacy as biological therapies in an oral formulation.

JAK Inhibitors Although several different kinases have been evaluated as potential treatment targets in RA, only JAK inhibitors have demonstrated safety and efficacy for the treatment of RA; they are classified as targeted synthetic (ts) DMARDS. The JAK family comprises four members (JAK1, JAK2, JAK3, and tyrosine kinase 2 [Tyk2]) that link extracellular cytokine receptors with intracellular signaling domains. They mediate signaling of the receptors for the common γ-chain-related cytokines IL-2, -4, -7, -9, -15, and -21, as well as IFN-γ and IL-6. These cytokines all play roles in promoting T- and B-cell activation as well as inflammation.

Tofacitinib is a selective JAK1 and JAK3 inhibitor with minor inhibitory effects on JAK2 and Tyk2, whereas baricitinib is a selective JAK1 and JAK2 inhibitor with moderate inhibition of Tyk2 and minimal inhibition of JAK3. Upadacitinib is a predominately

selective inhibitor of JAK1. It has been hypothesized that preferential inhibition of JAK1 might reduce dose-related toxicity, without a significant detriment of its efficacy. JAK inhibitors can be used as monotherapy or in combination with methotrexate. Possible side effects of these agents include elevated serum transaminases indicative of liver injury, neutropenia, increased cholesterol levels, and elevation in serum creatinine. Recent studies have found an increased risk of thrombosis, major adverse cardiovascular events and malignancies in patients taking tofacitinib compared with TNF inhibitors. Its use is also associated with an increased risk of infections, including bacterial infections and herpes zoster.

TREATMENT OF EXTRAARTICULAR MANIFESTATIONS

In general, treatment of the underlying RA favorably modifies extraarticular manifestations, and it appears that aggressive management of early disease can potentially prevent their occurrence in the first place. RA-ILD, however, can be particularly challenging to treat because some of the DMARDs used for the treatment of RA are associated with pulmonary toxicity, such as methotrexate and leflunomide. High doses of corticosteroids and adjunctive immunosuppressive agents, such as azathioprine, mycophenolate mofetil, and rituximab have been used for treatment of RA-ILD.

APPROACH TO THE PATIENT

Rheumatoid Arthritis

The treatment of RA adheres to the following principles and goals: (1) early, aggressive therapy to prevent joint damage and disability; (2) frequent modification of DMARD therapy to achieve treatment goals with utilization of combination therapy where appropriate; (3) individualization of DMARD therapy in an attempt to maximize response and minimize side effects; (4) minimal use of long-term glucocorticoid therapy; and (5) achieving, whenever possible, low disease activity or clinical remission. A considerable amount of evidence supports this intensive treatment approach.

As mentioned earlier, methotrexate is the DMARD of first choice for initial treatment of moderate to severe RA. Failure to achieve adequate improvement with methotrexate therapy calls for a change in DMARD therapy, usually a transition to an effective combination regimen. Effective combinations include methotrexate, sulfasalazine, and hydroxychloroquine (oral triple therapy); methotrexate and leflunomide; and methotrexate plus a biological. The combination of methotrexate and an anti-TNF agent, for example, has been shown in randomized controlled trials to be superior to methotrexate alone, not only for reducing signs and symptoms of disease but also for retarding the progression of structural joint damage. Predicting which patients are at higher risk for developing radiologic joint damage is imprecise at best, although some factors such as an elevated serum level of acute-phase reactants, high burden of joint inflammation, and the presence of erosive disease are associated with increased likelihood of developing structural injury.

In 2015, the ACR updated and published their guidelines for the treatment of RA. They do make a distinction in the treatment of patients with early (<6 months of disease duration) and established disease and highlight the use of a treat-to-target approach and the need to switch or add therapies for worsening or persistent moderate/high disease activity. For example, in patients with early RA who have persistent moderate/high disease activity on DMARD monotherapy, providers should consider escalation to combination DMARD therapy or switching to an anti-TNF +/– methotrexate or a non-TNF biologic +/– methotrexate. Since a more intensive initial approach (e.g., combination DMARD therapy) has been shown to produce superior long-term outcomes compared with starting methotrexate alone, the usual approach is to begin with methotrexate and rapidly step up (e.g., after 3–6 months) to a combination of DMARDs or an anti-TNF or non-TNF biological agent in the absence of an adequate therapeutic response.

TABLE 358-3 ACR/EULAR Provisional Definition of Remission in Rheumatoid Arthritis

At any time point, patient must satisfy all of the following:
Tender joint count ≤1
Swollen joint count ≤1
C-reactive protein ≤1 mg/dL
Patient global assessment ≤1 (on a 0–10 scale)
OR
At any time point, patient must have a Simplified Disease Activity Index score of ≤3.3

Abbreviations: ACR, American College of Rheumatology; EULAR, European League Against Rheumatism.

Source: Reproduced with permission from DT Felson et al; American College of Rheumatology/European League Against Rheumatism provisional definition of remission in rheumatoid arthritis for clinical trials. Arthritis Rheum 63:573, 2011.

Some patients may not respond to an anti-TNF drug or may be intolerant of its side effects. Initial responders to an anti-TNF agent who later experience worsening of their condition may benefit from switching to another anti-TNF agent or an alternative biological with a different mechanism of action. Indeed, some studies suggest that switching to an alternative biological such as abatacept is more effective than switching to another anti-TNF drug. Unacceptable toxicity from an anti-TNF agent may also call for switching to another biological or tsDMARD with a different mechanism of action or a conventional DMARD regimen.

Studies have also shown that oral triple therapy (hydroxychloroquine, methotrexate, and sulfasalazine) may be used effectively for the treatment of early RA. Treatment may be initiated with methotrexate alone and, lacking an adequate treatment response, followed within 6 months by a step-up to oral triple therapy.

A clinical state defined as low disease activity or remission is the optimal goal of therapy, although most patients never achieve complete remission despite every effort to achieve it. Composite indices, such as the Disease Activity Score-28 (DAS-28), are useful for classifying states of low disease activity and remission; however, they are imperfect tools due to the limitations of the clinical joint examination in which low-grade synovitis may escape detection. Complete remission has been stringently defined as the total absence of all articular and extraarticular inflammation and immunologic activity related to RA. However, evidence for this state can be difficult to demonstrate in clinical practice. In an effort to standardize and simplify the definition of remission for clinical trials, the ACR and EULAR developed two provisional operational definitions of remission in RA **(Table 358-3)**. A patient may be considered in remission if the patient (1) meets all the clinical and laboratory criteria listed in Table 358-3 or (2) has a composite SDAI score of <3.3. The SDAI is calculated by taking the sum of a tender joint and swollen joint count (using 28 joints), patient global assessment (0–10 scale), physician global assessment (0–10 scale), and CRP (in mg/dL). This definition of remission does not take into account the possibility of subclinical synovitis or that damage alone may produce a tender or swollen joint. Ignoring the semantics of these definitions, the aforementioned remission criteria are nonetheless useful for setting a level of disease control that will likely result in minimal or no progression of structural damage and disability.

PHYSICAL ACTIVITY AND ASSISTIVE DEVICES

In principle, all patients with RA should receive a prescription for exercise and physical activity. Dynamic strength training, community-based comprehensive physical therapy, and physical-activity coaching (emphasizing achieving 150 min of moderate-to-vigorous physical activity per week) have all been shown to improve muscle strength and perceived health status, as well as improve DAS-28 scores and inflammatory markers. Foot orthotics for painful valgus deformity decrease foot pain and may reduce disability and functional limitations. Judicious use of wrist splints can also decrease

pain; however, their benefits may be offset by decreased dexterity and variably curb grip strength.

SURGERY

Surgical procedures may improve pain and disability in RA with varying degrees of reported long-term success—most notably the hands, wrists, and feet. For large joints, such as the knee, hip, shoulder, or elbow, the preferred option for advanced joint disease may be total joint arthroplasty. A few surgical options exist for dealing with the smaller hand joints. Silicone implants are the most common prosthetic for MCP arthroplasty and are generally implanted in patients with severe decreased arc of motion, marked flexion contractures, MCP joint pain with radiographic abnormalities, and severe ulnar drift. Arthrodesis and total wrist arthroplasty are reserved for patients with severe disease who have substantial pain and functional impairment. These two procedures appear to have equal efficacy in terms of pain control and patient satisfaction. Numerous surgical options exist for correction of hallux valgus in the forefoot, including arthrodesis and arthroplasty, as well as primarily arthrodesis for refractory hindfoot pain.

OTHER MANAGEMENT CONSIDERATIONS

Pregnancy Up to 75% of female RA patients will note overall improvement in symptoms during pregnancy but often will flare after delivery. Flares during pregnancy are generally treated with low doses of prednisone; hydroxychloroquine and sulfasalazine are probably the safest DMARDs to use during pregnancy. Methotrexate and leflunomide therapy are contraindicated during pregnancy due to their teratogenicity in animals and humans. The experience with biologic agents has been insufficient to make specific recommendations for their use during pregnancy. Many patients will discontinue biologic agents during pregnancy; however, active inflammatory disease is associated with worse pregnancy outcomes, and thus controlling disease activity may take precedence. In general, biologics are thought to be safe through the second trimester.

Elderly Patients RA presents in up to one-third of patients after the age of 60; however, older individuals may receive less aggressive treatment due to concerns about increased risks of drug toxicity. Studies suggest that conventional DMARDs and biological agents are equally effective and safe in younger and older patients. Due to comorbidities, many elderly patients have an increased risk of infection. Aging also leads to a gradual decline in renal function that may raise the risk for side effects from NSAIDs and some DMARDS, such as methotrexate. Renal function must be taken into consideration before prescribing methotrexate, which is mostly cleared by the kidneys. To reduce the risks of side effects, methotrexate doses may need to be adjusted downward for the drop in renal function that usually comes with the seventh and eighth decades of life. Methotrexate is usually not prescribed for patients with a serum creatinine >2 mg/dL.

GLOBAL CHALLENGES

Developing countries are finding an increase in the incidence of noncommunicable, chronic diseases such as diabetes, cardiovascular disease, and RA in the face of ongoing poverty, rampant infectious disease, and poor access to modern health care facilities. In these areas, patients tend to have a greater delay in diagnosis and limited access to specialists and, thus, greater disease activity and disability at presentation. In addition, infection risk remains a significant issue for the treatment of RA in developing countries because of the immunosuppression associated with the use of glucocorticoids and most DMARDs. For example, in some developing countries, patients undergoing treatment for RA have a substantial increase in the incidence of tuberculosis, which demands the implementation of far more comprehensive screening practices and liberal use of isoniazid prophylaxis than in developed countries. The increased prevalence of hepatitis B and C, as well as human immunodeficiency virus (HIV), in these developing countries also poses challenges. Reactivation of viral hepatitis has been observed in association with some of the DMARDs, such as rituximab. Also, reduced access to antiretroviral therapy may limit the control of HIV infection and therefore the choice of DMARD therapies.

Despite these challenges, one should attempt to initiate early treatment of RA in the developing countries with the resources at hand. Hydroxychloroquine, sulfasalazine, and methotrexate are all reasonably accessible throughout the world where they can be used as both monotherapy and in combination with other drugs. The use of biological agents is increasing in the developed countries as well as in other areas around the world, although their use is limited by high cost; national protocols restrict their use, and concerns remain about the risk for opportunistic infections.

SUMMARY

Improved understanding of the pathogenesis of RA and its treatment has dramatically revolutionized the management of this disease. The outcomes of patients with RA are vastly superior to those of the prebiologic modifier era; more patients than in years past are able to avoid significant disability and continue working, albeit with some job modifications in many cases. The need for early and aggressive treatment of RA as well as frequent follow-up visits for monitoring of drug therapy has implications for our health care system. Primary care physicians and rheumatologists must be prepared to work together as a team to reach the ambitious goals of best practice. In many settings, rheumatologists have reengineered their practice in a way that places high priority on consultations for any new patient with early inflammatory arthritis.

The therapeutic regimens for RA are becoming increasingly complex with the rapidly expanding armamentarium. Patients receiving these therapies must be carefully monitored by both the primary care physician and the rheumatologist to minimize the risk of side effects and identify quickly any complications of chronic immunosuppression. Also, prevention and treatment of RA-associated conditions such as ischemic heart disease and osteoporosis will likely benefit from a team approach owing to the value of multidisciplinary care.

Research will continue to search for new therapies with superior efficacy and safety profiles and investigate treatment strategies that can bring the disease under control more rapidly and nearer to remission. However, prevention and cure of RA will likely require new breakthroughs in our understanding of disease pathogenesis. Several prevention trials in RA are currently underway and focus on a variety of prevention strategies in individuals who have serologic and/or clinical features at higher risk than the general population for developing RA. Equally important is the identification of predictive biomarkers that enable a personalized approach to DMARD therapy for RA.

359 Acute Rheumatic Fever

Joseph Kado, Jonathan Carapetis

Acute rheumatic fever (ARF) is a multisystem disease resulting from an autoimmune reaction to infection with group A *Streptococcus*. Although many parts of the body may be affected, almost all of the manifestations resolve completely. The major exception is cardiac valvular damage (rheumatic heart disease [RHD]), which may persist after the other features have disappeared.

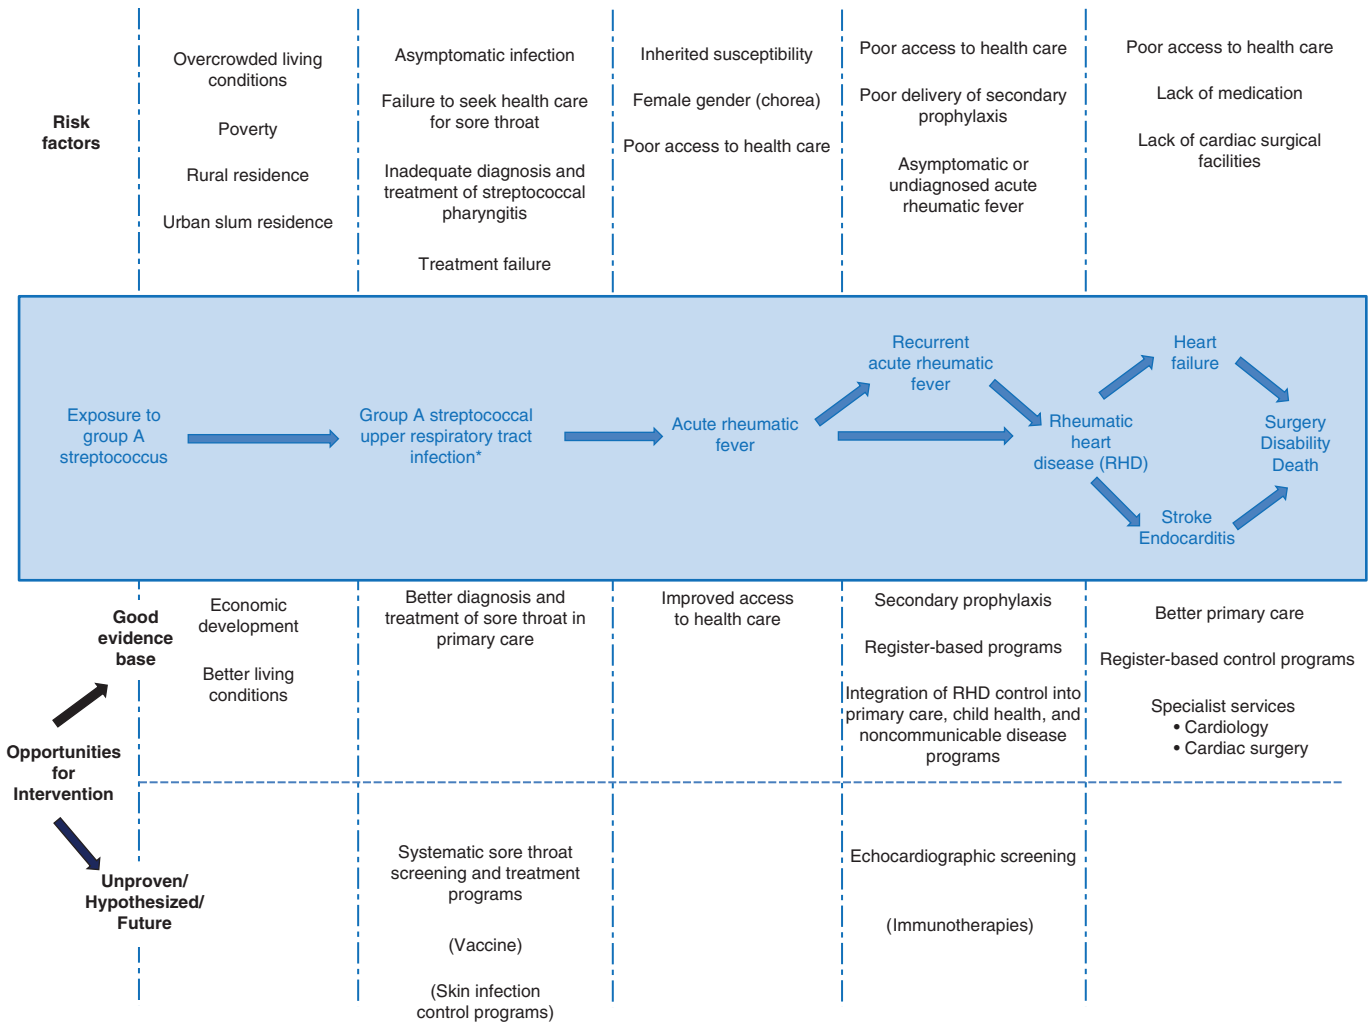
GLOBAL CONSIDERATIONS

ARF and RHD are diseases of poverty. They were common in all countries until the early twentieth century, when their incidence began to decline in industrialized nations. This decline was largely attributable to improved living conditions—particularly less crowded housing and better hygiene—which resulted in reduced transmission of group A streptococci. The introduction of antibiotics and improved systems of medical care had a supplemental effect.

The virtual disappearance of ARF and reduction in the incidence of RHD in industrialized countries during the first half of the twentieth century unfortunately was not replicated in developing countries, where these diseases continue unabated. RHD is the most common cause of acquired heart disease in children in developing countries and is a major cause of mortality and morbidity in adults as well. It has been estimated that between 29.7 and 43.1 million people worldwide are affected by RHD, with >300,000 deaths occurring each year. Some 95% of ARF cases and RHD deaths now occur in developing countries, with particularly high rates in sub-Saharan Africa, Pacific nations, Australasia, and South and Central Asia. The pathogenetic pathway from exposure to group A *Streptococcus* followed by pharyngeal or superficial skin infection and subsequent development of ARF, ARF recurrences, and development of RHD and its complications is associated with a range of risk factors and, therefore, potential interventions at each point **(Fig. 359-1)**. In affluent countries, many of these risk factors are well controlled, and where needed, interventions are in place. Unfortunately, the greatest burden of disease is found in developing countries, most of which do not have the resources, capacity, and/or interest to tackle this multifaceted disease. In particular, few developing countries have a coordinated, register-based RHD control program, which is proven to be cost-effective in reducing the burden of RHD. Enhancing awareness of RHD and mobilizing resources for its control in developing countries are issues requiring international attention.

EPIDEMIOLOGY

ARF is mainly a disease of children age 5–14 years. Initial episodes become less common in older adolescents and young adults and are rare in persons aged >30 years. By contrast, recurrent episodes of ARF remain relatively common in adolescents and young adults. This pattern contrasts with the prevalence of RHD, which peaks between 25 and 40 years. There is no clear gender association for ARF, but RHD more commonly affects females, sometimes up to twice as frequently as males.



**Increasing evidence of the role of streptococcal skin infection*

FIGURE 359-1 Pathogenetic pathway for acute rheumatic fever and rheumatic heart disease (RHD), with associated risk factors and opportunities for intervention at each step. Interventions in *parentheses* are either unproven or currently unavailable.

PATHOGENESIS

ORGANISM FACTORS

Conventional teaching has it that ARF is exclusively caused by infection of the upper respiratory tract with group A streptococci (Chap. 148). Although classically, certain M-serotypes (particularly types 1, 3, 5, 6, 14, 18, 19, 24, 27, and 29) were associated with ARF, recent evidence demonstrates that many more M-serotypes are rheumatogenic and that so-called "rheumatogenic motifs" are found in only a minority of serotypes associated with rheumatic fever. This epidemiologic evidence also points to a clear role of skin infection in the pathogenesis of ARF. The potential role of groups C and G streptococci is unclear at this time.

HOST FACTORS

Based on epidemiologic evidence, ~3–6% of any population may be susceptible to ARF, and this proportion does not vary dramatically between populations. Findings of familial clustering of cases and concordance in monozygotic twins—particularly for chorea—confirm that susceptibility to ARF is an inherited characteristic, with 44% concordance in monozygotic twins compared to 12% in dizygotic twins and heritability more recently estimated at 60%. Most evidence for host factors focuses on immunologic determinants. Some human leukocyte antigen (HLA) class II alleles, particularly HLA-DR7 and HLA-DR4, appear to be associated with susceptibility, whereas other class II alleles have been associated with protection (HLA-DR5, HLA-DR6, HLA-DR51, HLA-DR52, and HLA-DQ). Associations have also been described with polymorphisms at the tumor necrosis factor α locus (TNF-α-308 and TNF-α-238), high levels of circulating mannose-binding lectin, and Toll-like receptors. Recent genome-wide association studies in different populations have identified connections at the HLA region, particularly HLA-DQA1 to HLA-DQB1, and the immunoglobulin heavy chain locus.

THE IMMUNE RESPONSE

The most widely accepted theory of rheumatic fever pathogenesis is based on the concept of molecular mimicry, whereby an immune response targeted at streptococcal antigens (mainly thought to be on the M protein and the *N*-acetylglucosamine of group A streptococcal carbohydrate) also recognizes human tissues. In this model, cross-reactive antibodies bind to endothelial cells on the heart valve, leading to activation of the adhesion molecule VCAM-1, with resulting recruitment of activated lymphocytes and lysis of endothelial cells in the presence of complement. The latter leads to release of peptides including laminin, keratin, and tropomyosin, which, in turn, activates cross-reactive T cells that invade the heart, amplifying the damage and causing epitope spreading. An alternative hypothesis proposes that the initial damage is due to streptococcal invasion of epithelial surfaces, with binding of M protein to type IV collagen allowing it to become immunogenic, but not through the mechanism of molecular mimicry.

CLINICAL FEATURES

There is a latent period of ~3 weeks (1–5 weeks) between the precipitating group A streptococcal infection and the appearance of the clinical features of ARF. The exceptions are chorea and indolent carditis, which may follow prolonged latent periods lasting up to 6 months. Although many patients report a prior sore throat, the preceding group A streptococcal infection is commonly subclinical; in these cases, it can only be confirmed using streptococcal antibody testing. The most common clinical features are polyarthritis (present in 60–75% of cases) and carditis (50–75%). The prevalence of chorea in ARF varies substantially between populations, ranging from <2 to 30%. Erythema marginatum and subcutaneous nodules are now rare, being found in <5% of cases.

HEART INVOLVEMENT

Up to 75% of patients with ARF progress to RHD. The endocardium, pericardium, or myocardium may be affected. Valvular damage is the hallmark of rheumatic carditis. The mitral valve is almost always affected, sometimes together with the aortic valve; isolated aortic valve involvement is rare. Damage to the pulmonary or tricuspid valves is usually secondary to increased pulmonary pressures resulting from left-sided valvular disease. Early valvular damage leads to regurgitation. Over ensuing years, usually as a result of recurrent episodes, leaflet thickening, scarring, calcification, and valvular stenosis may develop (Fig. 359-2). See **Videos 359-1** and **359-2.** Therefore, the characteristic manifestation of carditis in previously unaffected individuals is mitral regurgitation, sometimes accompanied by aortic regurgitation. Myocardial inflammation may affect electrical conduction pathways, leading to P-R interval prolongation (first-degree atrioventricular block or rarely higher-level block) and softening of the first heart sound.

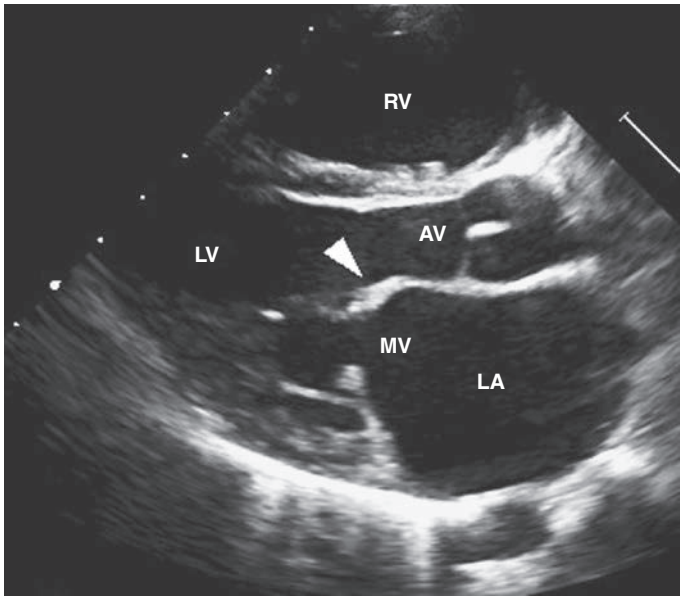


FIGURE 359-2 Transthoracic echocardiographic image from a 5-year-old boy with chronic rheumatic heart disease. This diastolic image demonstrates leaflet thickening, restriction of the anterior mitral valve leaflet tip and doming of the body of the leaflet toward the interventricular septum. This appearance (marked by the *arrowhead*) is commonly described as a "hockey stick" or an "elbow" deformity. AV, aortic valve; LA, left atrium; LV, left ventricle; MV, mitral valve; RV, right ventricle. *(Courtesy of Dr. Bo Remenyi, Department of Paediatric and Congenital Cardiac Services, Starship Children's Hospital, Auckland, New Zealand.)*

People with RHD are often asymptomatic for many years before their valvular disease progresses to cause cardiac failure. Moreover, particularly in resource-poor settings, the diagnosis of ARF is often not made, so children, adolescents, and young adults may have RHD but not know it. These cases can be diagnosed using echocardiography; auscultation is poorly sensitive and specific for RHD diagnosis in asymptomatic patients. Echocardiographic screening of school-aged children in populations with high rates of RHD is becoming more widespread and has been facilitated by improving technologies in portable echocardiography and the availability of consensus guidelines for the diagnosis of RHD on echocardiography (Table 359-1). Although a diagnosis of definite RHD on screening echocardiography should lead to commencement of secondary prophylaxis, the clinical significance of borderline RHD has yet to be determined.

JOINT INVOLVEMENT

The most common form of joint involvement in ARF is arthritis, i.e., objective evidence of inflammation, with hot, swollen, red, and/or tender joints, and involvement of more than one joint (i.e., polyarthritis). Polyarthritis is typically migratory, moving from one joint to another over a period of hours. ARF almost always affects the large joints—most commonly the knees, ankles, hips, and elbows—and is asymmetric. The pain is severe and usually disabling until anti-inflammatory medication is commenced.

Less severe joint involvement is also relatively common and has been recognized as a potential major manifestation in high-risk

TABLE 359-1 World Heart Federation Criteria for Echocardiographic Diagnosis of Rheumatic Heart Disease (RHD) in Individuals <20 Years of Age[a]

Definite RHD (either A, B, C, or D)
(A) Pathologic MR and at least two morphologic features of RHD of the mitral valve
(B) MS mean gradient ≥4 mmHg (note: congenital MV anomalies must be excluded)
(C) Pathologic AR and at least two morphologic features of RHD of the AV (note: bicuspid AV and dilated aortic root must be excluded)
(D) Borderline disease of both the MV and AV
Borderline RHD (either A, B, or C)
(A) At least two morphologic features of RHD of the MV without pathologic MR or MS
(B) Pathologic MR
(C) Pathologic AR
Normal Echocardiographic Findings (all of A, B, C, and D)
(A) MR that does not meet all four Doppler criteria (physiologic MR)
(B) AR that does not meet all four Doppler criteria (physiologic AR)
(C) An isolated morphologic feature of RHD of the MV (e.g., valvular thickening), without any associated pathologic stenosis or regurgitation
(D) Morphologic feature of RHD of the AV (e.g., valvular thickening), without any associated pathologic stenosis or regurgitation
Definitions of Pathologic Regurgitation and Morphologic Features of RHD
Pathologic MR: All of the following: seen in two views; in at least one view, jet length 2 cm; peak velocity ≥3 m/s; pansystolic jet in at least one envelope
Pathologic AR: All of the following: seen in two views; in at least one view, jet length ≥1 cm; peak velocity ≥3 m/s; pandiastolic jet in at least one envelope
Morphologic features of RHD in MV: anterior MV leaflet thickening ≥3 mm (age specific); chordal thickening; restricted leaflet motion; excessive leaflet tip motion during systole
Morphologic features of RHD in AV: irregular or focal thickening; coaptation defect; restricted leaflet motion; prolapse

[a]For criteria in individuals >20 years of age, see source document.

Abbreviations: AR, aortic regurgitation; AV, aortic valve; MR, mitral regurgitation; MS, mitral stenosis; MV, mitral valve.

Source: Reproduced with permission from B Remenyi et al: World Heart Federation criteria for echocardiographic diagnosis of rheumatic heart disease–an evidence-based guideline. Nat Rev Cardiol 9:297, 2012.

populations in the most recent revision of the Jones criteria. Arthralgia without objective joint inflammation usually affects large joints in the same migratory pattern as polyarthritis. In some populations, aseptic monoarthritis may be a presenting feature of ARF, which may, in turn, result from early commencement of anti-inflammatory medication before the typical migratory pattern is established.

The joint manifestations of ARF are highly responsive to salicylates and other nonsteroidal anti-inflammatory drugs (NSAIDs). Indeed, joint involvement that persists for more than 1 or 2 days after starting salicylates is unlikely to be due to ARF.

CHOREA

Sydenham's chorea commonly occurs in the absence of other manifestations, follows a prolonged latent period after group A streptococcal infection, and is found mainly in females. The choreiform movements affect particularly the head (causing characteristic darting movements of the tongue) and the upper limbs **(Chap. 436)**. They may be generalized or restricted to one side of the body (hemi-chorea). In mild cases, chorea may be evident only on careful examination, whereas in the most severe cases, the affected individuals are unable to perform activities of daily living. There is often associated emotional lability or obsessive-compulsive traits, which may last longer than the choreiform movements (which usually resolve within 6 weeks but sometimes may take up to 6 months). More than 50% of patients presenting with chorea will have carditis, for which reason echocardiography should be part of the workup.

SKIN MANIFESTATIONS

The classic rash of ARF is *erythema marginatum* **(Chap. 19)**, which begins as pink macules that clear centrally, leaving a serpiginous, spreading edge. The rash is evanescent, appearing and disappearing before the examiner's eyes. It occurs usually on the trunk, sometimes on the limbs, but almost never on the face.

Subcutaneous nodules occur as painless, small (0.5–2 cm), mobile lumps beneath the skin overlying bony prominences, particularly of the hands, feet, elbows, occiput, and occasionally the vertebrae. They are a delayed manifestation, appearing 2–3 weeks after the onset of disease, last for just a few days up to 3 weeks, and are commonly associated with carditis.

OTHER FEATURES

Fever occurs in most cases of ARF, although rarely in cases of pure chorea. Although high-grade fever (≥39°C) is the rule, lower grade temperature elevations are not uncommon. Elevated acute-phase reactants are also present in most cases.

EVIDENCE OF A PRECEDING GROUP A STREPTOCOCCAL INFECTION

With the exception of chorea and low-grade carditis, both of which may become manifest many months later, evidence of a preceding group A streptococcal infection is essential in making the diagnosis of ARF. Because most cases do not have a positive throat swab culture or rapid antigen test, serologic evidence is usually needed. The most common serologic tests are the anti-streptolysin O (ASO) and anti-DNase B (ADB) titers. Where possible, age-specific reference ranges should be determined in a local population of healthy people without a recent group A streptococcal infection.

CONFIRMING THE DIAGNOSIS

Because there is no definitive test, the diagnosis of ARF relies on the presence of a combination of typical clinical features together with evidence of the precipitating group A streptococcal infection, and the exclusion of other diagnoses. This uncertainty led Dr. T. Duckett Jones in 1944 to develop a set of criteria (subsequently known as the *Jones criteria*) to aid in the diagnosis. The most recent revision of the Jones criteria **(Table 359-2)** requires the clinician to determine if the patient is from a setting or population known to experience low rates of ARF. For this group, there is a set of "low-risk" criteria; for all others, there is a set of more sensitive criteria.

TREATMENT

Acute Rheumatic Fever

Patients with possible ARF should be followed closely to ensure that the diagnosis is confirmed, treatment of heart failure and other symptoms is undertaken, and preventive measures including commencement of secondary prophylaxis, inclusion on an ARF registry, and health education are commenced. Echocardiography should be performed on all possible cases to aid in making the diagnosis and to determine the severity at baseline of any carditis. Other tests that should be performed are listed in **Table 359-3**.

There is no treatment for ARF that has been proven to alter the likelihood of developing, or the severity of, RHD. With the exception of treatment of heart failure, which may be life-saving in cases of severe carditis, the treatment of ARF is symptomatic.

ANTIBIOTICS

All patients with ARF should receive antibiotics sufficient to treat the precipitating group A streptococcal infection **(Chap. 148)**. Penicillin is the drug of choice and can be given orally (as phenoxymethyl penicillin, 500 mg [250 mg for children ≤27 kg] PO twice daily, or amoxicillin, 50 mg/kg [maximum, 1 g] daily, for 10 days) or as a single dose of 1.2 million units (600,000 units for children ≤27 kg) IM benzathine penicillin G.

SALICYLATES AND NSAIDS

These may be used for the treatment of arthritis, arthralgia, and fever, once the diagnosis is confirmed. They are of no proven

TABLE 359-2 Jones Criteria

A. For All Patient Populations with Evidence of Preceding Group A Streptococcal Infection	
Diagnosis: initial ARF	2 major manifestations or 1 major plus 2 minor manifestations
Diagnosis: recurrent ARF	2 major or 1 major and 2 minor or 3 minor
B. Major Criteria	
Low-risk populations[a]	Moderate- and high-risk populations
Carditis[b]	Carditis
• Clinical and/or subclinical	• Clinical and/or subclinical
Arthritis	Arthritis
• Polyarthritis only	• Monoarthritis or polyarthritis
	• Polyarthralgia[c]
Chorea	Chorea
Erythema marginatum	Erythema marginatum
SC nodules	SC nodules
C. Minor Criteria	
Low-risk populations[a]	Moderate- and high-risk populations
Polyarthralgia	Monoarthralgia
Fever (≥38.5°C)	Fever (≥38°C)
ESR ≥60 mm in the first hour and/or CRP ≥3.0 mg/dL[d]	ESR ≥30 mm/h and/or CRP ≥3.0 mg/dL[d]
Prolonged PR interval[e], after accounting for age variability (unless carditis is a major criterion)	Prolonged PR interval[e], after accounting for age variability (unless carditis is a major criterion)

[a]Low-risk populations are those with ARF incidence ≤2 per 100,000 school-age children or all-age rheumatic heart disease prevalence of ≤1 per 1000 population per year. [b]Subclinical carditis indicates echocardiographic valvulitis. (See source document.) [c]Polyarthralgia should only be considered as a major manifestation in moderate- to high-risk populations after exclusion of other causes. As in past versions of the criteria, erythema marginatum and SC nodules are rarely "stand-alone" major criteria. Additionally, joint manifestations can only be considered in either the major or minor categories but not both in the same patient. (See source document for more information.) [d]CRP value must be greater than upper limit of normal for laboratory. Also, because ESR may evolve during the course of ARF, peak ESR values should be used. [e]Prolonged PR interval can only be considered in the absence of carditis as a major criterion.

Abbreviations: ARF, acute rheumatic fever; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

- Streptococcal serology (antistreptolysin and anti-DNase B)

In relevant situations:
- Throat swab
- Skin sore swab
- Blood cultures
- Synovial fluid aspirate
  - Ensure sample does not clot by using correct tubes that have been well mixed and transported promptly to the laboratory
  - Include request for cell count, microscopy, culture, and gonococcal polymerase chain reaction (PCR)
- Pregnancy test
- Creatinine test (UEC [urea, electrolytes, creatinine]) since nonsteroidal anti-inflammatory drugs can affect renal function

Tests to exclude alternative diagnoses, depending on clinical presentation and locally endemic infections:
- Autoantibodies, double-stranded DNA, anti–cyclic citrullinated peptide (anti-CCP) antibodies
- Urine for *Neisseria gonorrhoeae* molecular test
- Urine for *Chlamydia trachomatis* molecular test
- Serologic or other testing for viral hepatitis, *Yersinia* spp., cytomegalovirus (CMV), parvovirus B19, respiratory viruses, Ross River virus, Barmah Forest virus

value in the treatment of carditis or chorea. Aspirin is a common first-line choice, delivered at a dose of 50–60 mg/kg per day, up to a maximum of 80–100 mg/kg per day (4–8 g/d in adults) in 4–5 divided doses. At higher doses, the patient should be monitored for symptoms of salicylate toxicity such as nausea, vomiting, or tinnitus; if symptoms appear, lower doses should be used. When the acute symptoms are substantially resolved, usually within the first 2 weeks, patients on higher doses can have the dose reduced to 50–60 mg/kg per day for a further 2–4 weeks. Fever, joint manifestations, and elevated acute-phase reactants sometimes recur up to 3 weeks after the medication is discontinued. This does not indicate a recurrence and can be managed by recommencing salicylates for a brief period. Many clinicians prefer to use naproxen at a dose of 10–20 mg/kg per day, because it may be safer than aspirin and has the advantage of twice-daily dosing.

CONGESTIVE HEART FAILURE

Glucocorticoids The use of glucocorticoids in ARF remains controversial. Two meta-analyses have failed to demonstrate a benefit of glucocorticoids compared to placebo or salicylates in improving the short- or longer-term outcome of carditis. However, the studies included in these meta-analyses all took place >40 years ago and did not use medications in common usage today. Many clinicians treat cases of severe carditis (causing heart failure) with glucocorticoids in the belief that they may reduce the acute inflammation and result in more rapid resolution of failure. However, the potential benefits of this treatment should be balanced against the possible adverse effects. If used, prednisone or prednisolone is recommended at a dose of 1–2 mg/kg per day (maximum, 80 mg), usually for a few days or up to a maximum of 3 weeks.

MANAGEMENT OF HEART FAILURE

See Chap. 258.

BED REST

Traditional recommendations for long-term bed rest, once the cornerstone of management, are no longer widely practiced. Instead, bed rest should be prescribed as needed while arthritis and arthralgia are present and for patients with heart failure. Once symptoms are well controlled, gradual mobilization can commence as tolerated.

CHOREA

Medications to control the abnormal movements do not alter the duration or outcome of chorea. Milder cases can usually be managed by providing a calm environment. In patients with severe chorea, carbamazepine or sodium valproate is preferred to haloperidol. A response may not be seen for 1–2 weeks, and medication should be continued for 1–2 weeks after symptoms subside. There is recent evidence that corticosteroids are effective and lead to more rapid symptom reduction in chorea. They should be considered in severe or refractory cases. Prednisone or prednisolone may be commenced at 0.5 mg/kg daily, with weaning as early as possible, preferably after 1 week if symptoms are reduced, although slower weaning or temporary dose escalation may be required if symptoms worsen.

INTRAVENOUS IMMUNOGLOBULIN (IVIG)

Small studies have suggested that IVIg may lead to more rapid resolution of chorea but have shown no benefit on the short- or

long-term outcome of carditis in ARF without chorea. In the absence of better data, IVIg is *not* recommended except in cases of severe chorea refractory to other treatments.

PROGNOSIS

Untreated, ARF lasts on average 12 weeks. With treatment, patients are usually discharged from hospital within 1–2 weeks. Inflammatory markers should be monitored every 1–2 weeks until they have normalized (usually within 4–6 weeks), and an echocardiogram should be performed after 1 month to determine if there has been progression of carditis. Cases with more severe carditis need close clinical and echocardiographic monitoring in the longer term.

Once the acute episode has resolved, the priority in management is to ensure long-term clinical follow-up and adherence to a regimen of secondary prophylaxis. Patients should be entered onto the local ARF registry (if present) and contact made with primary care practitioners to ensure a plan for follow-up and administration of secondary prophylaxis before the patient is discharged. Patients and their families should also be educated about their disease, emphasizing the importance of adherence to secondary prophylaxis.

PREVENTION

PRIMARY PREVENTION

Ideally, primary prevention would entail elimination of the major risk factors for streptococcal infection, particularly overcrowded housing. This is difficult to achieve in most places where ARF is common.

Concerted international efforts are underway to develop a vaccine against group A *Streptococcus* that would prevent infection of the throat or skin and consequently prevent ARF in the absence of a suitable vaccine; however, the mainstay of primary prevention for ARF remains primary prophylaxis (i.e., the timely and complete treatment of group A streptococcal sore throat with antibiotics). If commenced within 9 days of sore throat onset, a course of penicillin (as outlined above for treatment of ARF) will prevent almost all cases of ARF that would otherwise have developed. In settings where ARF and RHD are common but microbiologic diagnosis of group A streptococcal pharyngitis is not available, such as in resource-poor countries, primary care guidelines often recommend that all patients with sore throat be treated with penicillin or, alternatively, that a clinical algorithm be used to identify patients with a higher likelihood of group A streptococcal pharyngitis. Although imperfect, such approaches recognize the importance of ARF prevention at the expense of overtreating many cases of sore throat that are not caused by group A *Streptococcus*. Although there is no proof that antibiotic treatment of group A streptococcal skin infections can prevent ARF, the increasing evidence that impetigo is strongly associated with ARF in some populations argues for a focus on treatment and prevention of group A streptococcal skin infections as part of a comprehensive ARF control strategy in regions with endemic impetigo.

SECONDARY PREVENTION

The mainstay of controlling ARF and RHD is secondary prevention. Because patients with ARF are at dramatically higher risk than the general population of developing a further episode of ARF after a group A streptococcal infection, they should receive long-term penicillin prophylaxis to prevent recurrences. The best antibiotic for secondary prophylaxis is benzathine penicillin G (1.2 million units, or 600,000 units if ≤27 kg) delivered every 4 weeks. It can be given every 3 weeks, or even every 2 weeks, to persons considered to be at particularly high risk, although in settings where good compliance with an every-4-week dosing schedule can be achieved, more frequent dosing is rarely needed. Oral penicillin V (250 mg) can be given twice daily instead but is less effective than benzathine penicillin G. Penicillin-allergic patients can receive erythromycin (250 mg) twice daily.

The duration of secondary prophylaxis is determined by many factors, in particular the duration since the last episode of ARF (recurrences become less likely with increasing time), age (recurrences are less likely with increasing age), and the severity of RHD (if severe, it may be prudent to avoid even a very small risk of recurrence because of the potentially serious consequences) **(Table 359-4)**. Secondary prophylaxis is best delivered as part of a coordinated RHD control program, based around a registry of patients. Registries improve the ability to follow patients and identify those who default from prophylaxis and to institute strategies to improve adherence.

TABLE 359-4 American Heart Association Recommendations for Duration of Secondary Prophylaxis[a]

CATEGORY OF PATIENT	DURATION OF PROPHYLAXIS
Rheumatic fever without carditis	For 5 years after the last attack or 21 years of age (whichever is longer)
Rheumatic fever with carditis but no residual valvular disease	For 10 years after the last attack, or 21 years of age (whichever is longer)
Rheumatic fever with persistent valvular disease, evident clinically or on echocardiography	For 10 years after the last attack, or 40 years of age (whichever is longer); sometimes lifelong prophylaxis

[a]These are only recommendations and must be modified by individual circumstances as warranted. Note that some organizations recommend a minimum of 10 years of prophylaxis after the most recent episode, or until 21 years of age (whichever is longer), regardless of the presence of carditis with the initial episode.

360 Systemic Sclerosis (Scleroderma) and Related Disorders

John Varga

DEFINITION AND CLASSIFICATION

Systemic sclerosis (SSc) is an orphan disease of unknown etiology, complex pathogenesis, and variable clinical presentations. SSc frequently follows a progressive course and is associated with significant disability and mortality. Virtually every organ can be affected **(Fig. 360-1)**.

There is marked variability among SSc patients in patterns of skin involvement and organ complications, rates of disease progression, response to treatment, disease severity, and survival. The early stages of SSc are associated with prominent inflammatory features, but over time, structural alterations in multiple vascular beds and visceral organ dysfunction due to fibrosis and atrophy progressively dominate the clinical picture. Recently developed classification criteria for the diagnosis of SSc (shown in **Table 360-1**) are >90% specific and selective.

Although thickened and indurated skin (*scleroderma*) is the distinguishing hallmark of SSc, similar skin changes can also be seen in localized forms of scleroderma, along with a variety of metabolic, inherited, autoimmune, and iatrogenic conditions **(Table 360-2)**. Patients with SSc can be broadly segregated into two major subsets defined by the pattern of skin involvement and associated with characteristic clinical and serologic features and natural history **(Table 360-3)**. Patients with diffuse cutaneous SSc (dcSSc) have extensive skin induration, starting in the fingers (sclerodactyly) and ascending from distal to proximal limbs and the trunk. In these patients, progressive skin disease, interstitial lung disease (ILD), and less commonly acute renal involvement may develop relatively early. In contrast, in patients with limited cutaneous SSc (lcSSc), Raynaud's phenomenon generally precedes sclerodactyly and other disease manifestations, sometimes by years. In these patients, skin involvement remains confined to the fingers, distal limbs, and face, while the trunk is spared. A subset of patients with lcSSc display the characteristic constellation of clinical findings (calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia), historically termed the *CREST syndrome*. In lcSSc, visceral organ involvement tends to follow an insidious and often benign course, while digital ischemic ulcers, pulmonary arterial hypertension (PAH), hypothyroidism, Sjogren's symptoms, and primary biliary cirrhosis may occur as late complications. In some patients, Raynaud's phenomenon and characteristic clinical and laboratory features of SSc occurs in the absence of detectable skin thickening. This relatively benign disease subset has been termed *SSc sine scleroderma.*

INCIDENCE AND PREVALENCE

SSc is an acquired sporadic disease with a worldwide distribution and affecting all races. In the United States, the incidence is 9–46 cases per million per year. There are an estimated 100,000 U.S. cases, although this number may be significantly higher if patients who do not fulfill classification criteria are also included. There are large regional variations in incidence rates of SSc, potentially reflecting differences in case definition, environmental exposures, or genetic susceptibility genes in populations with different ancestries. Prevalence rates in England, northern Europe, and Japan appear to be lower than in North America and Australia. Age, sex, and ethnicity influence disease susceptibility, and blacks have higher age-specific incidence rates and mortality. In common with other connective tissue diseases, SSc shows a strong female predominance (4.6:1), which is most pronounced in the childbearing years and declines after menopause. An additional risk factor for SSc is having an affected first-degree family member, which increases disease risk 13-fold. Although SSc can present at any age, the peak age of onset in women with both limited and diffuse cutaneous forms is 65–74 years, although in blacks, disease onset occurs at an earlier age. Furthermore, blacks with SSc are more likely to have diffuse cutaneous disease, ILD, and a worse prognosis.

GENETIC CONTRIBUTION TO DISEASE PATHOGENESIS

In general, the genetic associations of SSc identified to date make only a relatively modest contribution to disease susceptibility. Twin studies showed low disease concordance rates (4.7%) in monozygotic twins, a rate much lower than in other autoimmune diseases such as rheumatoid arthritis (12.3%). On the other hand, supporting the genetic contribution to disease susceptibility is the observation that 1.6% of SSc patients have a first-degree relative with SSc, a prevalence rate that is markedly increased compared to the general population. Moreover, the risk of Raynaud's phenomenon, ILD, and other autoimmune diseases, including systemic lupus erythematosus (SLE) **(Chap. 356)**, rheumatoid arthritis **(Chap. 358)**, and autoimmune thyroiditis **(Chap. 383)**, is also increased in first-degree relatives of patients with SSc. Current approaches to uncover the genetic factors that contribute to SSc include DNA sequencing and single nucleotide polymorphism (SNP) analysis of candidate genes and SNP analysis of the entire genome in a hypothesis-free manner. Genome-wide association studies (GWAS) involve large multicenter and multinational cohorts. A majority of the robustly validated genetic susceptibility loci for SSc are genes at the highly polymorphic human leukocyte antigen (HLA) region and other genes involved in innate and adaptive immunity and interferon responses, highlighting the importance of autoimmunity as the initial trigger for the disease. Genetic studies have shown associations with common (small effect size) variants related to B and T lymphocyte activation (*BANK1*, *BLK*, *CD247*, *STAT4*, *IL2RA*, *CCR6*, *IDO1*, *TNFSF4/OX40L*, *PTPN22*, and *TNIP1*). In addition, candidate gene studies and GWAS identified a strong and consistent association with HLA class II haplotypes on chromosome 6, including *HLA-DRB1*11:04*, *DQA1*05:01*, and *DQB1*03:01*, and the non-HLA histocompatibility complex (MHC) genes *NOTCH4* and *PSORSC1*. Other genetic variants associated with SSc are involved in innate immunity and type 1 interferon signaling (*IRF5*, *IRF7*, *STAT4*, *TNFAIP3*, and *TLR2*). Additional associations with *IL12RB2, IL-21,* the autophagy and apoptosis-related genes *DNASE1L3* and *SOX5*, and the

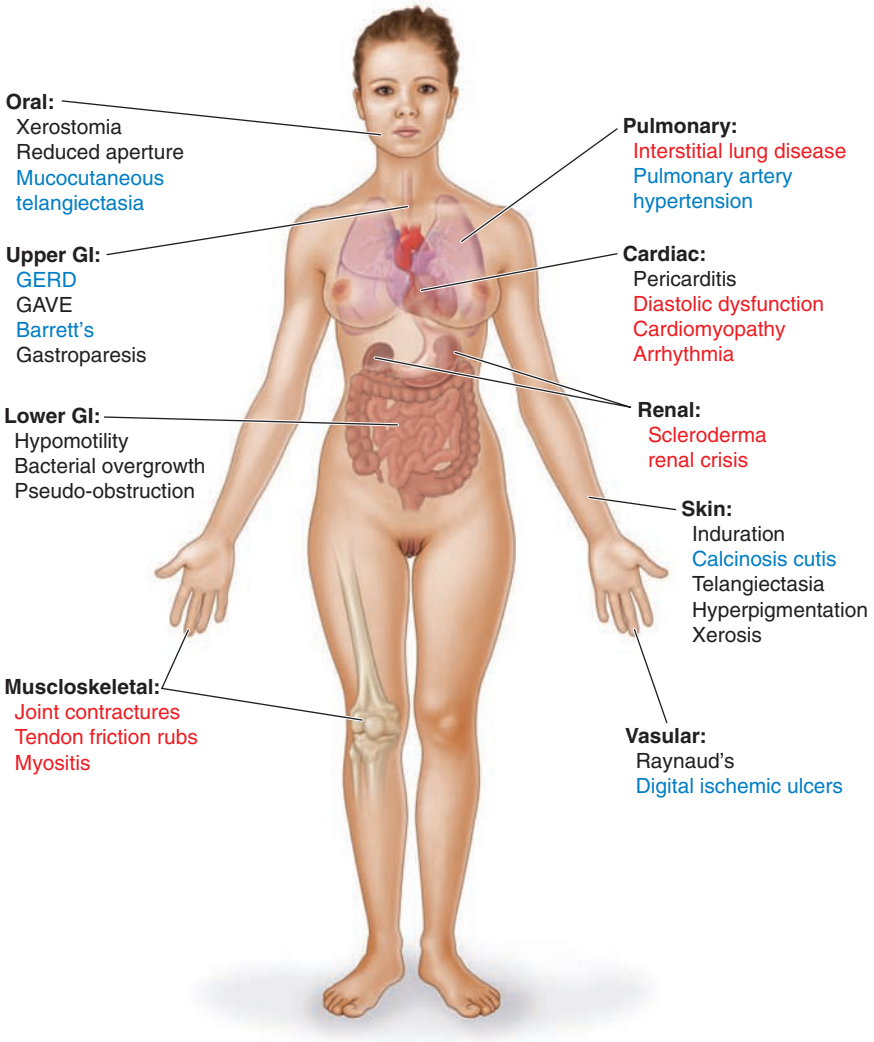

FIGURE 360-1 Multiorgan involvement in systemic sclerosis (SSc). Prominent complications of SSc: *red*, those more common in diffuse cutaneous SSc; *black*, those more common in limited cutaneous SSc; *blue*, complications common in both SSc subsets. GAVE, gastric antral vascular ectasia; GERD, gastroesophageal reflux disease; GI, gastrointestinal.

TABLE 360-1 Classification Criteria for Diagnosis of Systemic Sclerosis

ITEM	SUBITEM	WEIGHT/SCORE
Skin thickening (bilateral); fingers extending proximal to MCP joints		9
Skin thickening of fingers only	Puffy fingers	2
	Sclerodactyly (skin thickened distal to MCP joints)	4
Fingertip lesions	Digital tip ulcer	2
	Fingertip pitting scars	3
Mucocutaneous telangiectasia		2
Abnormal nailfold capillary pattern		2
Lung involvement	PAH	2
	Interstitial lung disease	2
Raynaud's phenomenon		3
SSc-specific autoantibodies	ACA	3
	Scl-70	
	RNA polymerase III	

Abbreviations: ACA, anticentromere antibodies; MCP, metacarpophalangeal joint; PAH, pulmonary arterial hypertension.

TABLE 360-2 Conditions Associated with Skin Induration

- Systemic sclerosis (SSc)
  - Limited cutaneous SSc
  - Diffuse cutaneous SSc
- Localized scleroderma
  - Guttate (plaque) morphea, diffuse (pansclerotic) morphea, bullous morphea
  - Linear scleroderma, coup de sabre, hemifacial atrophy
- Pansclerotic morphea
- Overlap syndromes
  - Mixed connective tissue disease
  - SSc/polymyositis
- Diabetic scleredema and scleredema of Buschke
- Scleromyxedema (papular mucinosis)
- Chronic graft-versus-host disease
- Diffuse fasciitis with eosinophilia (Shulman's disease, eosinophilic fasciitis)
- Stiff skin syndrome
- Pachydermoperiostosis (primary hypertrophic osteoarthropathy)
- Chemically induced and drug-associated scleroderma-like conditions
  - Vinyl chloride–induced disease
  - Eosinophilia-myalgia syndrome (associated with L-tryptophan contaminant exposure)
  - Nephrogenic systemic fibrosis (associated with gadolinium exposure)
- Paraneoplastic syndrome

TABLE 360-3 Subsets of Systemic Sclerosis (SSc): Features of Limited Cutaneous Versus Diffuse Cutaneous Disease

CHARACTERISTIC FEATURE	LIMITED CUTANEOUS SSc	DIFFUSE CUTANEOUS SSc
Skin involvement	Indolent onset. Limited to fingers, distal to elbows, face; slow progression	Rapid onset. Diffuse: fingers, extremities, face, trunk; rapid progression
Raynaud's phenomenon	Antedates skin involvement, sometimes by years; may be associated with critical ischemia in the digits	Onset coincident with skin involvement; critical ischemia less common
Musculoskeletal	Mild arthralgia	Severe arthralgia, carpal tunnel syndrome, tendon friction rubs
Interstitial lung disease	Slowly progressive, generally mild	Frequent, early onset and progression, can be severe
Pulmonary arterial hypertension	Frequent, late, may occur as an isolated complication	Often occurs in association with interstitial lung disease
Scleroderma renal crisis	Very rare	Occurs in 15%; generally early (<4 years from disease onset)
Calcinosis cutis	Frequent, prominent	Less common, mild
Characteristic autoantibodies	Anti-centromere	Anti–topoisomerase I (Scl-70), anti-RNA polymerase III

extracellular matrix–related genes *CSK*, *CAV1*, *PPARG*, and *GRB10* have been reported. In addition to SSc susceptibility, some of these genetic loci are associated with particular disease manifestations or serologic subsets, including ILD (*CTGF*, *CD226*), PAH (*TNIP1*), scleroderma renal crisis (*HLA-DRB1**), and anticentromere antibodies (*HLA-DPB1*05:01*). While the functional consequences of these gene variants and their potential roles in pathogenesis are not well understood, it seems likely that in combination they cause a state of altered immune regulation, leading to increased susceptibility to autoimmunity and persistent inflammation. Of note, several of the SSc genetic variants are also implicated in other autoimmune disorders, including SLE, Sjögren's syndrome, rheumatoid arthritis, multiple sclerosis, and psoriasis, suggesting common pathogenic pathways shared among these phenotypically dissimilar conditions. Notably, the genetic associations identified to date only explain a fraction of the heritability of SSc and focus on common variants. By contrast, next-generation sequencing, such as whole exome sequencing, may help identify additional genetic susceptibility factors in SSc, particularly rare (and potentially causal) coding variants and their association with specific phenotypes.

ENVIRONMENTAL AND OCCUPATIONAL EXPOSURES

The etiology of SSc is unknown. Given the relatively modest genetic contribution to susceptibility in SSc, environmental factors, such as infectious agents, microbiome, and occupational, dietary, lifestyle, and drug exposures, are likely to play a major role. Evidence suggests potential pathogenic roles for viruses, including parvovirus B19, Epstein-Barr virus (EBV), and cytomegalovirus (CMV), and *Rhodotorula glutinis*. Toxic oil syndrome, a novel disease with features suggestive of SSc, occurred as an epidemic outbreak in Spain in the 1980s and was linked to contaminated rapeseed oil used for cooking. Another epidemic outbreak, termed *eosinophilia-myalgia syndrome* (EMS), occurred in the United States in the 1990s and was linked to consumption of L-tryptophan-containing dietary supplements. Exposure to gadolinium contrast material in individuals with compromised renal function undergoing magnetic resonance scanning has been associated with nephrogenic systemic fibrosis. While each of these novel toxic-epidemic syndromes was characterized by chronic indurative skin changes and variable visceral organ involvement, the constellation of associated clinical, pathologic, and laboratory features distinguishes them from SSc. Occupational exposures tentatively linked with SSc include particulate silica (quartz), polyvinyl chloride, epoxy resins, welding fumes, and organic solvents and aromatic hydrocarbons including paint thinners, toluene, xylene, and trichloroethylene. These exposures can elicit cell type–specific stable and heritable epigenetic modifications such as DNA methylation and histone modification that could drive pathogenic alterations in cellular gene expression. Several of these epigenetic modifications are reversible and represent potential targets for therapy. Drugs implicated in SSc-like illnesses include bleomycin, pentazocine, cocaine, and appetite suppressants linked with PAH. Most recently, immune checkpoint inhibitors such as PD-1 blockers used in cancer therapy have been implicated as triggers for SSc-like illnesses. Radiation therapy for cancer has been linked with de novo onset of SSc as well as with exacerbation of preexisting SSc. In contrast to rheumatoid arthritis, cigarette smoking does not increase the risk of SSc. Although case reports and series describing the occurrence of SSc in women with silicone breast implants had raised concern regarding a putative pathogenic role of silicone in SSc, large-scale epidemiologic investigations found no evidence of increased prevalence of SSc.

PATHOGENESIS

The pathogenesis of SSc involves putative environmental insults that trigger epigenetic modifications in a genetically predisposed host, causing alterations in gene expression underlying durable changes in the behavior of multiple cell types **(Fig. 360-2)**.

Three cardinal pathomechanistic processes underlie the protean clinical manifestations and pathologic changes of SSc: (1) diffuse microangiopathy, (2) inflammation and autoimmunity, and (3) visceral and vascular fibrosis affecting multiple organs **(Fig. 360-3)**. While each of these distinct processes may be synchronously active in a given SSc patient, their relative severity, progression, and contribution to the overall clinical picture vary among individual patients and over time. In general, autoimmunity and reversible vascular reactivity are early features of SSc, whereas fibrosis and atrophy occur later in the disease.

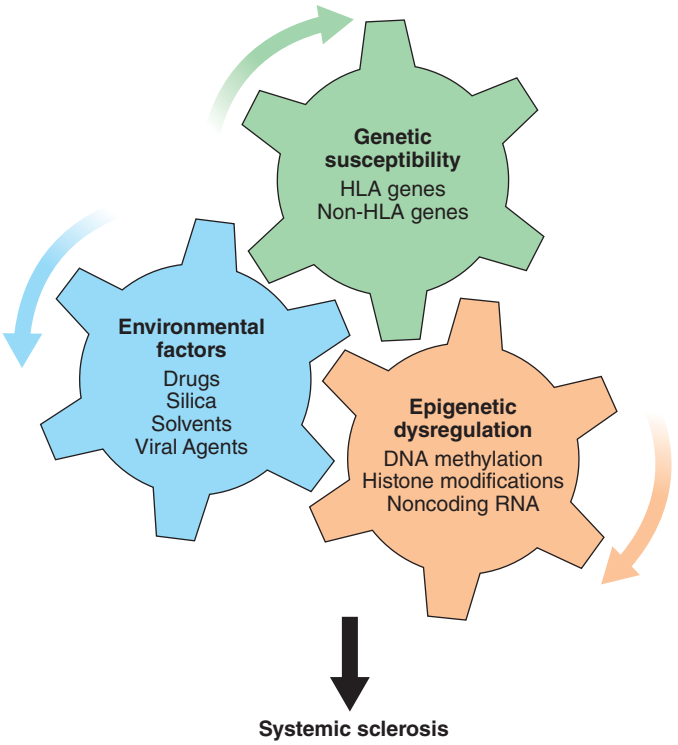

FIGURE 360-2 The interplay of genetic risk factors and environmental exposure–induced epigenetic modifications underlying the complex pathogenesis of systemic sclerosis. HLA, human leukocyte antigen. *(Reproduced with permission from Amr Sawalha and Pei-Suen Tsou, University of Pittsburgh and University of Michigan.)*

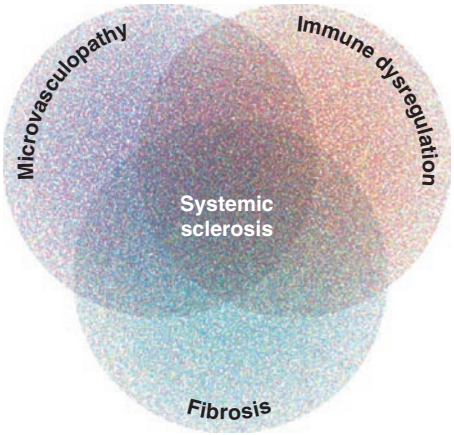

FIGURE 360-3 The pathogenic systemic sclerosis (SSc) triad. The characteristic constellation of synchronously occurring vasculopathy, autoimmunity/inflammation, and fibrosis distinguishes SSc and underlies its protean clinical manifestations.

ANIMAL MODELS OF DISEASE

There is no single animal model of SSc that fully reproduces the three cardinal processes that underlie pathogenesis. Tight-skin mice (Tsk1/+) spontaneously develop skin (hypodermal) fibrosis due to a duplication mutation in the fibrillin-1 gene. Mutant fibrillin-1 protein disrupts extracellular matrix assembly, leading to aberrant activation of the profibrotic transforming growth factor β (TGF-β). In humans, fibrillin-1 mutations are associated with Marfan's disease and stiff skin syndrome but have not been reported in SSc. In mice, skin and lung fibrosis accompanied by variable vasculopathy and autoimmunity can be elicited by repeated injection of bleomycin or angiotensin II or by transplantation of HLA-mismatched bone marrow or spleen cells. Targeted genetic modifications in mice give rise to new disease models for investigating the pathogenetic roles of individual molecules, pathways, and cell types. For example, mice lacking IRF5, the ciliary proteins SPAG17, tenascin-C, or peroxisome proliferator-activated receptor (PPAR)-γ, or constitutively overexpressing β-catenin, Wnt10b, sirtuin 3, Fra2, PDGFRα, or adiponectin are either resistant or hypersensitive to experimental scleroderma or spontaneously develop multiple-organ fibrosis. These disease models can be useful as experimental tools to understand SSc pathogenesis and discover and validate novel targets for therapy.

MICROANGIOPATHY

In a progressive model of disease pathogenesis **(Fig. 360-4)**, vascular injury is an early and possibly primary pathogenic event that underlies protean manifestations of small vessel vasculopathy.

Prominent microangiopathy in multiple vascular beds is a hallmark of SSc with important clinical sequelae including mucocutaneous telangiectasia, Raynaud's phenomenon, ischemic digital ulcers, scleroderma renal crisis, myocardial involvement, and PAH. Raynaud's phenomenon, commonly the initial manifestation of SSc, is characterized by altered blood-flow response to cold challenge in small digital arteries. This reversible functional abnormality is associated with autonomic and peripheral nervous system alterations, including impaired production of the neuropeptide calcitonin gene–related peptide from sensory afferent nerves and heightened sensitivity of α_2-adrenergic receptors on vascular smooth-muscle cells. Isolated (primary) Raynaud's disease is common, generally benign, and nonprogressive. In contrast, SSc-associated secondary Raynaud's phenomenon often progresses to irreversible structural changes in the small blood vessels, culminating in ischemic digital tip ulcers, necrosis, and amputation.

Viruses, cytotoxic factors, chemokines, thrombogenic microparticles, alternate complement pathway activation, and autoantibodies targeting endothelial cells, phospholipids, and β_2-glycoprotein I (β_2GPI) have all been implicated as putative triggers of endothelial cell injury in SSc. Endothelial damage disrupts the production of vasodilatory (nitric oxide and prostacyclin) and vasoconstricting (endothelin-1) substances, while causing upregulation of intercellular adhesion molecule 1 (ICAM-1) and other surface adhesion molecules. Microvessels show enhanced permeability and transendothelial leukocyte diapedesis, activation of coagulation cascades, elevated thrombin production, and impaired fibrinolysis. Spontaneous platelet aggregation causes release of serotonin, platelet-derived growth factor (PDGF), and platelet alpha granules including thromboxane, a potent vasoconstrictor. Smooth-muscle cell–like myointimal cells accumulate in the media, potentially arising through a process called endothelial-mesenchymal transition (EndoMT). The basement membrane is thickened and reduplicated, and perivascular adventitial fibrosis develops. The vasculopathic process primarily affects capillaries, arterioles, and less commonly even large vessels in many organs, resulting in impaired blood flow and tissue ischemia. Progressive luminal occlusion due to intimal and medial hypertrophy, combined with persistent endothelial cell damage and adventitial fibrosis, establish a vicious cycle that underlies fibroproliferative vasculopathy and culminates in the striking absence of small blood vessels (rarefaction) in late-stage disease. Recurrent ischemia-reperfusion generates reactive oxygen species (ROS) that further damage the endothelium through peroxidation of membrane lipids. Paradoxically, the process of revascularization that normally reestablishes blood flow to ischemic tissue is defective in SSc despite elevated levels of other angiogenic factors. Moreover, bone marrow–derived circulating endothelial progenitor cells are reduced in number and impaired in function.

There is increasing evidence implicating EndoMT in the pathogenesis of SSc vasculopathy. The process of EndoMT is characterized by transition of endothelial cells into myofibroblasts accompanied by loss of endothelial cell markers and acquisition of myofibroblast markers associated with nuclear localization of the transcription factor Snail1. In arterioles and small arteries, EndoMT leads to accumulation of endothelial cell–derived myofibroblasts in the intima and media, resulting in fibroproliferative vasculopathy and luminal occlusion. In contrast, EndoMT affecting the capillary vessels leads to a destructive vasculopathy characterized by loss of endothelial cells and accumulation of interstitial myofibroblasts derived from endothelial cells, resulting in interstitial fibrosis and microvessel rarefaction, as can be observed by nailfold capillaroscopy. Widespread capillary loss combined with fibroproliferative vasculopathy affecting arterioles and arteries and impaired ability to repair and replace damaged vessels are hallmarks of SSc.

INFLAMMATION AND AUTOIMMUNITY

Cellular Immunity While the initial events triggering the activation of innate and adaptive autoimmunity in SSc are unknown, a number of observations support the inflammatory/autoimmune nature of SSc: near-universal presence of circulating autoantibodies with defined specificities; clustering of SSc with other autoimmune diseases; activated immune cells, including autoreactive T cells with oligoclonal antigen receptors, within target organs; prominent type I interferon (IFN) signatures, characterized by elevated expression of IFN-regulated genes, in a variety of immune cell types in circulation and in skin biopsies; elevated circulating levels and spontaneous mononuclear cell secretion of cytokines and chemokines such as interleukin (IL) 6, tumor necrosis factor, IL-4, IL-10, IL-17, IL-33, CCL2, and CXCL4; genetic association of SSc (shared with other autoimmune diseases) with variants of MHC and other immune response genes; and the rapid clinical response, fibrosis resolution, and vascular regeneration observed in some SSc patients treated with immunomodulatory or immunoablative therapies.

Circulating monocytes from SSc patients overexpress IFN-regulated genes such as Siglec-1, have reduced levels of caveolin-1, and exhibit a profibrotic phenotype. In early (edematous) stage SSc, mononuclear cell infiltrates composed of activated T cells, monocytes/macrophages, and dendritic cells can be detected in skin, lungs, and other affected organs even prior to fibrosis or vascular damage. Dendritic cells in close proximity to activated fibroblasts and myofibroblasts express toll-like receptors (TLRs) that are activated by self-nucleic acids and other endogenous ligands. TLR stimulation induces the secretion

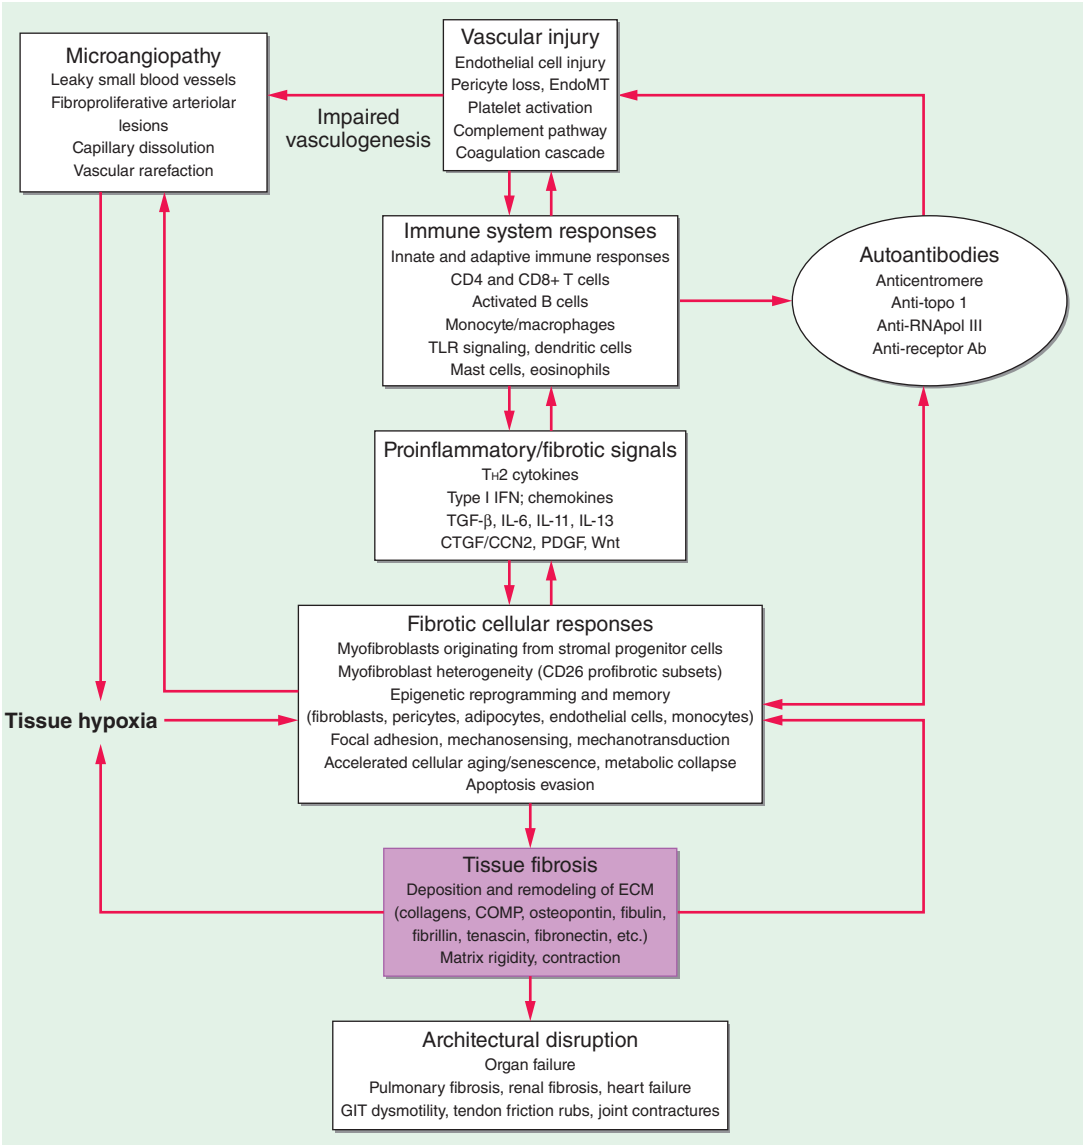

FIGURE 360-4 Integrated progressive model of systemic sclerosis (SSc) pathogenesis. Initial vascular insult in a genetically predisposed individual triggers a cascade of functional and structural vascular alterations associated with inflammation and autoimmunity. Early immune responses elicit fibroblast activation and differentiation, resulting in sustained pathologic fibrogenesis, irreversible tissue damage, and failure of affected organs. Vascular damage also leads to tissue ischemia that further contributes to progressive fibrosis and atrophy. Ab, antibody; CTGF, connective tissue growth factor; ECM, extracellular matrix; EndoMT, endothelial-mesenchymal transition; GIT, gastrointestinal tract; IFN, interferon; IL, interleukin; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor β; TLR, toll-like receptor.

of mediators including IFN, IL-10, thymic stromal lymphopoietin (TSLP), and CXCL4, shaping the adaptive immune response and contributing to loss of immune tolerance. Tissue-infiltrating T cells express CD45 and HLA-DR activation markers and display restricted T-cell receptor signatures indicative of oligoclonal expansion in response to recognition of as-yet-unknown antigen. Of note, in patients diagnosed with SSc in close temporal association with cancer who are positive for RNA polymerase III antibody, the tumor commonly harbors genetic alterations in RNApol3, which results in the generation of autoantigen-specific T-cell immunity and cross-reactive antibodies.

Circulating T cells in SSc express chemokine receptors and α_1 integrin, accounting for their enhanced binding to endothelium and to fibroblasts, while endothelial cells express ICAM-1 and other adhesion molecules that facilitate leukocyte diapedesis. Activated T cells show a T_H2-polarized immune response driven by dendritic cells. The T_H2 cytokines IL-4, IL-13, IL-33, and TSLP induce fibroblast activation, whereas the T_H1 cytokine interferon γ (IFN-γ) blocks cytokine-mediated fibroblast activation and exhibits antifibrotic properties. Evidence for altered T_H17 and regulatory T-cell function in SSc has been reported. Type 2 innate lymphoid cells (iLCs), a recently discovered distinct lymphoid cell population implicated in type 2 immunity and tissue remodeling, are also elevated in SSc skin biopsies. Alternately activated macrophages expressing CD163, which produce TGF-β and promote angiogenesis and tissue remodeling, are increased in the skin and lung in SSc. Regulatory T cells (Tregs) enforce immune tolerance, and although their frequency is elevated in the circulation and tissues in SSc patients, their immunosuppressive function appears to be defective. A recent report demonstrated that Tregs play a critical role in preventing spontaneous fibrosis in the skin, possibly by sequestering activated TGF-β. Some evidence implicates altered B-cell homeostasis and function in SSc. Circulating B cells show elevated CD19 and co-stimulatory molecules CD80 and CD86, suggesting B-cell chronic activation. Serum levels of a proliferation-inducing ligand (APRIL) and B-cell activating factor (BAFF), members of the TNF superfamily with potent effects on B-cell activation, are elevated in SSc and associated with extent of skin and lung involvement. B cells secrete IL-6, TGF-β, and other profibrotic cytokines implicated in pathogenesis. Thus, B-cell hyperactivity might directly contribute to the inflammatory and fibrotic processes in SSc, as well as generation of autoantibodies.

Humoral Autoimmunity Circulating antinuclear antibodies (ANAs) can be detected in virtually all patients with SSc, even in

early and possibly preclinical stages of disease. In addition, several SSc-specific autoantibodies with distinct patterns of immunofluorescence show strong associations with unique disease phenotypes as well as HLA haplotype (Table 360-4). Owing to their specificity, mutual exclusivity, and association with unique disease manifestations, SSc-associated autoantibodies have substantial utility in clinical practice for diagnosis and risk stratification, while their role in monitoring disease activity or response to therapy remains uncertain. Recently, antibodies directed against fibrillin-1, matrix metalloproteinases, cell surface markers, angiotensin II receptor, endothelin-1 receptor, or the PDGF receptor have been identified in patients with SSc, although their clinical relevance is not yet established. These antibodies have functional receptor agonist activity and might have direct pathogenic roles.

A variety of mechanisms have been proposed to account for the generation of SSc-associated autoantibodies. Proteolytic cleavage, increased expression or altered subcellular localization of normal proteins, or their alterations due to mutation in the case of certain tumors could lead to their immune recognition as neoepitopes, resulting in a break of immune tolerance.

FIBROSIS

Fibrosis synchronously affecting multiple organs is a distinguishing feature of SSc. The process is characterized by replacement of normal tissue architecture with rigid, avascular, and relatively acellular connective tissue. Fibrosis in SSc follows, and is a consequence of, inflammation and microvascular damage (Fig. 360-4). Fibroblasts are mesenchymal cells primarily responsible for the functional and structural integrity of connective tissue. Upon their activation by extracellular cues, fibroblasts proliferate; migrate; secrete collagens and other matrix molecules, growth factors, chemokines, and cytokines; and transdifferentiate into contractile myofibroblasts. Under normal conditions, these are responses self-limited to accomplish tissue regulated repair and regeneration. In contrast, when these responses become sustained and amplified, pathologic fibrosis results. A panoply of stimulatory signals are potentially implicated in SSc pathogenesis. In addition to TGF-β, these include paracrine mediators IL-6, IL-11, IL-13, and IL-23, morphogens and Wnt ligands, connective tissue growth factor (CTGF), PDGF, lysophosphatidic acid, endothelin-1, hypoxia, ROS, thrombin, and mechanical forces; these signals might contribute to sustained fibroblast activation underlying maladaptive repair in SSc. Buildup of damage-associated endogenous ligands for TLR4 (EDA-fibronectin and tenascin-C) and TLR9 (mitochondrial DNA) within the microenvironment further contributes to nonresolving fibrosis via unchecked TLR activation and innate immune signaling.

In addition to tissue-resident fibroblasts and transformed myofibroblasts, bone marrow–derived circulating mesenchymal progenitor cells also contribute to fibrosis. The factors that regulate the differentiation of mesenchymal progenitor cells and their trafficking from the circulation into lesional tissue are unknown. Endothelial cells in injured arterioles and small arteries undergo EndoMT, giving rise to myofibroblasts that drive perivascular fibrosis. Epithelial cells, preadipocytes, and tissue fibroblasts are all putative sources of pathogenic myofibroblasts. Although myofibroblasts are transiently found in normal wound healing, their persistence in fibrotic tissue, possibly due to their ability to evade apoptosis, contributes to scar formation.

Explanted SSc fibroblasts display an abnormally activated phenotype ex vivo, characterized by increased collagen production, spontaneous ROS generation, prominent stress fibers, and constitutive expression of alpha smooth-muscle actin. Persistence of the "scleroderma phenotype" during serial ex vivo passage of SSc fibroblasts may reflect autocrine TGF-β stimulatory loops, deregulated microRNA expressions, cell-autonomous metabolic changes, or stable acquired epigenetic modifications. More recently, tools such as single-cell RNA sequencing have revealed functional heterogeneity among fibrotic fibroblasts.

PATHOLOGY

While pathologic findings vary across anatomic sites, the distinguishing hallmarks of SSc irrespective of the organ system are widespread microangiopathy (fibroproliferative vasculopathy), capillary loss and obliteration, and fibrosis. In early-stage disease, perivascular inflammatory cell infiltrates composed of T and B lymphocytes, activated monocytes and macrophages, and mast cells may be detected in multiple organs. A noninflammatory obliterative microangiopathy in the heart, lungs, kidneys, and gastrointestinal tract is a prominent late finding. Fibrosis most prominently affects the skin, lungs, cardiovascular system, gastrointestinal tract, tendon sheaths, perifascicular tissue surrounding skeletal muscle, and some endocrine organs such as the thyroid gland. Excessive accumulation of collagens and other structural matrix macromolecules progressively disrupts normal architecture, resulting in impaired function and failure of affected organs.

SKIN

In the skin, the dermis is thickened due to accumulation of broad bundles of homogenized collagen oriented parallel to the epithelium (Fig. 360-5*A*). Adnexal glands are atrophic, and loss of periadnexal and intradermal white adipose tissue and its replacement with collagen can be striking. While perivascular mononuclear cell infiltrates may be seen early, established skin fibrosis shows absence of inflammation.

LUNGS

Autopsy studies universally show evidence of lung involvement in both limited and diffuse cutaneous subsets of SSc. Most common is the nonspecific interstitial pneumonia (NSIP) pattern characterized variable interstitial fibrosis and mild chronic inflammation with T lymphocytes, macrophages, and eosinophils. With progression, interstitial fibrosis and vascular damage dominate, often coexisting within the same biopsy. The usual interstitial pneumonia (UIP) pattern of spatial and temporal heterogeneity of inflammation and fibrosis and fibrotic foci, a hallmark of idiopathic pulmonary fibrosis, is less common in SSc (Fig. 360-5*B*). Fibrosis of the alveolar septae results in obliteration of the airspaces and loss of pulmonary blood vessels. This process impairs gas exchange and contributes to pulmonary hypertension. Intimal

thickening of the pulmonary arteries, best seen with elastin stain, underlies SSc-associated PAH (Fig. 360-5*C*) and, at autopsy, is often associated with pulmonary emboli and myocardial fibrosis. Patients with SSc-associated PAH also show fibrosis and intimal proliferation in preseptal venules and veins in the lung, accounting for veno-occlusive disease. Lymphocytic bronchiolitis involving the submucosa of the terminal bronchioles is occasionally seen.

GASTROINTESTINAL TRACT

Pathologic changes can be found at any level from the mouth to the rectum. Atrophy and fibrosis of the muscularis propria and characteristic vascular lesions are prominent in the lower esophagus, while striated muscle in the upper third of the esophagus is generally spared. Collagenous replacement of the intestinal tract architecture results in impaired smooth-muscle contractility and diminished peristaltic activity, underlying gut dysmotility, bacterial overgrowth, small-bowel pseudo-obstruction, and perforation. Chronic gastroesophageal reflux is associated with esophageal inflammation, mucosal ulceration, and stricture formation and may lead to Barrett's metaplasia with attendant risk of adenocarcinoma. Esophageal dilatation and reflux may aggravate ILD due to chronic microaspiration.

KIDNEYS

In the kidneys, vascular lesions affecting the interlobular and arcuate arteries predominate. Chronic renal ischemia is associated with shrunken glomeruli. Patients with scleroderma renal crisis, a life-threatening acute complication of SSc, show acute fibrinoid necrosis of afferent arterioles, followed by intimal proliferation (onion-skin pattern) and ischemic collapse of glomeruli. These changes are reminiscent of thrombotic microangiopathies such as atypical hemolytic-uremic syndrome (Chap. 115) and are accompanied by thrombosis, thrombocytopenia due to platelet consumption, and intravascular hemolysis. Evidence of complement activation may be seen in kidney biopsies. Extensive vascular thrombosis, glomerular collapse, and peritubular capillary deposits predict irreversible renal failure.

HEART

Subclinical cardiac pathology is common in SSc and may affect the myocardium and pericardium. The characteristic arteriolar lesions in the heart are concentric intimal hypertrophy and luminal narrowing, patchy contraction band necrosis, loss of cardiac myocytes, and myocardial fibrosis due to microvascular involvement and ischemia-reperfusion injury. Fibrosis of the conduction system is also common, especially at the sinoatrial node. The frequency of epicardial atherosclerotic coronary artery disease may be increased in SSc compared to the general population, similar to other systemic inflammatory diseases. Pericardial involvement with chronic inflammatory infiltrates and fibrinous exudates is common and is sometimes associated with pericardial effusions.

PATHOLOGY IN OTHER ORGANS

Synovitis of the hands may occur in SSc; with disease progression, the synovium becomes fibrotic, and in contrast to rheumatoid disease, pannus formation and bone resorption are uncommon. Fibrosis of tendon sheaths and fascia, sometimes accompanied by calcifications, produces palpable and sometimes audible tendon friction rubs. Inflammation and, in later stages, atrophy and fibrosis of skeletal muscles are common findings and are similar to those in polymyositis. Fibrosis of the thyroid and of the minor salivary glands may be seen and underlie hypothyroidism and the sicca syndrome. Placentas from SSc pregnancies show decidual vasculopathy, which is associated with poor perinatal outcomes and fetal death.

CLINICAL FEATURES

OVERVIEW

SSc is truly a systemic disease that can affect virtually any organ (Fig. 360-1 and Table 360-5). Although a dichotomous stratification into diffuse and limited cutaneous subsets (Table 360-2) is useful, SSc is far more complex, and multiple distinct clusters or endophenotypes of SSc with characteristic manifestations and trajectories and outcomes can be recognized within each subset. Unique endophenotypes associate with autoantibodies with distinct and mutually exclusive specificities (Table 360-4). Moreover, patients with "overlap" have typical features of SSc coexisting with clinical and laboratory evidence of another autoimmune disease, most commonly polymyositis, Sjögren's syndrome, polyarthritis, autoimmune liver disease, or SLE.

TABLE 360-5 Frequency of Clinical Organ Involvement in Limited Cutaneous and Diffuse Cutaneous Systemic Sclerosis (SSc)

FEATURES	LIMITED CUTANEOUS SSc (%)	DIFFUSE CUTANEOUS SSc (%)

Clinical cardiac involvement	9	12
Scleroderma renal crisis	2	15
Calcinosis cutis	40	35

[a]Approximately 10% of patients have SSc *sine* scleroderma.

FIGURE 360-6 Digital necrosis. Sharply demarcated necrosis of the fingertip secondary to ischemia in a patient with limited cutaneous systemic sclerosis (SSc) associated with severe Raynaud's phenomenon.

INITIAL CLINICAL PRESENTATION

Characteristic initial presentation is quite different in patients with the diffuse (dcSSc) versus limited (lcSSc) cutaneous forms of the disease. In dcSSc, the interval between Raynaud's phenomenon and onset of other disease manifestations is typically brief (weeks to months). Soft tissue swelling, puffy fingers, and pruritus are signs of the early inflammatory "edematous" phase. The fingers, distal limbs, and face are usually affected first. Diffuse hyperpigmentation of the skin, carpal tunnel syndrome, arthralgias, muscle weakness, fatigue, and decreased joint mobility are common. During the ensuing weeks to months, the inflammatory edematous phase evolves into the "fibrotic" phase, with skin induration associated with hair loss, reduced production of skin oils, and decline in sweating capacity. Progressive flexion contractures of the fingers ensue. The wrists, elbows, knees, and ankles become stiff due to fibrosis of the supporting joint structures. While advancing skin involvement is the most visible manifestation of early dcSSc, important and clinically silent internal organ involvement can occur during this stage. The initial 4 years from disease onset is the period of most rapidly evolving and potentially irreversible lung and renal damage. If organ failure does not occur during this phase of dcSSc, the systemic process may plateau and stabilize.

Compared to dcSSc, the course of lcSSc tends to be more indolent. The interval between onset of Raynaud's phenomenon and disease manifestations such as gastroesophageal reflux disease (GERD), cutaneous telangiectasia, ischemic digital ulcers, or soft tissue calcifications can be as long as years. Scleroderma renal crisis, significant ILD, and tendon friction rubs occur rarely in lcSSc, whereas PAH and overlap with keratoconjunctivitis sicca, polyarthritis, cutaneous vasculitis, and biliary cirrhosis can develop even many years after disease onset.

ORGAN INVOLVEMENT

RAYNAUD'S PHENOMENON

Raynaud's phenomenon, the most frequent extracutaneous complication of SSc, is characterized by episodic vasoconstriction in the fingers and toes, sometimes also affecting the tip of the nose and earlobes. Attacks are reversible, and can be triggered by a decrease in temperature, as well as emotional stress and vibration. Attacks typically start with pallor of the fingers, followed by cyanosis of variable duration. Hyperemia ensues spontaneously or with rewarming of the digit. The progression of the three color phases reflects the underlying vasoconstriction, ischemia, and reperfusion. It is important to note that up to 5% of the general population has Raynaud's phenomenon. In the absence of signs or symptoms of an underlying condition, Raynaud's phenomenon is classified as primary (Raynaud's disease), which represents an exaggerated physiologic vasomotor response to cold. Secondary Raynaud's phenomenon occurs in SSc and other connective tissue diseases, hematologic and endocrine conditions, and occupational disorders, and can complicate treatment with beta blockers and anticancer drugs such as cisplatin and bleomycin. Distinguishing primary Raynaud's disease from secondary Raynaud's phenomenon can present a diagnostic challenge. Raynaud's disease is supported by the following: absence of an underlying cause; a family history of Raynaud's phenomenon; absence of digital tissue necrosis or ulceration; and a negative ANA test. Secondary Raynaud's phenomenon tends to occur at an older age, is more severe (episodes are more frequent, prolonged, and painful), and is frequently complicated by ischemic digital ulcers and loss of digits **(Fig. 360-6)**.

Nailfold capillaroscopy using a low-power stereoscopic microscope or ophthalmoscope permits visualization of nailbed cutaneous capillaries under immersion oil **(Fig. 360-7)**. Raynaud's disease is associated with evenly spaced parallel vascular loops, whereas in secondary Raynaud's phenomenon, nailfold capillaries are distorted with widened and irregular loops, dilated lumen, microhemorrhages, and areas of vascular "dropout." Thus, nailfold capillaroscopy can be helpful for both differentiating primary from secondary Raynaud's phenomenon and for establishing the early diagnosis of SSc.

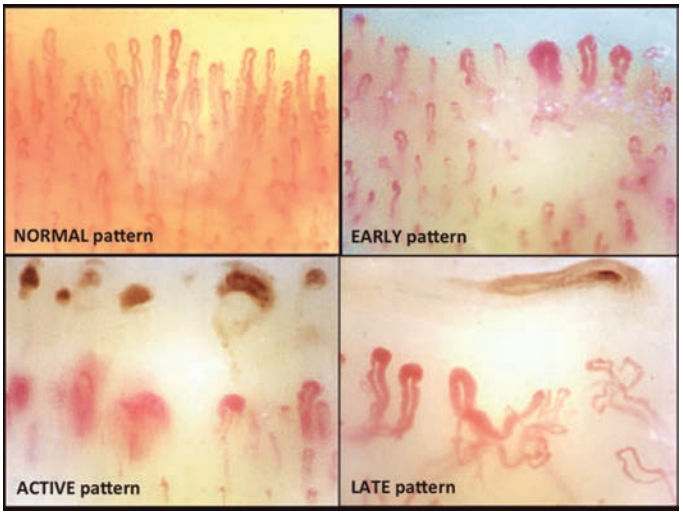

FIGURE 360-7 Systemic sclerosis–associated nailfold capillary alterations. In healthy subjects, note regularly arrayed and uniform-size "hairpin" microvessels. In early pattern, note dilations of microvessels and symmetrically increased microvessels (giant capillaries). In active pattern, note giant capillaries, collapse with microhemorrhages, and loss of capillaries. In late pattern, note massive loss of capillaries, fibrosis, and neoangiogenesis with secondary dilations (nailfold videocapillaroscopy; magnification 220×). *(Courtesy Professor Maurizio Cutolo, University of Genoa, Italy.)*

SKIN FEATURES

Bilateral symmetrical skin thickening is the hallmark that distinguishes SSc from other connective tissue diseases. Skin involvement starts in the fingers and characteristically advances from distal to proximal extremities in an ascending fashion. Some patients note diffuse tanning in the absence of sun exposure as a very early manifestation. In dark-skinned individuals, vitiligo-like hypopigmentation may occur. Pigment loss sparing the perifollicular areas gives rise to a "salt-and-pepper" appearance of the skin, most prominently on the scalp, upper back, and chest. Dermal sclerosis obliterating hair follicles, sweat glands, and eccrine and sebaceous glands causes hair loss, decreased sweating, and xerosis and itching in affected areas of the skin. Transverse creases on the dorsum of the fingers disappear **(Fig. 360-8)**. Fixed flexion contractures of the fingers cause reduced hand mobility and lead to muscle atrophy. Skin and subjacent tendon fibrosis accounts for fixed contractures of the wrists, elbows, and knees. Thick ridges at the neck due to firm adherence of skin to the underlying platysma muscle interfere with neck extension.

Patients with established SSc may show a characteristic "mauskopf" facial appearance with taut and shiny skin, loss of wrinkles, and occasionally an expressionless facies due to reduced mobility of the eyelids, cheeks, and mouth. Thinning of the lips with accentuation of the central incisor teeth and prominent perioral radial furrowing (rhytides) complete the picture. Reduced oral aperture (microstomia) interferes with eating and oral hygiene. The nose assumes a pinched, beak-like appearance. In late-stage disease, the skin becomes thin and atrophic and is firmly bound to the subcutaneous fat (tethering). Dilated skin capillaries 2–20 mm in diameter (telangiectasia), reminiscent of hereditary hemorrhagic telangiectasia, are frequently on the face, hands, lips, and oral mucosa **(Fig. 360-9)**. The number of telangiectasias correlates with the severity of microvascular disease, including PAH. Breakdown of atrophic skin leads to chronic ulcerations at the extensor surfaces of the proximal interphalangeal joints, the volar pads of the fingertips, and bony prominences such as elbows and malleoli. Ulcers are often painful, heal slowly, and become secondarily infected, resulting in osteomyelitis. Healing of ischemic fingertip ulcerations leaves characteristic fixed digital "pits." Loss of soft tissue at the fingertips due to ischemia may be associated with striking resorption of the terminal phalanges (acro-osteolysis) **(Fig. 360-10)**.

Dystrophic calcifications in the skin, subcutaneous, and soft tissues (calcinosis cutis) in the presence of normal serum calcium and phosphate levels occur in up to 40% of patients, most commonly in those with long-standing anti-centromere antibody–positive lcSSc. Calcific deposits, composed of calcium hydroxyapatite crystals, vary in size from tiny punctate lesions to large conglomerate masses, and can be readily visualized on plain radiographs or dual-energy CT. These deposits occur when calcium precipitates in tissue damaged by inflammation, hypoxia, or local trauma. Common locations include the finger pads, palms, extensor surfaces of the forearms, and the olecranon and prepatellar bursae **(Fig. 360-11)**. Large calcific deposits can cause pain and nerve compression and may ulcerate through the

overlying skin with drainage of chalky white material and secondary infections. Paraspinal sheet calcifications may cause neurologic complications.

PULMONARY FEATURES

The two principal forms of lung involvement in SSc, ILD and pulmonary vascular disease, are frequent and together account for a majority of SSc-related deaths. Survival is particularly poor in SSc patients with concurrent presence of these two processes. Less common pulmonary complications of SSc include aspiration pneumonitis complicating chronic gastroesophageal reflux, pulmonary hemorrhage due to endobronchial telangiectasia, obliterative bronchiolitis, pleural reactions, restrictive physiology due to chest wall fibrosis, spontaneous pneumothorax, and drug-induced lung toxicity. The incidence of lung cancer is increased in SSc.

Interstitial Lung Disease While evidence of ILD can be found in up to 65% of SSc patients by high-resolution computed tomography (HRCT), clinically significant ILD develops in 16–43%; the frequency varies depending on the detection method used. Risk factors for significant ILD include male sex, African-American race, diffuse skin involvement, severe gastroesophageal reflux, and presence of topoisomerase-I (Scl-70) autoantibodies, whereas anti-centromere antibody–positive patients have a reduced risk of ILD. Additional risk factors for significant ILD include low forced vital capacity (FVC) or single-breath diffusing capacity of the lung for carbon monoxide (DL_{CO}) at initial presentation. Esophageal dilatation with chronic acid reflux in SSc causes recurrent micro-aspiration, a risk factor for the development and progression of ILD. The most rapid progression in ILD generally occurs early in the disease course (within the first 3–5 years), when the FVC can decline by 30% per year. In contrast, new onset of ILD is rare in SSc patients with long-standing disease.

Pulmonary involvement can remain asymptomatic until it is advanced. The most common presenting respiratory symptoms—exertional dyspnea, fatigue, and reduced exercise tolerance—are subtle and slowly progressive. A chronic dry cough may be present. Physical examination may reveal fine inspiratory "Velcro" crackles at the lung bases. Pulmonary function testing (PFT) is relatively insensitive for detecting early pulmonary involvement. In patients with established SSc-ILD, PFT typically shows a restrictive ventilatory defect (FVC <70% predicted and/or forced expiratory volume in 1 s [FEV_1]/FVC ratio >0.8) and reduced total lung capacity (TLC) and diffusing capacity (DL_{CO}). A reduction in DL_{CO} that is significantly out of proportion to the reduction in lung volumes should raise suspicion for pulmonary vascular disease but may also be due to anemia. Oxygen desaturation with exercise is common.

Chest radiography can be used as an initial screening tool to rule out infection and other causes of respiratory symptoms in SSc, but compared to HRCT, it is relatively insensitive for detection of early ILD. Characteristic imaging findings include lower lobe subpleural reticular linear opacities and ground-glass opacifications with an apicobasal gradient, even in asymptomatic patients with normal PFTs **(Fig. 360-12)**. Additional HRCT findings include mediastinal lymphadenopathy, pulmonary nodules, traction bronchiectasis, and uncommonly, honeycomb changes. The extent of interstitial changes on chest HRCT at baseline is a predictor of ILD progression and mortality. While bronchoalveolar lavage (BAL) can demonstrate inflammatory cells in the lower respiratory tract and may be useful for ruling out tuberculosis and other infections, it does not appear to be useful for SSc diagnosis or for identifying reversible alveolitis. Surgical lung biopsy in SSc is

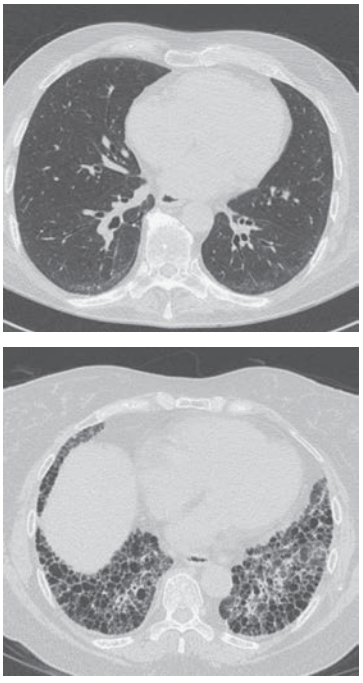

FIGURE 360-12 High-resolution chest CT findings in systemic sclerosis. ***Top panel:*** Early interstitial lung disease with subpleural reticulations and ground-glass opacities in the lower lobes. Patient in supine position. ***Bottom panel:*** Extensive lung fibrosis with coarse reticular honeycombing and traction bronchiectasis. *(Courtesy of Rishi Agrawal, Northwestern University.)*

indicated only in patients with atypical findings on chest imaging. The histologic pattern on lung biopsy may predict the risk of progression of ILD, with the NSIP pattern having a better prognosis than UIP.

Pulmonary Arterial Hypertension PAH results from vascular remodeling of small (<500 μm) pulmonary arteries. PAH develops in 8–12% of patients with SSc as a late complication and can be an isolated abnormality or associated with ILD. PAH is defined as a mean pulmonary artery pressure ≥20 mmHg with a pulmonary capillary wedge pressure ≤15 mmHg and pulmonary vascular resistance >3 Wood units. The natural history of SSc-associated PAH is variable but often follows a progressive course leading to right heart failure. The 3-year survival of SSc patients with untreated PAH is <50%. Risk factors include limited cutaneous disease, older age at disease onset, high numbers of cutaneous telangiectasia, and antibodies to centromere, U3-RNP (fibrillarin), and B23. Mutations in the *BMPR2* gene implicated in idiopathic PAH are not associated with SSc-PAH.

In SSc, PAH is often asymptomatic in early stages. Patients present with exertional dyspnea and reduced exercise capacity. With progression, angina, near-syncope, and symptoms and signs of right-sided heart failure appear. Physical examination may show tachypnea, a loud pulmonic component of the S_2 heart sound, pulmonic/tricuspid regurgitation murmur, palpable right ventricular heave, elevated jugular venous pressure, and dependent edema. Doppler echocardiography is a noninvasive screening method for estimating the pulmonary arterial pressure. In light of the poor prognosis of untreated PAH and better therapeutic response in patients with early diagnosis, SSc patients should be screened for PAH at initial evaluation and annually thereafter. Estimated pulmonary artery systolic pressure >40 mmHg at rest or tricuspid regurgitation jet velocities >3 m/s suggest PAH. Pulmonary function testing may show a reduced DL_{CO} in isolation or out of proportion with the severity of restriction. Because echocardiography can over- or underestimate pulmonary artery pressures, cardiac catheterization is required to confirm the diagnosis of suspected PAH; assess its severity, including the degree of right heart dysfunction; rule out veno-occlusive disease and other cardiac (postcapillary) causes of pulmonary hypertension; and provide prognostic parameters. Distinguishing PAH in SSc patients from pulmonary hypertension secondary to pulmonary fibrosis and hypoxia can be difficult. Serum levels of N-terminal pro-brain natriuretic peptide (NT-proBNP) correlate with the presence and severity of PAH, as well as survival. While NT-proBNP can be useful in PAH screening and in monitoring the response to treatment, elevated levels are not specific for PAH and also occur in other forms of right and left heart disease. Despite more favorable hemodynamics of SSc-associated PAH, its prognosis is worse and treatment response poorer than for idiopathic PAH. This is most likely due to frequent concurrence of ILD and cardiac disease in patients.

GASTROINTESTINAL INVOLVEMENT

Variable involvement of the gastrointestinal (GI) tract, which can affect any level, is the most common internal organ manifestation of SSc, seen in up to 90% of SSc patients with both limited and diffuse cutaneous disease (Table 360-6). Severe GI tract involvement is associated with male sex and specific autoantibodies. The pathologic findings of GI involvement in SSc include fibrosis, smooth-muscle atrophy, and obliterative small vessel vasculopathy throughout the length of the GI tract. Together they have major impact on quality of life, malnutrition, and mortality.

Upper Gastrointestinal Tract Involvement Decreased oral aperture interferes with regular dental hygiene. Loss of periodontal ligament attaching teeth to the alveolar bone leads to teeth loosening. Additional oropharyngeal manifestations due to a combination of xerostomia, shortened frenulum, and resorption of the mandibular condyles cause much distress. Most SSc patients show symptoms of GERD (heartburn, regurgitation, and dysphagia) due to a combination of reduced lower esophageal sphincter pressure resulting in reflux, impaired esophageal clearance of refluxed gastric contents due to diminished motility, and delayed gastric emptying. Calcium channel antagonists and phosphodiesterase inhibitors commonly used to treat Raynaud's phenomenon in SSc can further aggravate reflux. Esophageal manometry shows abnormal motility in most patients, even in the absence of symptoms. Common extraesophageal GERD manifestations in SSc include hoarseness, cough, and chronic microaspiration, which can aggravate underlying ILD. Characteristic chest CT findings include dilated patulous esophagus with intraluminal air. Esophageal dilation is associated with the severity of ILD. Endoscopy may be indicated in patients with dysphagia in order to rule out opportunistic infections with *Candida*, herpes virus, and cytomegalovirus. Severe erosive esophagitis may be found in patients with minimal symptoms. Esophageal strictures and Barrett's esophagus may complicate chronic GERD in SSc patients. Because Barrett's metaplasia is associated with increased risk of adenocarcinoma, these patients require regular surveillance endoscopy with biopsy.

Gastroparesis with early satiety, abdominal distention, and aggravated reflux symptoms is common. Barium contrast studies are neither sensitive nor specific for evaluation of gastric involvement in SSc. Gastric antral vascular ectasia (GAVE) in the antrum may occur. These subepithelial lesions, reflecting the widespread small vessel vasculopathy of SSc, are called "watermelon stomach" due to their endoscopic appearance. GAVE may present with recurrent episodes of GI bleeding, resulting in chronic unexplained anemia. Patients with SSc show increased prevalence of *Helicobacter pylori* infection in the stomach.

Lower Gastrointestinal Tract and Anorectal Involvement Weight loss and malnutrition due to a combination impaired intestinal motility, malabsorption, and chronic diarrhea secondary to bacterial overgrowth are common. Fat and protein malabsorption and vitamin B_{12} and vitamin D deficiency ensue and may be further exacerbated by pancreatic insufficiency. Disturbed intestinal motor function can also lead to episodic intestinal pseudo- obstruction, with symptoms that are indistinguishable from those of delayed gastric emptying. Patients present with acute abdominal pain, nausea, and vomiting, and radiographic studies show acute intestinal obstruction. A major diagnostic challenge is differentiating pseudo-obstruction, which responds to supportive care and intravenous nutritional supplementation, from mechanical obstruction. Colonic involvement in SSc may result in constipation, occasionally complicated by sigmoid volvulus, fecal incontinence, GI bleeding from telangiectasia, and rectal prolapse. In late-stage SSc, wide-mouth sacculations or diverticula occur in the

TABLE 360-6 Prominent Gastrointestinal Manifestations of Systemic Sclerosis and Their Management

Abbreviation: SIBO, small intestinal bacterial overgrowth.

colon and occasionally cause perforation and bleeding. An unusual radiologic finding is pneumatosis cystoides intestinalis, which is due to air trapping in the bowel wall that may rarely rupture and cause benign pneumoperitoneum. Studies of the fecal microbiota in SSc show a reduction in protective butyrate-producing bacteria, potentially promoting a proinflammatory intestinal microenvironment. Although the liver is rarely affected in patients with SSc, primary biliary cirrhosis may occur, particularly in patients with limited cutaneous disease.

Edward Stern and Christopher Denton, Royal Free Hospital, London, UK.)*

RENAL INVOLVEMENT: SCLERODERMA RENAL CRISIS

Scleroderma renal crisis presents with accelerated hypertension accompanied by acute kidney injury and progressive failure. This acute life-threatening complication occurs in <15% of SSc patients, almost always within 4 years of disease onset. Scleroderma renal crisis can occasionally even be the presenting manifestation of SSc. While short-term survival in scleroderma renal crisis was <10% prior to the advent of angiotensin-converting enzyme (ACE) inhibitors, outcomes for this serous complication have shown great improvement. The pathogenesis involves obliterative vasculopathy of the renal arcuate and interlobular arteries, with consequent intravascular hemolysis **(Fig. 360-13)**. Progressive reduction in renal blood flow, aggravated by vasospasm, leads to increased juxtaglomerular renin secretion and angiotensin II generation, with further renal vasoconstriction resulting in a vicious cycle that culminates in accelerated hypertension. Risk factors for scleroderma renal crisis include African-American race, male sex, and diffuse or progressive skin involvement. Up to 50% of patients with scleroderma renal crisis have antibodies to anti-RNA polymerase III, whereas patients with anti-centromere antibodies appear protected. Palpable tendon friction rubs, pericardial effusion, new unexplained anemia, and thrombocytopenia may be harbingers of impending scleroderma renal crisis. High-risk patients with early-stage SSc should monitor their blood pressure daily. Because glucocorticoid use is associated with scleroderma renal crisis, prednisone in high-risk SSc patients should be taken only when absolutely required and at low doses (<10 mg/d).

Patients with scleroderma renal crisis characteristically present with accelerated hypertension (generally >150/90 mmHg) and progressive oliguric renal insufficiency. However, ~10% of patients present with blood pressure in the normal range. Normotensive renal crisis is generally associated with a poor outcome. Headache, blurred vision, congestive heart failure, and pulmonary edema may accompany elevation of blood pressure. Moderate thrombocytopenia and microangiopathic hemolysis with fragmented red blood cells can be seen, and urinalysis typically shows mild proteinuria, granular casts, and microscopic hematuria. Progressive oliguric renal failure over several days generally follows. Scleroderma renal crisis is sometimes misdiagnosed as thrombotic thrombocytopenic purpura (TTP) or other forms of thrombotic microangiopathy. In such cases, renal biopsy and determination of serum von Willebrand factor–cleaving protease activity may be of benefit. The presence of oliguria or a creatinine >3 mg/dL at initial presentation predicts poor outcome (permanent hemodialysis and mortality), as do vascular thrombosis and glomerular ischemic collapse on renal biopsy. Crescentic glomerulonephritis in the setting of SSc has been described and may be associated with myeloperoxidase-specific antineutrophil cytoplasmic antibodies (ANCAs). Membranous glomerulonephritis may occur in patients treated with D-penicillamine. Asymptomatic renal impairment can occur in up to half of SSc patients, is commonly associated with other vascular manifestations, and rarely progresses to end-stage renal failure.

CARDIAC INVOLVEMENT

Although it is often silent, cardiac involvement is detected in 10–50% of SSc patients screened with sensitive diagnostic tools. Clinical cardiac involvement is more frequent in dcSSc than in lcSSc and may be primary or secondary to PAH, ILD, or renal involvement. Cardiac involvement in SSc is associated with poor outcomes. The endocardium, myocardium, and pericardium may each be affected separately or together. Pericardial involvement is manifested as pericarditis, pericardial effusions, constrictive pericarditis, and rarely, cardiac tamponade. Conduction system fibrosis is common and may be silent or manifested by heart block. Other arrhythmias include premature ventricular contractions, atrial fibrillation, and supraventricular tachycardia. Microvascular involvement, recurrent vasospasm, and ischemia-reperfusion injury contribute to patchy myocardial fibrosis, and the resulting systolic or diastolic left ventricular dysfunction may progress to overt heart failure. Acute or subacute myocarditis leading to left ventricular dysfunction may occur, best diagnosed by cardiac magnetic resonance imaging or endomyocardial biopsy. While conventional echocardiography has low sensitivity for detecting preclinical heart involvement in SSc, newer modalities such as tissue Doppler echocardiography (TDE), cardiac MRI, and nuclear imaging (single-photon emission CT [SPECT]) reveal a high prevalence of abnormal myocardial function or perfusion. The serum levels of NT-proBNP, a ventricular hormone elevated in SSc-PAH, may also have utility as a marker of primary cardiac involvement.

MUSCULOSKELETAL COMPLICATIONS

Musculoskeletal complications are commonly seen in SSc. Carpal tunnel syndrome may be a presenting disease manifestation, and generalized arthralgia and stiffness are prominent in early disease. Mobility of both small and large joints is progressively impaired, and fixed contractures at the proximal interphalangeal joints and wrists ensue. Large joint contractures occur in patients with dcSSc and are frequently accompanied by tendon friction rubs. These are characterized by coarse leathery crepitation heard or palpated upon passive joint movement and are caused by fibrosis and adhesion of the tendon sheaths and fascial planes at the affected joint. The presence of tendon friction rubs is associated with increased risk for renal and cardiac complications and reduced survival. Synovitis seen on ultrasound or MRI is common; occasional SSc patients develop erosive polyarthritis in the hands, and some may have a seropositive rheumatoid arthritis overlap. Muscle weakness is common and multifactorial; deconditioning, disuse

atrophy, malnutrition, inflammation, and fibrosis may all contribute. A chronic noninflammatory form of myopathy characterized by atrophy and fibrosis with mildly elevated muscle enzymes occurs in late-stage SSc. Bone resorption in the terminal phalanges causes the characteristic loss of the distal tufts (acro-osteolysis) (Fig. 360-5). Resorption of the mandibular condyles can lead to bite difficulties. Osteolysis can also affect the ribs and distal clavicles.

LESS RECOGNIZED DISEASE MANIFESTATIONS

Dry eyes and dry mouth (sicca complex) are common in SSc. Biopsy of the minor salivary glands in these cases shows fibrosis rather than focal lymphocytic infiltration characteristic of primary Sjögren's syndrome **(Chap. 361)**. Hypothyroidism resulting from Graves' or Hashimoto's disease is common, particularly in lcSSc, and may be underrecognized. Whereas the central nervous system is generally spared in SSc, unilateral or bilateral sensory trigeminal neuropathy can occur. Erectile dysfunction is a frequent and occasionally initial disease manifestation. Inability to attain or maintain penile erection is due to vascular insufficiency and fibrosis of corporeal smooth muscle and responds poorly to medical therapy. Sexual performance is also adversely affected in women. While fertility is not impaired in SSc, pregnancy is associated with a higher risk of adverse fetal outcomes. Furthermore, cardiopulmonary involvement may worsen during pregnancy, and new onset of scleroderma renal crisis has been described.

Cancer Epidemiologic studies indicate an increased cancer risk in SSc. Lung cancer and esophageal adenocarcinoma typically occur in the setting of long-standing ILD or GERD and may be linked to chronic inflammation and tissue repair. In contrast, breast, lung, and ovarian carcinomas and lymphomas tend to occur in close temporal association with the onset of SSc, particularly in patients who have autoantibodies to RNA polymerase III. In this scenario, SSc may represent a paraneoplastic syndrome that is triggered by the antitumor immune response.

LABORATORY EVALUATION AND BIOMARKERS

Mild microcytic anemia is frequent and may indicate recurrent GI bleeding caused by GAVE or chronic esophagitis. Macrocytic anemia may be caused by folate and vitamin B_{12} deficiency due to small-bowel bacterial overgrowth and malabsorption or by drugs such as methotrexate. Microangiopathic hemolytic anemia caused by mechanical fragmentation of red blood cells during their passage through microvessels coated with fibrin or platelet thrombi is a hallmark of scleroderma renal crisis. The erythrocyte sedimentation rate (ESR) is generally normal in SSc; an elevation may signal coexisting myositis or malignancy.

Antinuclear autoantibodies are detected in almost all patients with SSc. Anti-topoisomerase I (Scl-70) and anti-centromere antibodies are mutually exclusive and highly specific for SSc. Topoisomerase I (Scl-70) antibodies are associated with increased risk of ILD and poor outcomes. Anti-centromere antibodies are associated with PAH, but only infrequently with significant cardiac, pulmonary, or renal involvement. Nucleolar immunofluorescence pattern may indicate antibodies to U3-RNP (fibrillarin), Th/To, or PM/Scl, whereas speckled immunofluorescence indicates antibodies to RNA polymerase III, associated with increased risk of scleroderma renal crisis and malignancy **(Fig. 360-14)**.

DIAGNOSIS, STAGING, AND MONITORING

The diagnosis of SSc is made primarily on clinical grounds and is generally straightforward in patients with established disease. Diagnostic criteria developed for classification are >90% specific and sensitive for SSc. The presence of skin induration with a characteristic symmetric distribution pattern associated with typical visceral organ manifestations establishes the diagnosis with a high degree of certainty. In lcSSc, a history of Raynaud's phenomenon and GERD symptoms, coupled with sclerodactyly and nailfold capillary changes, often in combinations with cutaneous telangiectasia and calcinosis cutis, helps to establish the diagnosis. Primary Raynaud's disease is a benign condition that must be differentiated from early or limited SSc. Nailfold microscopy is particularly helpful in this situation, because in contrast to SSc, nailfold capillaries are normal. Diagnosing SSc at an early stage may be a challenge. In dcSSc, initial symptoms are often nonspecific, Raynaud's phenomenon may be absent, and physical examination may only show upper extremity edema and puffy fingers. Early-stage SSc might be initially misdiagnosed as arthritis, SLE, myositis, or, most commonly, undifferentiated connective tissue disease leading to delays in diagnosis. Within weeks to months, Raynaud's phenomenon and advancing skin induration appear. SSc-specific autoantibodies provide a high degree of diagnostic certainty. Raynaud's phenomenon with fingertip ulcerations or other evidence of digital ischemia, coupled with telangiectasia, distal esophageal dysmotility, unexplained ILD or PAH, or accelerated hypertension with renal failure in the absence of clinically evident skin induration, suggests the diagnosis of SSc *sine* scleroderma. Patients with a new diagnosis of SSc should be screened for ILD, followed by regular pulmonary monitoring for several years **(Fig. 360-15)**.

MANAGEMENT OF SYSTEMIC SCLEROSIS

OVERVIEW: GENERAL PRINCIPLES

To date, no therapy has been shown to significantly alter the natural history of SSc. In contrast, numerous interventions are effective in alleviating the symptoms, slowing the progression of the cumulative organ damage, and reducing disability. Moreover, a significant decrease in disease-related mortality has been noted during the past 25 years. In light of the marked heterogeneity in disease manifestations, course, and outcomes, optimized care for patients with SSc requires a thoughtful "precision medicine" approach that is tailored specifically to each individual patient's unique needs.

The following general principles should guide management **(Table 360-7)**: prompt and accurate diagnosis; patient subclassification and risk stratification based on clinical, radiologic, and laboratory evaluation, including autoantibody profiles and prognostic and predictive biomarkers; early recognition of organ-based complications and assessment of their extent, severity, and likelihood of deterioration; regular monitoring for disease progression, new complications, and response to and side effects of therapy; adjusting therapy; and patient education. In order to minimize the risk of irreversible organ damage, management should be individualized and proactive, with regular screening and initiation of appropriate intervention at the earliest possible opportunity. In light of the complex and multisystemic nature of the SSc, a team-oriented management approach integrating appropriate specialists should be pursued. Most patients are treated with a combination of drugs that impact different aspects of the disease. Patients should be encouraged to become familiar with potential complications and therapeutic options, including interventional trials, and natural history and should be empowered to partner with their treating physicians. This requires a long-term relationship between patient and physician, with ongoing counseling, encouragement, and two-way dialogue.

DISEASE-MODIFYING THERAPY: IMMUNOSUPPRESSIVE AGENTS

Immunosuppressive agents used in other autoimmune diseases have generally shown modest or no benefit in SSc. Glucocorticoids alleviate stiffness and aching in early inflammatory-stage dcSSc but do not influence the progression of skin or internal organ involvement. Since their use is associated with an increased risk of scleroderma renal crisis, glucocorticoids should be given only when absolutely necessary, at the lowest dose possible, and for brief periods only.

Cyclophosphamide has been extensively studied in light of its efficacy in the treatment of vasculitis **(Chap. 363)**, SLE **(Chap. 356)**, and other autoimmune diseases **(Chap. 355)**. Both oral and intravenous cyclophosphamide have been shown to reduce the progression of SSc-associated ILD, with stabilization and, rarely, modest improvement

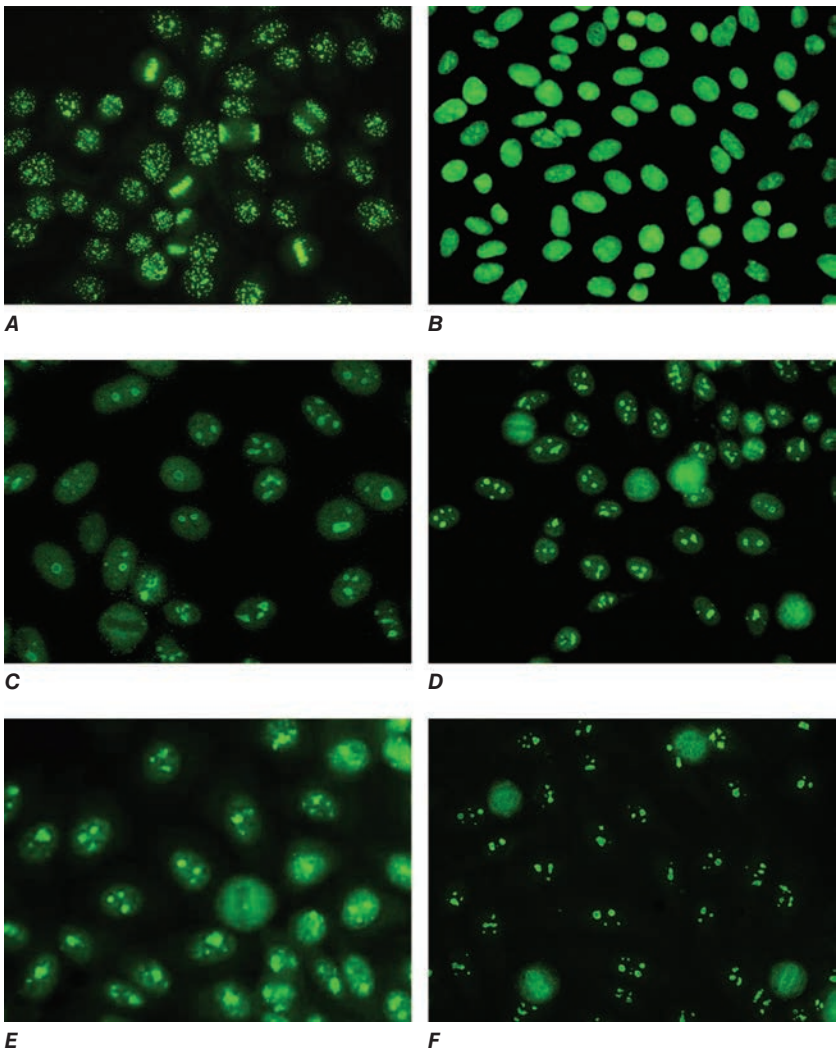

FIGURE 360-14 SSc-associated autoantibodies: immunofluorescence. Indirect immunofluorescence of SSc serum samples using HEp-2 substrate. Representative images show (***A***) anti-centromere; (***B***) anti-Scl-70/topoisomerase I; (***C***) anti-PM/Scl; (***D***) anti-Th/To; (***E***) anti-RNA polymerase III; and (***F***) anti-fibrillarin/U3RNP antibodies. Variations in immunostaining are clues to autoantibody specificity, but immunoassays with purified autoantigens are needed to confirm antigen specificity. *(Courtesy of Marvin Fritzler and Susan Copple, Inova Diagnostics Inc., San Diego, CA.)*

of pulmonary function, HRCT findings, respiratory symptoms, and skin induration. These benefits of cyclophosphamide need to be balanced against its potential toxicity, including bone marrow suppression, opportunistic infections, hemorrhagic cystitis and bladder cancer, premature ovarian failure, and late secondary malignancies.

Methotrexate had modest effect on SSc skin involvement in small studies. Mycophenolate mofetil was evaluated in both open-label and randomized controlled trials. Both skin induration and ILD improved in patients treated with mycophenolate mofetil, and the drug was well tolerated. Tocilizumab, a monoclonal antibody that blocks IL-6 receptor signaling, also showed benefit on both skin and lung involvement in randomized SSc trials. Open-label studies and small clinical trials provide some support for rituximab, a monoclonal antibody directed against the mature B-cell marker CD20, along with extracorporeal photopheresis, IV immunoglobulin, and abatacept, a fusion protein that inhibits T-cell co-stimulation and function. The use of cyclosporine, azathioprine, hydroxychloroquine (Plaquenil), thalidomide, and rapamycin for SSc therapy is currently not well supported by the literature. Intensive immune ablation using high-dose chemotherapy, followed by autologous hematopoietic stem cell reconstitution therapy (HSCT), was associated with durable remission and improved long-term survival in multiple randomized clinical trials. Currently, HSCT is indicated for selected patients with severe SSc but carries potential morbidity and mortality, as well as significant cost. Additional forms of potentially disease-modifying cellular therapies are under investigation.

Antifibrotic Therapy Because tissue fibrosis underlies organ damage in SSc, drugs that interfere with the fibrotic process represent a rational therapeutic approach. In older retrospective studies, D-penicillamine was shown to stabilize skin induration, prevent new internal organ involvement, and improve survival. However, a randomized controlled clinical trial in early active SSc found no difference in the extent of skin involvement between patients treated with standard-dose (750 mg/d) or very low-dose (125 mg every other day) D-penicillamine. Recent clinical trials show benefit of the tyrosine kinase inhibitor nintedanib, alone or in combination with mycophenolate, in patients with SSc-ILD, with significant slowing of the loss of lung function.

Vascular Therapy The goal of Raynaud's therapy is to control episodes, prevent and enhance the healing of ischemic complications, and slow the progression of obliterative vasculopathy. Patients should dress warmly, minimize cold exposure, and avoid drugs that precipitate or exacerbate vasospastic episodes. Extended-release dihydropyridine calcium channel blockers such as amlodipine and nifedipine, as well as diltiazem, ameliorate Raynaud's phenomenon, but their use is often limited by side effects (palpitations, dependent edema, worsening gastroesophageal reflux). While ACE inhibitors do not reduce the

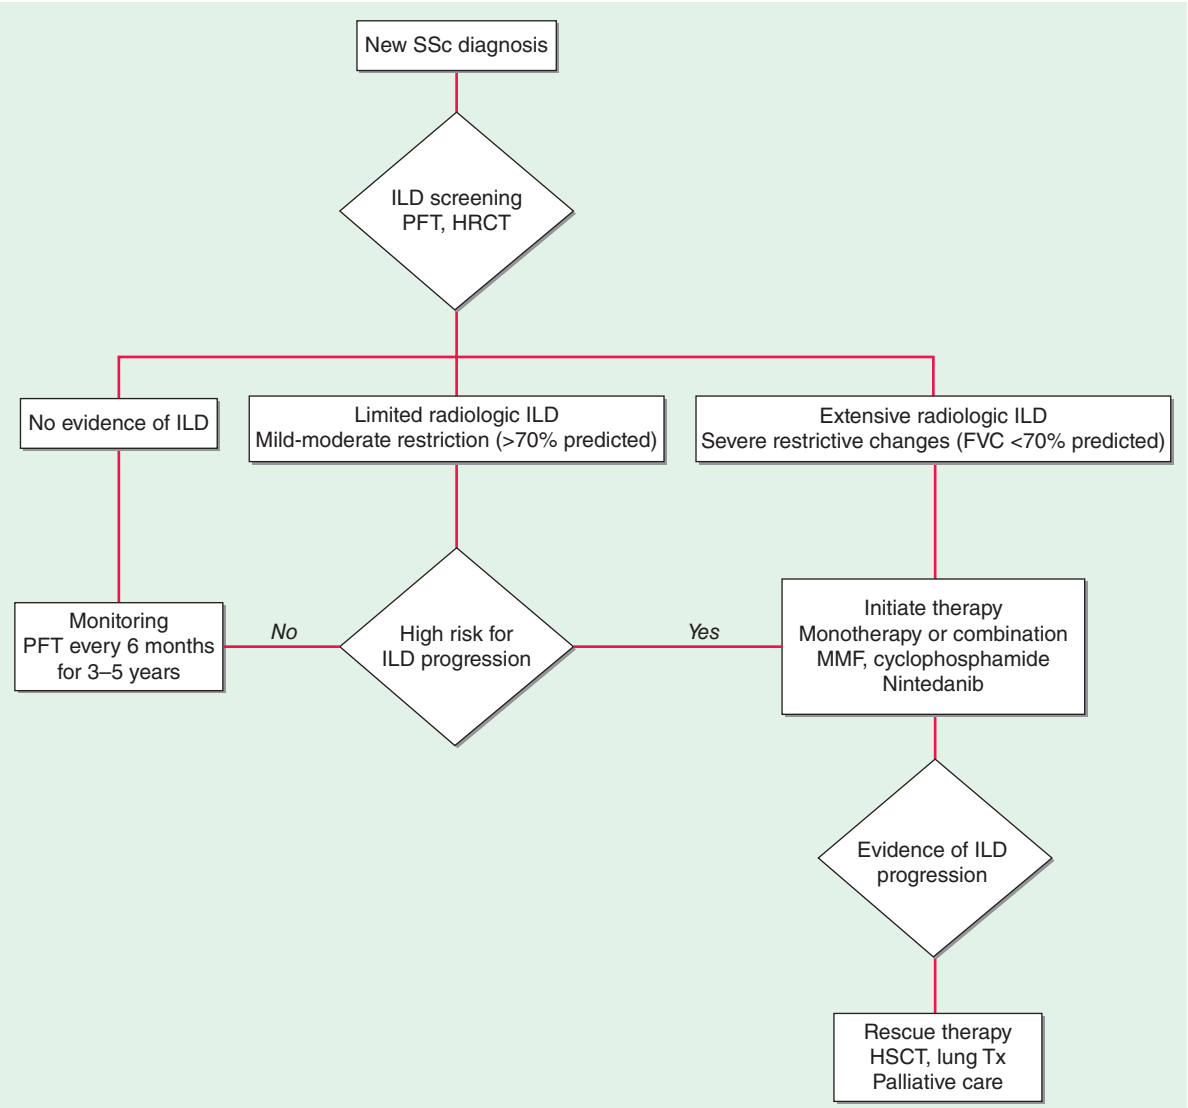

FIGURE 360-15 Proposed algorithm for screening, monitoring, and treatment of systemic sclerosis (SSc)-associated interstitial lung disease (ILD). FVC, forced vital capacity; HRCT, high-resolution computed tomography; HSCT, hematopoietic stem cell transplantation; MMF, mycophenolate mofetil; PFT, pulmonary function testing; Tx, transplantation. *(Adapted from A Perelas et al: Lancet Respir Med 8:304, 2020.)*

frequency or severity of episodes, angiotensin II receptor blockers such as losartan are effective and well tolerated. Patients with Raynaud's phenomenon unresponsive to these therapies may require the addition of α_1-adrenergic receptor blockers (e.g., prazosin), phosphodiesterase-5 inhibitors (e.g., sildenafil), topical nitroglycerine, and intermittent IV infusions of prostaglandins. Low-dose aspirin and dipyridamole prevent platelet aggregation and may have a role as adjunctive agents. In patients with ischemic digital tip ulcerations, the endothelin-1 receptor antagonist bosentan reduces the risk of new ulcers. Digital sympathectomy and intradigital injections of botulinum type A (Botox) may be considered in patients with severe ongoing ischemia. Empirical long-term therapy with statins and antioxidants may retard the progression of vascular damage and obliteration. There is limited evidence-based information for the treatment of cardiac complications of SSc, which should be guided by specialists experienced in their diagnosis and management. While selective beta blockers such as metoprolol can precipitate vasospasm, nondihydropyridine calcium channel blockers can be used for rate control in atrial arrhythmias, and nonselective alpha/beta blockers such as carvedilol can be used for improving myocardial perfusion and left ventricular systolic function.

TABLE 360-7 Key Principles in Management

- Establish early and accurate diagnosis.
- Detect and evaluate internal organ involvement.
- Define clinical disease stage and activity.
- Tailor individualized therapy to each patient's unique needs.
- Assess treatment response, and adjust therapy as needed; monitor for disease activity, progression, and new complications.

TREATMENT

SSC-ASSOCIATED INTERSTITIAL LUNG DISEASE

ILD is a leading cause of death in patients with SSc. However, because the course of SSc-associated ILD is highly variable, it is important to identify patients who are at high risk for disease progression. The extent of ILD on HRCT and the FVC at initial evaluation and the decline in FVC during the preceding 12-month period are helpful in identifying these patients. Additionally, male sex, older age at initial presentation, progressive skin involvement, and myocardial disease may be risk factors for ILD progression. Patients at high risk for ILD should be monitored by performing PFTs every 6 months (Fig. 360-15); serial HRCT imaging is not recommended. Cyclophosphamide, given IV or orally for 6–12 months,

and mycophenolate mofetil slow the decline in lung function and improve respiratory symptoms, but cyclophosphamide is associated with more frequent side effects. The efficacy and optimal duration of antifibrotic therapy with nintedanib, which was recently approved for SSc-associated ILD, are currently under investigation. In patients who show continued progression of ILD despite medical therapy, lung transplantation might be considered as a life-prolonging procedure, although significant GERD contributing to organ rejection is a concern in SSc. Recurrence of SSc-ILD in transplanted lung allografts has not been reported.

TREATMENT OF GASTROINTESTINAL COMPLICATIONS

Because oral problems, including decreased oral aperture, decreased saliva production, gum recession, periodontal disease, and teeth loss, are common, regular dental care is recommended. Gastroesophageal reflux is very common in SSc and may occur in the absence of symptoms. Patients should be instructed to elevate the head of the bed, eat frequent small meals, and avoid alcohol, caffeine, known reflux exacerbants, and meals before bedtime. Proton pump inhibitors to reduce acid reflux may need to be given in relatively high doses. Prokinetic agents such as metoclopramide, erythromycin (a motilin agonist), and domperidone may occasionally be helpful in SSc but are frequently associated with side effects. Botulinum toxin injection sometimes ameliorates impaired gastric emptying. Antireflux procedures such as Nissen fundoplication can result in secondary achalasia and generally should be avoided. Episodic bleeding from GAVE (watermelon stomach) may be treated with endoscopic ablation using laser or argon plasma photocoagulation, although it commonly recurs. In some patients, enteral feeding and/or decompression via percutaneous gastrostomy or jejunostomy may become necessary. Small intestinal bacterial overgrowth secondary to gut dysmotility causes abdominal bloating and diarrhea and may lead to malabsorption and severe malnutrition. Short courses of rotating broad-spectrum antibiotics such as metronidazole, erythromycin, and rifaximin can eradicate bacterial overgrowth. Small bowel hypomotility may respond to octreotide, but pseudo-obstruction is difficult to treat. Fecal incontinence, a frequent but underreported complication, may respond to antidiarrheal medication, biofeedback, sphincter augmentation, and sacral neuromodulation. Potential malnutrition should be routinely assessed.

TREATMENT OF PULMONARY ARTERIAL HYPERTENSION

In SSc, PAH carries an extremely poor prognosis and accounts for 30% of deaths. Because PAH is asymptomatic until advanced, patients with SSc should be screened at initial evaluation and regularly thereafter. Treatment is generally started with an oral endothelin-1 receptor antagonist such as bosentan or a phosphodiesterase-5 inhibitor such as sildenafil. Recently, the soluble guanylate cyclase stimulator riociguat, which acts by increasing the production of nitric oxide, and the selective IP prostacyclin receptor agonist selexipag were shown to improve PAH symptoms and survival. Patients may also require diuretics and digoxin. If hypoxemia is documented, supplemental oxygen should be prescribed in order to avoid secondary pulmonary vasoconstriction. Prostacyclin analogues such as epoprostenol or treprostinil can be given by continuous IV or SC infusion or via intermittent nebulized inhalations. Combination therapy with different classes of agents acting additively or synergistically is often necessary. Lung transplantation remains an option for selected SSc patients with PAH who fail medical therapy, and 2-year survival rates (64%) are comparable to those of idiopathic ILD or PAH.

MANAGEMENT OF RENAL CRISIS

Scleroderma renal crisis represents a medical emergency. Since its outcome is largely determined by the extent of renal damage at the time that aggressive therapy is initiated, prompt recognition of impending or early scleroderma renal crisis is essential, and efforts should be made to avoid its occurrence. High-risk SSc patients (early disease, extensive and progressive skin involvement, tendon friction rubs, and anti-RNA polymerase III antibodies) should be instructed to monitor their blood pressure daily and report significant alterations immediately. Potentially nephrotoxic drugs should be avoided, and glucocorticoids should be used only when absolutely necessary and at low doses. Patients presenting with scleroderma renal crisis should be immediately hospitalized. Once other causes of acute renal disease are excluded, treatment should be started promptly with titration of short-acting ACE inhibitors, with the goal of rapid normalization of the blood pressure. In patients with persistent hypertension, addition of angiotensin II receptor blockers, calcium channel blockers, endothelin-1 receptor blockers, prostacyclins, and direct renin inhibitors should be considered. In light of evidence for intrarenal complement pathway activation in some patients with scleroderma renal crisis, addition of eculizumab to ACE inhibitors may be considered. Up to two-thirds of patients with scleroderma renal crisis necessitate dialysis. Substantial renal recovery can occur following an episode of scleroderma renal crisis, and renal replacement therapy can be ultimately discontinued in 30–50% of patients. Kidney transplantation is appropriate for patients unable to discontinue dialysis after 2 years. Survival of transplanted SSc patients is comparable to that of other diseases, and recurrence of renal crisis is rare.

SKIN CARE

Because skin involvement in SSc is never life-threatening and stabilizes, and may even regress spontaneously, disease management should not be dictated by its cutaneous manifestations. The inflammatory symptoms of early skin involvement can be controlled with antihistamines and short-term use of low-dose glucocorticoids (<5 mg/d of prednisone). Cyclophosphamide and methotrexate have modest effects on skin induration. Because the skin is dry, the use of hydrophilic ointments and bath oils is encouraged, and regular skin massage is helpful. Telangiectasia, which presents a cosmetic problem, especially on the face, can be treated with pulsed dye laser. Ischemic digital ulcerations should be protected by occlusive dressings to promote healing and prevent infection. Infected skin ulcers are treated with topical antibiotics and surgical debridement. While no therapy has been shown to be effective in preventing soft-tissue calcific deposition or promoting its dissolution, reports support the use of minocycline, bisphosphonates, and topical or IV sodium thiosulfate (STS). Additional approaches include carbon dioxide laser treatment, extracorporeal shock-wave lithotripsy, and surgical high-speed microdrilling.

TREATMENT OF MUSCULOSKELETAL COMPLICATIONS

Arthralgia and joint stiffness are very common and distressing manifestations in early-stage disease. Short courses of nonsteroidal anti-inflammatory agents, methotrexate, and cautious use of low-dose glucocorticoids alleviate symptoms. Physical and occupational therapy can be effective for preventing loss of musculoskeletal function and joint contractures and should be initiated early.

COURSE

The natural history of SSc is highly variable and difficult to predict, especially in early stages of the disease. Patient with dcSSc tend to have a more rapidly progressive course and worse prognosis than those with lcSSc. Inflammatory symptoms of early dcSSc, such as fatigue, edema, joint pain, and pruritus, subside, and skin thickening reaches a plateau at 2–4 years after disease onset. It is during the early edematous/inflammatory stage that life-threatening visceral organ involvement may develop. While existing visceral organ involvement, such as ILD, may progress even after skin involvement peaks, new organ involvement is rare. Scleroderma renal crisis generally occurs within the first 4 years of disease. In late-stage disease (>6 years), the skin is usually soft and atrophic. Skin regression characteristically occurs in an order that is the reverse of initial involvement, with softening on the trunks followed by proximal and finally distal extremities; however, sclerodactyly and

fixed finger contractures generally persist. Relapse or recurrence of skin thickening after peak skin involvement has been reached is uncommon. Patients with lcSSc follow a clinical course that is markedly different than that of dcSSc. Raynaud's phenomenon typically precedes other disease manifestations by years or even decades. Visceral organ complications such as PAH generally develop late and progress slowly.

PROGNOSIS

SSc confers a substantial increase in the risk of premature death. Age- and gender-adjusted mortality rates are five- to eightfold higher compared to the general population, and more than half of all patients with SSc die from their disease. In one population-based study of SSc, the median survival was 11 years. In patients with dcSSc, 5- and 10-year survival rates are 70% and 55%, respectively, whereas in patients with lcSSc, 5- and 10-year survival rates are 90% and 75%, respectively. The prognosis correlates with the extent of skin involvement, which itself is a surrogate for visceral organ involvement. Major causes of death are PAH, pulmonary fibrosis, GI involvement, and cardiac disease. Scleroderma renal crisis is associated with a 30% 3-year mortality. Lung cancer and excess cardiovascular deaths also contribute to increased mortality. Markers of poor prognosis include male gender, African-American race, older age at disease onset, extensive skin thickening with truncal involvement, palpable tendon friction rubs, and evidence of significant or progressive visceral organ involvement. Laboratory predictors of increased mortality at initial evaluation include an elevated ESR, anemia, proteinuria, and anti–topoisomerase I (Scl-70) antibodies. In one study, SSc patients with extensive skin involvement, lung vital capacity <55% predicted, significant GI involvement (pseudo-obstruction or malabsorption), clinical cardiac involvement, or scleroderma renal crisis had a 9-year survival <40%. The severity of PAH predicts mortality, and patients with mean pulmonary arterial pressure ≥45 mmHg had a 33% 3-year survival. The advent of ACE inhibitors in scleroderma renal crisis had a dramatic impact on survival, increasing survival from <10% at 1 year in the pre–ACE inhibitor era to >70% 3-year survival at the present time. Moreover, 10-year survival in SSc improved from <60% in the 1970s to >66–78% in the 1990s, a trend that reflects both earlier detection and better management of complications.

LOCALIZED SCLERODERMA

The term *scleroderma* describes a group of localized skin disorders (Table 360-1). These occur more commonly in children than in adults and, in marked contrast to SSc, are generally not complicated by Raynaud's phenomenon or significant internal organ involvement. Morphea presents as solitary or multiple circular patches of thick skin or, rarely, as widespread induration (generalized or pansclerotic morphea); the fingers are generally spared. Linear scleroderma may affect subcutaneous tissues, leading to fibrosis and atrophy of supporting structures, tendons, muscle, and even bone. In children, the growth of affected long bones can be retarded. When linear scleroderma crosses large joints, significant contractures can develop.

MIXED CONNECTIVE TISSUE DISEASE

Patients who have lcSSc coexisting with features of SLE, polymyositis, and rheumatoid arthritis may have mixed connective tissue disease (MCTD). This overlap syndrome is generally associated with the presence of high titers of autoantibodies to U1-RNP. The characteristic initial presentation is Raynaud's phenomenon associated with puffy fingers and myalgia. Over time, sclerodactyly, soft-tissue calcinosis, and cutaneous telangiectasia may appear. Skin rash suggestive of SLE (malar erythema, photosensitivity) or dermatomyositis (heliotrope rash on the eyelids, erythematous rash on knuckles) occurs. Arthralgia is common, and some patients develop erosive polyarthritis. Pulmonary fibrosis and isolated or secondary PAH may develop. Other manifestations include esophageal dysmotility, pericarditis, Sjögren's syndrome, and renal disease, especially membranous glomerulonephritis. Laboratory evaluation shows elevated ESR and hypergammaglobulinemia. While anti-U1RNP antibodies are detected in high titers, SSc-specific autoantibodies are absent. In contrast to SSc, MCTD often responds to glucocorticoids, and the long-term prognosis is better than that of SSc. Whether MCTD is truly a distinct entity or is a subset of SLE or SSc remains controversial.

EOSINOPHILIC FASCIITIS (DIFFUSE FASCIITIS WITH EOSINOPHILIA)

Eosinophilic fasciitis is a rare idiopathic disorder of adults associated with abrupt skin induration. The skin characteristically shows a coarse cobblestone "peau d'orange" appearance. In contrast to SSc, Raynaud's phenomenon and SSc-associated internal organ involvement and autoantibodies are absent. Furthermore, skin involvement spares the fingers. Full-thickness biopsy of the lesional skin reveals fibrosis of the subcutaneous fascia, with variable inflammation and eosinophil infiltration. In the acute phase of the illness, peripheral blood eosinophilia may be prominent. MRI appears to be a sensitive tool for the diagnosis of eosinophilic fasciitis. Eosinophilic fasciitis can occur in association with, or preceding, various myelodysplastic syndromes or multiple myeloma. Although glucocorticoids cause prompt resolution of eosinophilia, the skin shows slow and variable improvement. The prognosis of patients with eosinophilic fasciitis is generally good.

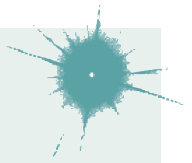
361 Sjögren's Syndrome

Haralampos M. Moutsopoulos, Clio P. Mavragani



DEFINITION, INCIDENCE, AND PREVALENCE

Sjögren's syndrome is a prototype autoimmune disease characterized by lymphocytic infiltration of the exocrine glands resulting in xerostomia, dry eyes (keratoconjunctivitis sicca), and profound B-cell hyperactivity. The syndrome has unique features since it presents with a wide clinical spectrum from organ-specific to systemic disease; can occur alone or in association with other systemic rheumatic diseases, more commonly rheumatoid arthritis, limited scleroderma, and systemic lupus erythematosus; and displays high probability of the development of lymphoma. Because of all these characteristics, it is an ideal model to study not only autoimmunity but also lymphoid malignancy.

Middle-aged women (female-to-male ratio 10-20:1) are primarily affected, although Sjögren's syndrome may occur at any age, including childhood. Patients with earlier disease onset express a more aggressive disease phenotype manifested by a high occurrence of systemic manifestations and serum autoantibodies. The prevalence of Sjögren's syndrome is ~0.5–1%, while 5–20% of patients with other autoimmune diseases can express sicca manifestations.

PATHOGENESIS

The autoimmune phenomena observed in Sjögren's syndrome include lymphocytic infiltration of the exocrine glands (primarily salivary and lachrymal glands) and B lymphocyte hyperreactivity. The latter is mainly manifested by hypergammaglobulinemia and the presence of serum autoantibodies toward non-organ-specific antigens such as immunoglobulins (rheumatoid factors) and extractable cellular antigens (Ro52, Ro60, and La). The major infiltrating cells in the affected exocrine glands are activated T lymphocytes. In labial minor salivary gland tissues with extensive lymphocytic infiltrations, B-cell populations prevail. Other cellular subsets detected in the labial minor salivary gland histopathologic lesion of Sjogren's syndrome include follicular, myeloid, and plasmacytoid dendritic cells, as well as macrophages. Inflammasome activation and macrophages positive for interleukin (IL) 18 in the salivary gland lesion have been shown to be associated with adverse predictors for lymphoma development.

The interplay of endogenous (e.g., intracellular stress, inappropriate overexpression of endogenous nucleic acids) and exogenous triggers (e.g., viruses, hormonal triggers, stressful life events) in a background of a genetically determined hyperactive immune response seems to be crucial for the initiation and perpetuation of the disease. Ductal and acinar epithelial cells appear to play a significant role in the initiation and perpetuation of autoimmune injury. These cells (1) express inappropriately costimulatory molecules and the intracellular autoantigens Ro and La on their cell surfaces, acquiring the capacity to provide signals essential for lymphocytic activation; (2) produce proinflammatory cytokines and lymphocyte-attracting chemokines necessary for sustaining the autoimmune lesion and allowing the formation of ectopic germinal centers; (3) express functional receptors of innate immunity, particularly Toll-like receptors (TLRs) 3, 7, and 9 molecules, which may account for the initiation of the autoimmune reactivity; and (4) display immunoregulatory molecules such as ICAM and CD40. Glandular epithelial cells also seem to have an active role in the production of B cell–activating factor (BAFF), which is induced after stimulation with type I and II interferons. Circulating BAFF has been found to be elevated also in the serum of Sjögren's syndrome patients, especially those with hypergammaglobulinemia and serum autoantibodies, and probably accounts for the antiapoptotic effect on B lymphocytes.

In contrast to B and T lymphocytes, glandular epithelial cells display increased rates of apoptotic death. Established risk genetic loci implicated in Sjögren's syndrome include the human leukocyte antigen DQA1*0501 allele, as well as variants involved in the interferon/BAFF axis (*IRF 5, STAT 4, BAFF*), B-cell function (*EBF1, BLK*), and chronic inflammation (*TNFAIP3*).

CLINICAL MANIFESTATIONS

The majority of patients with Sjögren's syndrome have symptoms related to impaired exocrine gland, particularly lacrimal and salivary gland, function. The disease evolution is slow and, in the majority of patients, runs a benign course. Studies have shown that prior to disease onset, patients with Sjögren's syndrome experience major stressful life events with which they cannot cope adequately.

The principal oral symptom of Sjögren's syndrome is dryness (xerostomia). Patients report difficulty in swallowing dry food, a burning mouth sensation, an increase in dental caries, and problems in wearing complete dentures. Physical examination shows a dry, erythematous, sticky oral mucosa. There is atrophy of the filiform papillae on the dorsum of the tongue, and saliva from the major glands is either not expressible or cloudy. Intermittent or persistent enlargement of the parotid or other major salivary glands occurs in two-thirds of patients with Sjögren's syndrome. Diagnostic tests include sialometry and several imaging techniques, including ultrasound, MRI, and magnetic resonance sialography of the major salivary glands. In particular, salivary gland ultrasound is an emerging tool of both diagnostic and prognostic utility. Biopsy of the labial minor salivary gland allows histopathologic confirmation of focal lymphocytic infiltrates.

Ocular involvement is the other major manifestation of Sjögren's syndrome. Patients usually report a sandy or gritty feeling under the eyelids. Other ocular symptoms include burning, accumulation of secretions in thick strands at the inner canthi, decreased tearing, redness, itching, eye fatigue, and increased photosensitivity. These symptoms are attributed to the destruction of corneal and bulbar conjunctival epithelium, a pathology termed *keratoconjunctivitis sicca*. Diagnostic evaluation of keratoconjunctivitis sicca includes measurement of tear flow by Schirmer's I test, determination of tear composition by tear breakup time or tear lysozyme content, and slit-lamp examination of the cornea and conjunctiva after lissamine green or Rose Bengal staining that reveals punctuate corneal and bulbar conjunctival ulcerations and attached filaments.

Involvement of other exocrine glands, which occurs less frequently, includes a decrease in mucous gland secretions of the upper and lower respiratory tree, resulting in dry nose, throat, and trachea (xerotrachea). In addition, diminished secretion of the exocrine glands of the gastrointestinal tract leads to esophageal mucosal dysmotility and atrophic gastritis. Dyspareunia, in premenopausal women, due to dryness of the external genitalia and dry skin also may occur.

Extraglandular (systemic) manifestations are seen in one-third of patients with Sjögren's syndrome (Table 361-1) and can be classified as follows: **nonspecific**, **periepithelial** (surrounding of epithelial tissues by lymphocytes), **immune complex–mediated**, and **lymphoma**. **Nonspecific** manifestations include fatigability, low-grade fever, Raynaud's phenomenon, myalgias, arthralgias, and arthritis. Arthritis in patients with primary Sjögren's syndrome is nonerosive. **Periepithelial** pathology due to periepithelial accumulation of lymphocytes results from the involvement of parenchymal organs such as the lungs, kidneys, and liver. On the basis of this observation, one of the authors (H.M.M.) has coined the term **autoimmune epithelitis**. Lung involvement is usually manifested with dry cough and rarely with dyspnea. The underlying lung pathology includes peribronchial infiltrates (bronchitis sicca) and interstitial pneumonitis. Renal involvement includes interstitial nephritis, clinically manifested by hyposthenuria and renal tubular dysfunction with or without acidosis. Untreated acidosis may lead to nephrocalcinosis. **Immune complex–mediated** disease is expressed with vasculitis affecting primarily small-sized vessels, mainly manifested with purpura and rarely with urticarial rash, skin ulcerations, mononeuritis multiplex, and membranoproliferative glomerulonephritis

TABLE 361-1 Prevalence of Extraglandular Manifestations in Primary Sjögren's Syndrome

CLINICAL MANIFESTATION	PERCENT	REMARKS
Nonspecific		
Fatigability/myalgias	25	Fibromyalgia
Arthralgias/arthritis	60	Usually nonerosive, leading to Jaccoud's arthropathy
Raynaud's phenomenon	37	In one-third of patients, precedes sicca manifestations
Periepithelial		
Lung involvement	14	Small airway disease/lymphocyte interstitial pneumonitis
Kidney involvement	9	Interstitial kidney disease is usually asymptomatic
Liver involvement	6	Primary biliary cirrhosis stage I
Immune complex–mediated		
Small vessel vasculitis	9	Purpura, urticarial lesions
Peripheral neuropathy	2	Polyneuropathy, either sensory or sensorimotor
Glomerulonephritis	2	Membranoproliferative
Lymphoma		
Lymphoma	6	Glandular MALT[a] lymphoma is most common

[a]Mucosa-associated lymphoid tissue.

associated with mixed type II or III cryoglobulinemia. Central nervous system involvement is rarely recognized. A few cases of myelitis associated with antibodies to aquaporin 4 have been described.

Sjögren's syndrome is characterized by the highest risk for lymphoma development among all autoimmune diseases. Tongue atrophy, persistent parotid gland enlargement, purpura, mixed type II cryoglobulinemia, low serum C4 complement levels, autoantibodies (rheumatoid factor, anti-Ro52, anti-Ro60, anti-La), and extensive lymphocytic infiltration in minor salivary glands are among the main features predicting the development of lymphoma. Most lymphomas are extranodal, low-grade, marginal zone B cell and are usually detected incidentally during evaluation of the labial minor salivary gland biopsy. The affected lymph nodes are usually peripheral. Survival rates are decreased in patients with B symptoms, lymph node mass >7 cm in diameter, and high or intermediate histologic grade. Despite that, pathogenesis of lymphoma in the setting of Sjögren's syndrome remains to be elucidated, and genetic alterations involved in chronic inflammatory, B-cell activation and the type I interferon pathways, as well as epigenetic abnormalities, have been shown to be significant contributors.

Recent data reveal an increased risk for multiple myeloma as well for Sjögren's syndrome patients with anti-Ro52, anti-Ro60, or anti-La autoantibodies. In line with observations in rheumatoid arthritis and systemic lupus erythematosus, patients with Sjögren's syndrome also display an increased risk of cardiovascular disease.

Routine laboratory tests in Sjögren's syndrome can reveal leukopenia and infrequently lymphopenia. In two-thirds of patients, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, antinuclear antibodies, rheumatoid factors, and antibodies against Ro52/Ro60 and La autoantigens are detected. Anticentromere autoantibodies are present in Sjögren's patients with a clinical picture similar to that of limited scleroderma **(Chap. 360)**, while the presence of antimitochondrial antibodies may connote liver involvement in the form of autoimmune cholangitis **(Chap. 346)**. Autoantibodies to 21-hydroxylase are found in patients with a blunted adrenal response, while autoantibodies to citrullinated peptides are seen in Sjögren's patients with arthritis. Anticalponin-3 antibodies have been recently associated with the occurrence of peripheral neuropathies.

TABLE 361-2 Differential Diagnosis of Sicca Symptoms

XEROSTOMIA	DRY EYE	BILATERAL PAROTID GLAND ENLARGEMENT
Viral infections (HCV, HIV)	Inflammation	Viral infections
Drugs	Stevens-Johnson syndrome	Mumps
Psychotherapeutic	Pemphigoid	Influenza
Parasympatholytic	Chronic conjunctivitis	Epstein-Barr virus
Antihypertensive	Chronic blepharitis	Coxsackievirus A
Psychogenic origin	Sjögren's syndrome	Cytomegalovirus
Irradiation	Toxicity	HIV, HCV
Diabetes mellitus	Burns	Sarcoidosis, tuberculosis
Trauma	Drugs	IgG4 syndrome
Sjögren's syndrome	Neurologic conditions	Sjögren's syndrome
Amyloidosis	Impaired lacrimal gland function	Metabolic disorders
Autoimmune thyroid disease	Impaired eyelid function	Diabetes mellitus
	Miscellaneous	Hyperlipoproteinemias (types IV and V)
	Trauma	Chronic pancreatitis
	Hypovitaminosis A	Hepatic cirrhosis
	Blink abnormality	Endocrine
	Anesthetic cornea	Acromegaly
	Lid scarring	Gonadal hypofunction
	Epithelial irregularity	Lymphoma
	Autoimmune thyroid disease	

Abbreviation: HCV, hepatitis C virus.

TABLE 361-3 Differential Diagnosis of Sjögren's Syndrome

HIV INFECTION AND SICCA SYNDROME	SJÖGREN'S SYNDROME	SARCOIDOSIS
Predominant in young males	Predominant in middle-aged women	No age or sex preference
Lack of autoantibodies to Ro and/or La	Presence of autoantibodies	Lack of autoantibodies to Ro and/or La
Lymphoid infiltrates of salivary glands by CD8+ T lymphocytes	Lymphoid infiltrates of salivary glands by CD4+ T lymphocytes	Granulomas in salivary glands
Association with HLA-DR5	Association with HLA-DR3 and DRw52	Unknown
Positive serologic tests for HIV	Negative serologic tests for HIV	Negative serologic tests for HIV

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Sjögren's syndrome should be suspected if a patient presents with eye and/or mouth dryness, major salivary gland enlargement, or systemic manifestations such as Raynaud's phenomenon, palpable purpura, or symptomatology of renal tubular acidosis. A careful history of medications causing dryness should be obtained. Recently, cases of Sjögren's syndrome were triggered by PD-1/PD-L1 checkpoint inhibitors.

The workup should include eye tests that might reveal keratoconjunctivitis sicca, salivary flow tests or ultrasonography, and serum evaluation for specific autoantibodies. Testing for chronic viral infections (hepatitis C virus, HIV), chest x-ray to rule out sarcoidosis, protein electrophoresis, IgG4 serum levels, and autoantibodies to thyroid antigens can be also offered. Labial biopsy is valuable to rule out conditions that may cause dry mouth, dry eyes, or parotid gland enlargement **(Tables 361-2 and 361-3)**. Classification criteria are not valuable for everyday practice but are of paramount importance for research. A diagnostic algorithm based on recent classification criteria is presented **(Fig. 361-1)**.

TREATMENT

Sjögren's Syndrome

Treatment of Sjögren's syndrome aims to relieve symptoms and limit the damage from chronic xerostomia and keratoconjunctivitis sicca through substitution or stimulation of impaired secretions.

To replace deficient tears, several ophthalmic preparations are readily available (hydroxypropyl methylcellulose; polyvinyl alcohol; 0.5% methylcellulose; Hypo Tears). If corneal ulcerations are present, eye patching and boric acid ointments are recommended, as well as cyclosporine eye drops. Certain drugs that may decrease lacrimal and salivary secretions, such as diuretics, antihypertensive drugs, anticholinergics, and antidepressants, should be avoided.

For xerostomia, the best replacement is water. Propionic acid gels may be used to treat vaginal dryness. To stimulate secretions, orally administered pilocarpine (5 mg thrice daily) or cevimeline (30 mg thrice daily) appears to improve sicca manifestations, and both are well tolerated. Hydroxychloroquine (200 mg daily) is helpful for arthralgias and mild arthritis.

Patients with renal tubular acidosis should receive sodium bicarbonate by mouth (0.5–2 mmol/kg in four divided doses). Glucocorticoids and monoclonal antibody to CD20 (rituximab) appear to be effective in patients with systemic disease, particularly in those with purpura and arthritis. Novel monoclonal antibodies targeting the CD40L/CD40 costimulatory pathway or the BAFF receptor seem to be promising therapeutic strategies for the management of Sjögren's syndrome patients with systemic manifestations. Treatment of lymphoma in the setting of Sjögren's syndrome follows the general guidelines for lymphoma management in the general population.

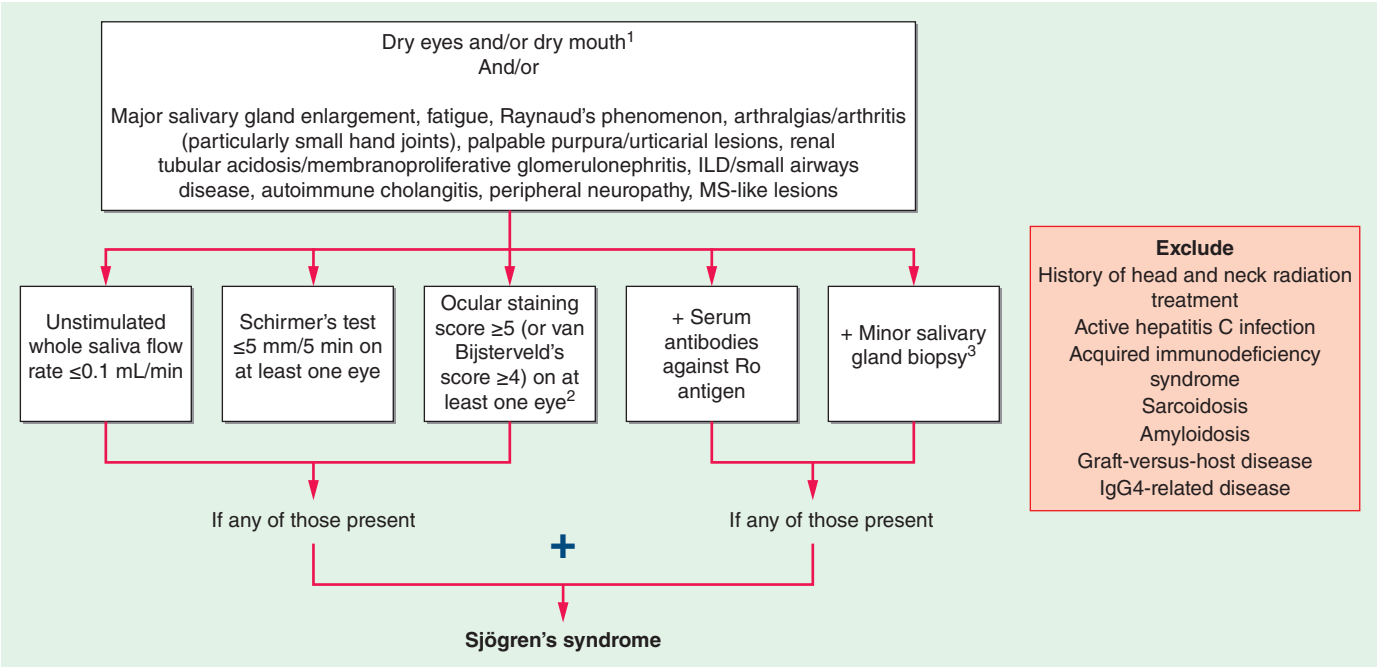


FIGURE 361-1 Diagnostic algorithm for Sjögren's syndrome. [1]Defined as a positive response to at least one of the following questions: (a) Have you had daily, persistent, troublesome dry eyes for more than 3 months? (b) Do you have a recurrent sensation of sand or gravel in the eyes? (c) Do you use tear substitutes more than three times a day? (d) Have you had a daily feeling of dry mouth for more than 3 months? (e) Do you frequently drink liquids to aid in swallowing dry food? [2]Ocular staining score described in Whitcher et al. van Bijsterveld score described in van Bijsterveld et al. [3]Focus score count ≥1 (based on the number of foci per 4 mm of salivary gland tissue) following a protocol described in Daniels et al. ILD, interstitial lung disease; MS, multiple sclerosis.

362 Spondyloarthritis

Joel D. Taurog, Lianne S. Gensler, Nigil Haroon

Spondyloarthritis (SpA) refers to a group of overlapping disorders that share clinical features, genetic associations, and pathogenic mechanisms. The classic designations include ankylosing spondylitis (AS), reactive arthritis (ReA), psoriatic arthritis (PsA), arthritis associated with inflammatory bowel disease (IBD), juvenile spondyloarthritis (JSpA), and undifferentiated SpA. These disorders are broadly classified as predominantly axial SpA, affecting the spine, pelvis, and thoracic cage, or predominantly peripheral SpA, affecting the extremities.

ANKYLOSING SPONDYLITIS AND AXIAL SPONDYLOARTHRITIS

Axial spondyloarthritis (axSpA) is the current term used to describe the most common inflammatory disorder affecting the axial skeleton, with variable involvement of peripheral joints and extraarticular structures. AxSpA includes patients with significant radiographic damage of the sacroiliac joints, classically termed AS and now considered radiographic axial spondyloarthritis (r-axSpA), and those patients with a similar clinical presentation but lacking significant radiographic sacroiliitis. In this latter group, some eventually develop significant radiographic sacroiliitis; however, many do not. The general concept of axSpA is supported by classification criteria formulated in 2009 (Table 362-1). AxSpA patients with sacroiliitis on MRI without significant damage on x-ray are categorized as having nonradiographic axial spondyloarthritis (nr-axSpA).

EPIDEMIOLOGY

The estimated adult prevalence of AS in 20 countries during the past 2 decades is ~0.17% (range 0.02–0.5%). In the few studies that have addressed ax-SpA, prevalence is ~1.3- to 2-fold higher than that of AS. AS shows a striking correlation with the histocompatibility antigen HLA-B27 and occurs worldwide roughly in proportion to the prevalence of B27. In North American whites, the prevalence of B27 is 6%, whereas it is 80–90% in patients with AS.

In population surveys, AS is found in 1–6% of adults inheriting B27, whereas the prevalence is 10–30% among B27+ adult first-degree relatives of AS probands. The concordance rate in identical twins is about 65%. Susceptibility to AS is determined largely by genetic factors, with B27 comprising ~20% of the genetic component. Single-nucleotide polymorphism (SNP) analysis has identified 115 additional non-HLA alleles that altogether contribute another ~7–8% of genetic susceptibility. The prevalence of HLA-B27 in nr-axSpA is somewhat lower than in AS and the proportion of females is higher. Little information is available about non-HLA susceptibility loci in nr-axSpA, which is genetically more heterogeneous than AS.

TABLE 362-1 ASAS Criteria for Classification of Axial Spondyloarthritis (to be applied for patients with back pain ≥3 months and age of onset <45 years)[a]

SACROILIITIS ON IMAGING PLUS ≥1 SpA FEATURE	OR	HLA-B27 PLUS ≥2 OTHER SpA FEATURES
Sacroiliitis on imaging • Active (acute) inflammation on MRI highly suggestive of SpA-associated sacroiliitis[b] and/or • Definite radiographic sacroiliitis according to modified New York criteria[c]		SpA features • Inflammatory back pain[d] • Arthritis[e] • Enthesitis (heel)[f] • Anterior uveitis[g] • Dactylitis[e] • Psoriasis[e] • Crohn's disease or ulcerative colitis[e] • Good response to NSAIDs[h] • Family history of SpA[i] • HLA-B27 • Elevated CRP[j]

[a]Sensitivity 83%, specificity 84%. The imaging arm (sacroiliitis) alone has a sensitivity of 66% and a specificity of 97%. [b]Bone marrow edema and/or osteitis on short tau inversion recovery (STIR) or gadolinium-enhanced T1 image. [c]Bilateral grade ≥2 or unilateral grade 3 or 4. [d]See text for criteria. [e]Past or present, diagnosed by a physician. [f]Past or present pain or tenderness on examination at calcaneus insertion of Achilles tendon or plantar fascia. [g]Past or present, confirmed by an ophthalmologist. [h]Substantial relief of back pain at 24–48 h after a full dose of NSAID. [i]First- or second-degree relatives with ankylosing spondylitis (AS), psoriasis, uveitis, reactive arthritis (ReA), or inflammatory bowel disease (IBD). [j]After exclusion of other causes of elevated CRP.

PATHOLOGY

Sacroiliitis is typically an early manifestation of axSpA, whether or not it is evident radiographically. In biopsy and autopsy studies of sacroiliac joints, covering a range of disease durations, synovitis and myxoid marrow represent the earliest changes, followed by pannus and subchondral granulation tissue. Marrow edema, enthesitis, and chondroid differentiation are also found. Macrophages, T cells, plasma cells, and osteoclasts are prevalent. If the process progresses, eventually the eroded joint margins are replaced by fibrocartilage regeneration and then by ossification.

In the spine, inflammatory granulation tissue is seen in the paravertebral connective tissue at the junction of annulus fibrosus and vertebral bone, or even along the entire outer annulus. The outer annular fibers are eroded and eventually replaced by bone, forming an early syndesmophyte, which then grows by endochondral ossification, ultimately bridging the adjacent vertebral bodies **(Fig. 362-1F, G)**. Progression of this process can lead to "bamboo spine." Other spinal lesions include osteoporosis (loss of trabecular bone despite accretion of periosteal bone), erosion of vertebral bodies at the disk margin, and inflammation and destruction of the disk-bone border. Inflammatory arthritis of the facet joints is common, with erosion of joint cartilage by pannus often followed by bony ankylosis. This may precede formation of syndesmophytes bridging the adjacent disks. Bone mineral density is diminished in the spine and proximal femur early in the disease course.

Peripheral synovitis in AS shows marked vascularity, evident as tortuous macrovascularity seen during arthroscopy. Lining layer hyperplasia, lymphoid infiltration, and pannus formation are also found. Central cartilaginous erosions from proliferation of subchondral granulation tissue are common. The characteristics of peripheral arthritis in AS are shared by other forms of SpA and are distinct from those of RA.

Extensive investigation has implicated the *enthesis*, the fibrocartilaginous region where a tendon, ligament, or joint capsule attaches to bone, as a primary site of pathology in AS and other SpAs, at both axial and peripheral sites. Entheses transduce mechanical forces from muscles to bones and hence are widely distributed anatomically. Enthesitis is associated with prominent edema of the adjacent bone marrow and is often characterized by erosive lesions that eventually undergo ossification.

Subclinical intestinal inflammation has been found in the colon or distal ileum in most patients with SpA. The histology is described below under "IBD-Associated Arthritis."

PATHOGENESIS

AS is immune-mediated, and increasing evidence suggests more of an autoinflammatory rather than antigen-specific autoimmune pathogenesis. Uncertainty remains regarding the primary site of disease initiation. The dramatic response of the disease to therapeutic blockade of tumor necrosis factor (TNF) or IL-17A indicates that these cytokines play a central immunopathogenic role. Genes related to TNF pathways show association with AS, including *TNFRSF1A*, *TNFAIP3*, *LTBR*, and *TBKBP1*. Genes in the IL-23/IL-17 pathway show association with AS, including *IL23R*, *PTER4*, *IL12B*, *CARD9*, *IL6R*, *TYK2*, *JAK2*, and *STAT3*. Of these 12 genes, 11 are also associated with IBD, and 6 with psoriasis. Serum levels of IL-23 and IL-17 are elevated in AS patients. In mice, tissue-resident thymus-dependent T cells expressing γ/δ T-cell receptors and IL-23 receptors are found at entheses, in the aortic root, and near the ciliary body in the eye. These cells express abundant IL-17 and IL-22 upon exposure to systemic IL-23. This finding suggests that site-specific innate immune cells play a critical role in the anatomic specificity of these lesions. IL-23 signals through the Janus kinase (Jak) TYK2. *TYK2* loss of function SNPs are protective against AS, and Tyk2 inhibition blocks IL-23-dependent immunity and SpA progression in a mouse model.

High levels of circulating γδ T cells expressing IL-23 receptors and producing IL-17 have been found in AS patients. Recent studies of human spinal entheses identified IL-23-producing CD14+ myeloid cells and IL-17A-producing γδ-T cells. One subset of these γδ-T cells lacked IL-23 receptors. This population evidently produces IL-17A independently of IL-23 and may explain the therapeutic failure in ax-SpA of agents targeting IL-23, despite the positive response of peripheral SpA to these agents and the dramatic response of both axial and peripheral SpA to agents targeting IL-17A **(see Fig. 362-3)**.

Other associated genes encode other cytokines or cytokine receptors (*IL1R1*, *IL1R2*, *IL7R*, *IL27*), transcription factors involved in the differentiation of immune cells (*RUNX3*, *EOMES*, *BACH2*, *NKX2-3*, *TBX21*), or other molecules involved in activation or regulation of immune or inflammatory responses (*FCGR2A*, *ZMIZ1*, *NOS2*, *ICOSLG*).

The inflamed sacroiliac joint is infiltrated with CD4+ and CD8+ T cells and macrophages and shows high levels of TNF, particularly early in the disease. Abundant transforming growth factor β (TGF-β) is found in more advanced lesions. Peripheral synovitis in SpA is characterized by neutrophils, macrophages expressing CD68 and CD163, CD4+ and CD8+ T cells, and B cells. There is prominent staining for intercellular adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), matrix metalloproteinase 3 (MMP-3), and myeloid-related proteins 8 and 14 (MRP-8 and MRP-14).

Gut microbiota dysbiosis is consistently found in SpA patients and animal models, and in both may be influenced by HLA genotype, including HLA-B27. Bacteria species with mucolytic properties are expanded in patients, suggesting a pathogenic role for degradation of intestinal mucus. Overlapping features with ReA and IBD and involvement of the IL-23/IL-17 pathway, which is fundamentally associated with host defense at mucosal sites, provide additional support for the importance of the microbiome in SpA pathogenesis. It has been hypothesized that systemic inflammation, dysbiosis, and increased intestinal permeability form an amplification loop driving sustained inflammation in SpA.

HLA-B27 plays a direct role in AS pathogenesis, but its precise molecular role remains unresolved. Rats transgenic for HLA-B27 develop arthritis and spondylitis, and this is unaffected by the absence of CD8. It thus appears that classical peptide antigen presentation to CD8+ T cells may not be the primary disease mechanism. However, the association of AS with ERAP1 and ERAP2, which strongly influence the MHC class I peptide repertoire, suggests that peptide binding to

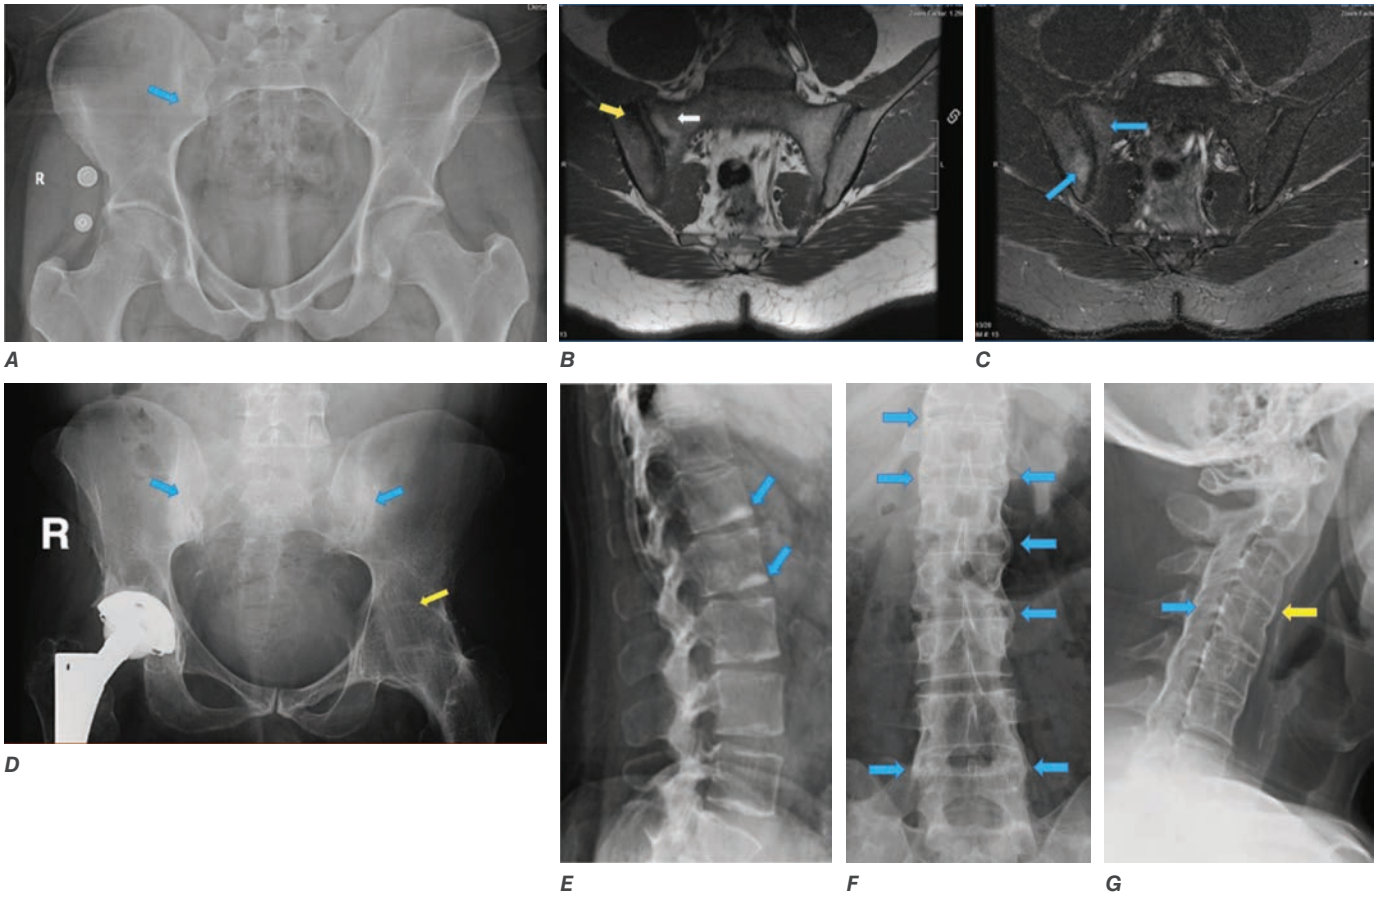

FIGURE 362-1 Imaging in nonradiographic axial spondyloarthritis (nr-axSpA) and in ankylosing spondylitis (radiographic axial spondyloarthritis).

A. Anterior posterior (AP) pelvis radiograph in a patient with nr-axSpA, showing insignificant sacroiliac (SI) joint changes. There is minimal right-sided SI joint sclerosis (*blue arrow*).
B. T1-weighted MRI of the sacrum from the patient shown in A. The *yellow arrow* indicates cortical erosion of the right SI joint and the *white arrow* indicates subchondral fat.
C. Short tau inversion recovery (STIR) sequence MRI from the same patient shows bone marrow edema on both sides of the SI joint (*blue arrows*).
D. AP pelvis radiograph in a patient with AS. Blue arrows indicate advanced bilateral radiographic sacroiliitis (sclerosis, partial fusion, erosions). There is severe bilateral hip disease with autofusion on the left (*yellow arrow*), and diffuse osteoporosis.
E. Lateral lumbar spine radiograph in a patient with AS. *Blue arrows* indicate Romanus lesions (shiny corners).
F. AP lumbar spine radiograph in a patient with AS. *Blue arrows* indicate bridging syndesmophytes.
G. Lateral cervical spine radiograph in a patient with AS. There is complete ankylosis of the facet joints (*blue arrow*) and bridging syndesmophytes throughout (*yellow arrow*).

B27 is nonetheless important. CD8+ T cells are decreased in peripheral blood and increased in synovial fluid in AS patients, but their role in AS pathogenesis remains unclear. The B27 heavy chain has an unusual tendency to misfold, a process that can be proinflammatory. Genetic and functional studies in humans have suggested a role for natural killer (NK) cells in AS, possibly through interaction with B27 heavy chain homodimers. SpA-prone B27 rats show defective dendritic cell function and share with AS patients a characteristic "reverse interferon" gene expression signature in antigen-presenting cells. A recent study provided evidence for an interaction between HLA-B27 and activin receptor-like kinase-2, a bone morphogenic protein family member, mutations of which are associated with fibrodysplasia ossificans progressiva, a disease of uncontrolled bone formation.

Enthesitis can arise in healthy individuals from repetitive mechanical strain at a particular anatomic site. In SpA, it is thought that the threshold for strain-induced entheseal inflammation is lowered by genetic factors and/or microbial products, resulting in widespread, chronic lesions arising at entheseal sites subjected only to normal use. Supporting this concept, mice transgenic for constitutive TNF production develop peripheral enthesitis and arthritis mediated by innate immunity, and nonweightbearing reduces inflammation and new bone formation at these sites.

New bone formation in AS appears to be largely based on enchondral bone formation and occurs only in the periosteal compartment. It correlates with lack of regulation of the Wnt signaling pathway, which controls the differentiation of mesenchymal cells into osteophytes, by the inhibitors DKK-1 and sclerostin. Indirect evidence and data from animal models also implicate bone morphogenic proteins, hedgehog proteins, and prostaglandin E_2. Patients with high inflammatory markers and inflammation at vertebral corners on MRI are the ones most likely to develop syndesmophytes. Mounting evidence suggests that early and prolonged anti-TNF therapy may decrease spinal fusion. Vertebral inflammatory lesions that undergo metaplasia to fat (increased T1-weighted signal) are a preferential site of subsequent syndesmophyte formation despite anti-TNF therapy, whereas early acute inflammatory lesions resolve, reinforcing the importance of early treatment to resolve inflammation.

CLINICAL MANIFESTATIONS

The initial AS symptoms are usually first noticed in late adolescence or early adulthood, at a median age in the mid-twenties. In 5% of patients, symptoms begin after age 40. The initial symptom is pain that can be either sharp or dull, insidious in onset, felt deep in the lower lumbar or gluteal region, and accompanied by low-back morning stiffness of up to a few hours' duration that improves with activity and returns following inactivity. Within a few months, the pain usually becomes persistent and bilateral. Nocturnal exacerbation of pain often forces the patient to rise and move around.

In some patients, bony tenderness (presumably reflecting enthesitis or osteitis) accompanies back pain or stiffness, whereas in others it may

be the predominant complaint. Common sites include the costosternal junctions, spinous processes, iliac crests, greater trochanters, ischial tuberosities, tibial tubercles, and heels. Hip and shoulder ("root" joint) arthritis is considered part of axial disease. Hip arthritis occurs in 25–35% of patients. Severe isolated hip arthritis or bony chest pain may be the presenting complaint, and symptomatic hip disease can dominate the clinical picture, especially in those with juvenile-onset disease. Arthritis of peripheral joints is usually asymmetric and may occur at any point in the disease course. Neck pain and stiffness from cervical spine involvement may be later manifestations but are occasionally dominant symptoms. Chest pain is common at any stage of ax-SpA and if not accurately diagnosed can be confused with cardiovascular disease.

In juvenile spondyloarthritis, peripheral arthritis and enthesitis predominate, with axial symptoms supervening in late adolescence.

Initially, axial physical findings mirror the inflammatory process. The most specific findings involve loss of spinal mobility, with limitation of anterior and lateral flexion and extension of the lumbar spine and of chest expansion. Limitation of motion is usually out of proportion to the degree of bony ankylosis and may reflect muscle spasm secondary to pain and inflammation. Pain in the sacroiliac joints may be elicited either with direct pressure or with stress on the joints. In addition, there is commonly tenderness upon palpation of the posterior spinous processes and other sites of symptomatic bony tenderness.

The modified Schober test is a useful measure of lumbar spine flexion. The patient stands erect, with heels together, and marks are made on the spine at the lumbosacral junction (identified by a horizontal line between the posterosuperior iliac spines) and 10 cm above. The patient then bends forward maximally with knees fully extended, and the distance between the two marks is measured. This distance increases by ≥2 cm with normal mobility. Chest expansion is measured as the difference between maximal inspiration and maximal forced expiration at the levels of either the fourth intercostal space or the xiphisternum, with the patient's hands resting on or just behind the head. Normal chest expansion is ≥2.5 cm. Lateral bending measures the distance the patient's middle finger travels down the leg with maximal lateral bending. Normal is >10 cm.

Limitation or pain with motion of the hips or shoulders is usually present if these joints are involved. It should be emphasized that in early, mild, or atypical cases, the symptoms and/or physical findings may be subtle and/or nonspecific.

The course of ax-SpA is extremely variable, ranging from the individual with mild stiffness and normal radiographs to the patient with a totally fused spine and severe bilateral hip arthritis, severe peripheral arthritis, and extraarticular manifestations. Available data on natural history pertain predominantly to AS, although the prevalence of peripheral arthritis, enthesitis, psoriasis, and IBD appears to be similar in nr-axSpA and AS. Pain tends to be persistent early in the disease and intermittent later, with alternating exacerbations and quiescent periods. In a typical severe untreated case with progression to syndesmophyte formation, the posture undergoes characteristic changes, with obliterated lumbar lordosis, buttock atrophy, and accentuated thoracic kyphosis. There may be a forward stoop of the neck or flexion contractures at the hips, compensated by flexion at the knees. Disease progression can be estimated clinically from loss of height, limitation of chest expansion and spinal flexion, and increasing occiput-to-wall distance. Occasional individuals are encountered with advanced deformities who deny ever having significant symptoms.

The factors most predictive of radiographic progression (see below) are the presence of existing syndesmophytes, high inflammatory markers, and smoking. In some but not all studies, onset of AS in adolescence and early hip involvement correlate with a worse prognosis. In women, AS tends to progress less frequently to total spinal ankylosis, although there may be an increased prevalence of peripheral arthritis. Peripheral arthritis occurs in up to 30% of patients. Pregnancy has no consistent effect on AS, with symptoms improving, remaining the same, or deteriorating in one-third of pregnant patients, respectively. However, those requiring biologic therapy before pregnancy are quite likely to flare during the second and third trimester if the medication is discontinued during pregnancy.

The most serious complication of advanced spinal disease is spinal fracture, which can occur with even minor trauma to the rigid, osteoporotic spine. The lower cervical spine is most commonly involved. These fractures are often displaced, causing spinal cord injury. A recent survey suggested a >10% lifetime risk of fracture. Occasionally, fracture through a diskovertebral junction and adjacent neural arch, termed *pseudoarthrosis*, most common in the thoracolumbar spine, can be an unrecognized source of persistent localized pain and/or neurologic dysfunction. Wedging of thoracic vertebrae can lead to accentuated kyphosis.

The most common extraarticular manifestation is acute anterior uveitis, which occurs in up to 50% of patients and can antedate the spondylitis. Attacks are typically unilateral, causing pain, photophobia, and pain with accommodation. These may recur, often in the opposite eye. Cataracts and secondary glaucoma may ensue. Up to 60% of patients with AS have inflammation in the colon or ileum. This is usually asymptomatic, but overt IBD occurs in 5–10% of patients with AS (see "IBD-Associated Arthritis," below). About 10% of patients meeting criteria for AS have psoriasis (see "Psoriatic Arthritis," below). Occasional patients are seen with AS in association with skin manifestations seen in SAPHO syndrome (see below), such as acne fulminans or hidradenitis suppurativa. There is an apparently increased risk of ischemic heart disease. Aortic insufficiency occurs in a small percentage of patients, usually after longstanding disease. Third-degree heart block may occur alone or together with aortic insufficiency, and association with lesser degrees of heart block has been described. Cauda equina syndrome and upper pulmonary lobe fibrosis are rare late complications. Prostatitis has been reported to have an increased prevalence. Amyloidosis is rare **(Chap. 112)**.

Several validated measures of disease activity and functional outcome are in widespread use in the study and management of ax-SpA, particularly the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) and the Ankylosing Spondylitis Disease Activity Score (ASDAS), both measures of disease activity; the Bath Ankylosing Spondylitis Functional Index (BASFI), a measure of limitation in activities of daily living; and several measures of radiographic changes. The new Assessment of Spondyloarthritis international Society (ASAS) Health Index is a spondyloarthritis-specfic tool for assessing impairment of function and health. Despite persistence of the disease, most patients remain gainfully employed. Some but not all studies of survival in AS have suggested that AS shortens life span, compared with the general population. Mortality attributable to AS is largely the result of spinal trauma, aortic insufficiency, respiratory failure, amyloid nephropathy, or complications of therapy such as upper gastrointestinal hemorrhage. The impact of biologic therapy on outcome and mortality is not yet known, except for significantly improved work productivity.

LABORATORY FINDINGS

No laboratory test is diagnostic of AS. In most ethnic groups, HLA-B27 is present in 75–90% of patients. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are often, but not always, elevated. Mild anemia may be present. Patients with severe disease may show elevated alkaline phosphatase. Elevated serum IgA is common. Rheumatoid factor, anti-cyclic citrullinated peptide (CCP), and antinuclear antibodies (ANAs) are largely absent unless caused by a coexistent disease, although ANAs may appear with anti-TNF therapy. Circulating levels of CD8+ T cells tend to be low, and serum matrix metalloproteinase 3 levels correlate with disease activity. Synovial fluid from peripheral joints is nonspecifically inflammatory. Restricted chest wall motion causes decreased vital capacity, but ventilatory function is usually well maintained.

RADIOGRAPHIC FINDINGS (FIG. 362-1)

By definition, the diagnosis of AS is associated with advanced radiographically demonstrable sacroiliitis, usually symmetric. The earliest changes by standard radiography are blurring of the cortical margins of the subchondral bone, followed by erosions and sclerosis. Progression of the erosions leads to "pseudowidening" of the joint space; as fibrous and then bony ankylosis supervene, the joints may become obliterated.

In the lumbar spine, progression of the disease can lead to loss of lordosis, and osteitis of the anterior corners of the vertebral bodies

with subsequent erosion, and new bone formation causing "squaring" or even "barreling" of one or more vertebral bodies. Progressive ossification leads to eventual formation of marginal syndesmophytes, visible on plain films as bony bridges connecting successive vertebral bodies anteriorly and laterally.

Only a minority of patients meeting criteria for nr-axSpA develop radiographic sacroiliitis within a decade or more, and even fewer develop spinal changes. MRI is thus much more useful for the timely diagnosis of ax-SpA, provided that it is done correctly. *It must be emphasized that MRI protocols routinely used to evaluate low back pain have low sensitivity for detecting inflammation and often give false-negative results in ax-SpA.* Active sacroiliitis is best visualized by dynamic MRI on semicoronal slices with fat saturation, either T2-weighted turbo spin-echo sequence or short tau inversion recovery (STIR) with high resolution, or T1-weighted images with contrast enhancement. These techniques identify early intraarticular inflammation, cartilage changes, and underlying bone marrow edema in sacroiliitis (Fig. 362-1). These protocols are also sensitive for evaluation of acute and chronic spinal changes. Bone marrow edema alone is not specific for spondyloarthritis. The presence of erosions enhances specificity and is best detected on conventional T1-weighted images. Optimal MRI results require a high index of suspicion, an appropriate protocol, an experienced radiologist, and close communication between radiologist and clinician.

Reduced bone mineral density can be detected by dual-energy x-ray absorptiometry of the femoral neck and the lumbar spine. Employing a lateral projection of the L3 vertebral body can prevent falsely elevated readings related to spinal ossification.

DIAGNOSIS

It is important to recognize ax-SpA before the development of irreversible deformity. This goal is challenging for several reasons: (1) only a minority of back pain patients have ax-SpA; (2) an early diagnosis often relies on clinical grounds and/or an appropriate MRI protocol requiring considerable expertise; (3) young individuals with symptoms of ax-SpA often do not seek medical care; and (4) reliance on definite radiographic sacroiliitis causes early or mild cases to be missed. The classification criteria for ax-SpA proposed by ASAS are shown in Table 362-1. They were developed for research purposes only and should not be strictly applied as diagnostic criteria but can be considered an aid to diagnosis. They are applicable to individuals with ≥3 months of back pain and age of onset <45 years. Active inflammation of the sacroiliac joints as determined by MRI is considered equivalent to definite radiographic sacroiliitis (see below).

AxSpA must be differentiated from numerous other causes of low-back pain, some substantially more common than axSpA. Increased specificity is obtained when the nature and pattern of the pain and the age of the patient are considered. The most typical symptom is inflammatory back pain (IBP), present in 70–80% of patients with axSpA. In chronic (≥3 months) back pain, IBP has the following characteristic features: (1) age of onset <40 years; (2) insidious onset; (3) improvement with exercise; (4) no improvement with rest; (5) pain at night with improvement upon getting up; (6) morning stiffness >30 min; (7) awakening from back pain during only the second half of the night; and (8) alternating buttock pain. The presence of two or more of these features should arouse suspicion for IBP, and four or more can be considered presumptively diagnostic. The most common causes of back pain other than SpA are primarily mechanical or degenerative rather than primarily inflammatory. These are less likely to show clustering of SpA features, but IBP can be present in up to 30% of patients with mechanical back pain.

Less-common causes of back pain must also be differentiated from axSpA, including infectious spondylitis, spondylodiskitis, or sacroiliitis; and primary or metastatic tumor. Ochronosis can produce a phenotype similar to AS. Calcification and ossification of paraspinous ligaments occur in *diffuse idiopathic skeletal hyperostosis* (DISH), which occurs in middle age and above and is usually asymptomatic. Ligamentous calcification gives the appearance of "flowing wax" on the anterior bodies of the vertebrae. Intervertebral disk spaces are preserved, and sacroiliac and facet joints appear normal, helping to differentiate DISH from spondylosis and from AS, respectively. Both primary and secondary hyperparathyroidism can cause subchondral bone resorption around the SI joints, with bilateral widened and ill-defined joints on radiographs, but without joint space narrowing.

An algorithm for making or excluding the diagnosis of ax-SpA in patients with chronic back pain is shown in **Fig. 362-2**.

TREATMENT

Axial Spondyloarthritis

All management of ax-SpA should include an exercise program to maintain posture and range of motion. Exercise videos are available from the Spondylitis Association of America *(https://spondylitis.org/resources-support/educational-materials-resources/back-in-action-again/.)*

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the first line of pharmacologic therapy. They reduce pain and tenderness and increase mobility in many patients. Continuous high-dose NSAID therapy may slow radiographic progression, particularly in patients who are at higher risk for progression. However, many patients have persistent symptoms despite NSAID therapy and may benefit from biologic therapy. Patients with AS treated with the anti-TNF agents infliximab (chimeric human/mouse anti-TNF monoclonal antibody), etanercept (soluble p75 TNF receptor–IgG fusion protein), adalimumab or golimumab (human anti-TNF monoclonal antibodies), or certolizumab pegol (humanized mouse anti-TNF monoclonal antibody) have shown rapid, profound, and sustained reductions in all clinical and laboratory measures of disease activity. In a good response, there is significant improvement in both objective and subjective indicators of disease activity and function, including morning stiffness, pain, spinal mobility, peripheral joint swelling, CRP, ESR, and bone mineral density. MRI studies indicate substantial resolution of bone marrow edema, enthesitis, and joint effusions in the sacroiliac, facet, and peripheral joints. These results have been obtained in large randomized controlled trials of all five agents and many open-label studies. About one-half of the patients achieve a ≥50% reduction in the BASDAI. The response tends to persist over time and remission of symptoms is feasible in a proportion of patients. Predictors of the best responses include younger age, shorter disease duration, higher baseline inflammatory markers, and lower baseline functional disability. Nonetheless, some patients with long-standing disease and even spinal ankylosis obtain significant benefit. There is greater chance of slowing syndesmophyte formation with sustained therapy, especially if started early. The response of patients with nr-axSpA to anti-TNF therapy is generally similar to that of patients with AS.

Typically, infliximab is given intravenously, 5 mg/kg body weight, and then repeated 2 weeks later, again 6 weeks later, and then at 6- to 8-week intervals. Etanercept is given by subcutaneous injection, 50 mg once weekly. Adalimumab is given by subcutaneous injection, 40 mg biweekly. Golimumab is given by subcutaneous injection, 50 mg every 4 weeks. Certolizumab pegol is given by subcutaneous injection, 200 mg biweekly or 400 mg every 4 weeks. Dosage adjustments can be considered in selected cases.

These potent immunosuppressive agents are relatively safe, but patients are at increased risk for serious infections, including disseminated tuberculosis. Hypersensitivity infusion or injection site reactions are not uncommon. Cases of anti-TNF-induced psoriasis have been increasingly recognized. Rare cases of systemic lupus erythematosus (SLE)–related disease have been reported, as have hematologic disorders such as pancytopenia, demyelinating disorders, exacerbation of congestive heart failure, and severe liver disease. The overall incidence of malignancy is not increased in AS patients treated with anti-TNF therapy, but isolated cases of hematologic malignancy have occurred shortly after initiation of treatment.

Because of the expense, potentially serious side effects, and unknown long-term effects of these agents, their use should be

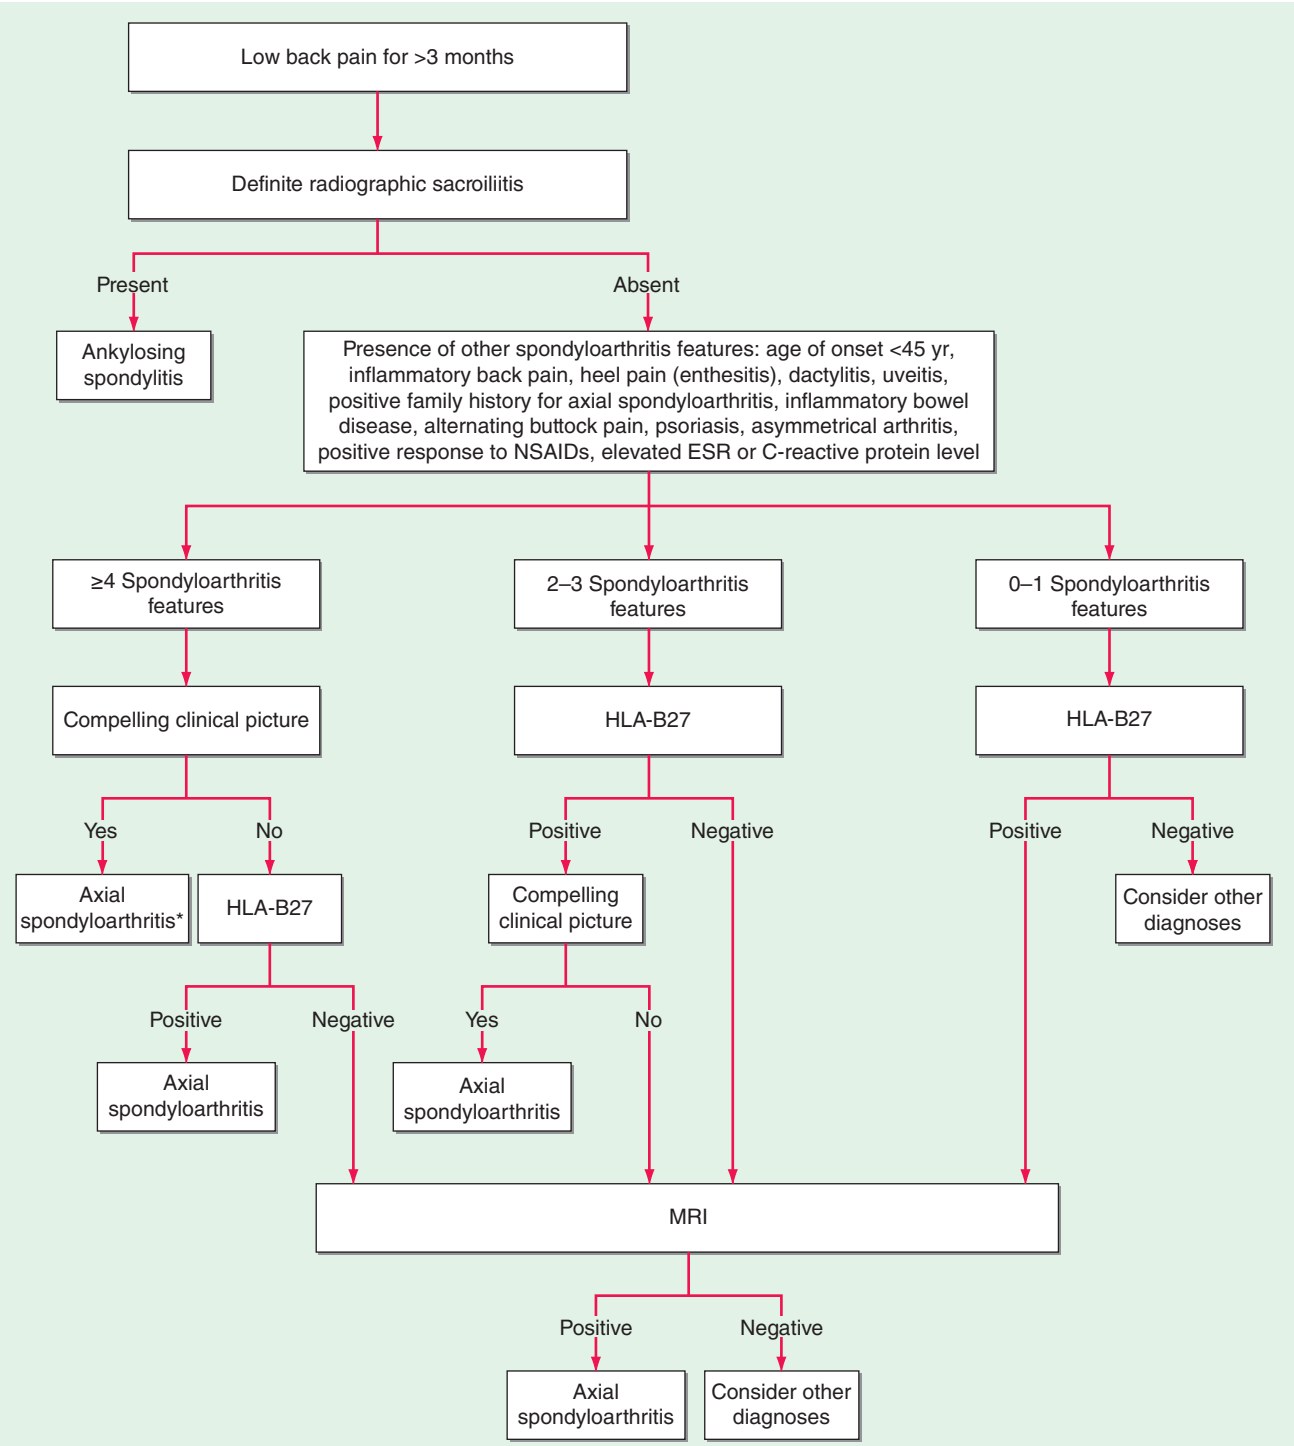

FIGURE 362-2 Algorithm for the diagnosis or exclusion of axial spondyloarthritis. The algorithm is designed for use in patients with at least a 3-month history of unexplained chronic low-back pain. Definite radiographic sacroiliitis is based on the modified New York criteria for ankylosing spondylitis (*van der Linden S et al: Arthritis Rheum 27:361, 1984*). The algorithm is adapted from *van den Berg R et al: Ann Rheum Dis 72:1646, 2013.* The determination of whether or not a clinical picture is compelling is based on the relative weights of the spondyloarthritis features (*Feldtkeller E et al: Rheumatology [Oxford] 52:1648, 2013*) and on clinical judgment. The list of clinical features includes features of both axial and peripheral spondyloarthritis. *Confirming MRI is recommended. *(From Taurog JD et al: N Engl J Med 374:2563, 2016.)*

restricted to patients with a definite diagnosis and active disease that is inadequately responsive to therapy with at least two different NSAIDs. Before initiation of anti-TNF therapy, all patients should be tested for latent tuberculosis (TB) and for hepatitis B, and treated appropriately if either is found. Contraindications to TNF inhibitors include active infection or high risk of infection; multiple sclerosis; and history of hematologic malignancy, SLE, or related autoimmunity. Pregnancy and breast-feeding are no longer considered contraindications if appropriate precautions are taken. Certolizumab pegol's label includes minimal transplacental or breast milk transfer. However, infants exposed to anti-TNF in utero should not be given live vaccines before age 6 months. Switching to a second anti-TNF agent may be effective, especially if there was a response to the first that was lost, rather than primary failure.

Secukinumab, a human monoclonal antibody to IL-17A, and ixekizumab, a humanized monoclonal antibody to IL-17A, are FDA-approved for use in AS and show efficacy similar to that of anti-TNF. Both are effective in some patients who have failed or not tolerated anti-TNF therapy, as well as in patients naïve to biologic therapy. Both are also effective in nr-axSpA. The recommended

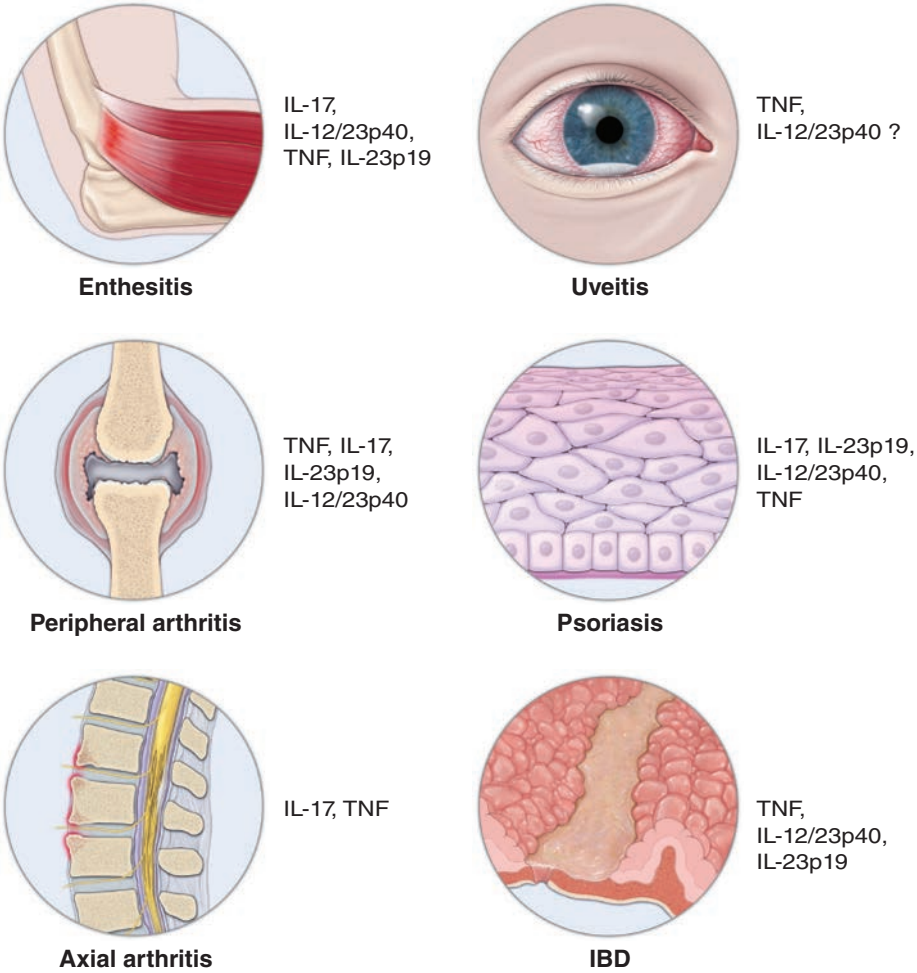

FIGURE 362-3 Proposed hierarchy of cytokine participation in disease pathogenesis in affected tissues in spondyloarthritis, based on the therapeutic response in clinical trials to biologic agents targeting the indicated cytokines. Peripheral arthritis, enthesitis, and psoriasis respond to agents targeting IL-17A, IL-23 (p19 subunit), IL-12/23 (p40 subunit), and TNF. Axial arthritis responds to anti-TNF and anti-IL17A, but failed to respond to anti-IL-23 and anti-IL12/23. Uveitis responds to anti-TNF, and anecdotally to anti-IL-12/23. The effect of anti-IL-17A in uveitis is not yet resolved. IBD responds to anti-TNF, anti-IL-23, and anti-IL-12/23, but failed to respond to anti-IL-17A and anti-IL-17 receptor. *(Adapted from S Siebert et al: Ann Rheum Dis 78:1015, 2019.)*

dose of secukinumab is 150 mg subcutaneously weekly for 4 weeks, and then at 4-week intervals. The recommended initiation of ixekizumab is with two 80 mg injections, followed by 80 mg every 4 weeks. Precautions regarding infection are similar to those for anti-TNF agents. An additional concern is potential exacerbation of underlying IBD, whether previously recognized or not, and careful monitoring is advised.

Two antibodies targeting IL-23, ustakinumab and risankizumab, failed to show efficacy in AS, whereas both show efficacy in psoriatic arthritis (see **Fig. 362-3**).

Sulfasalazine, in doses of 2–3 g/d, is used for peripheral arthritis. Methotrexate, although widely used, has not been shown to be of benefit in AS, nor has any therapeutic role for oral glucocorticoids been documented.

The oral Janus kinase (JAK) inhibitors, tofacitinib, upadacitinib, and filgotinib, have all shown efficacy in AS in clinical trials, with reduction of inflammation evident on MRI, and further clinical trials are in progress. Precautions regarding infection are similar to those for anti-TNF agents, with additional concern for herpes zoster.

The most common indication for surgery in patients with AS is severe hip joint arthritis, the pain and stiffness of which are usually dramatically relieved by total hip arthroplasty. Rare patients may benefit from surgical correction of extreme flexion deformities of the spine or of atlantoaxial subluxation.

Attacks of uveitis are usually managed effectively with local glucocorticoids and mydriatic agents, although systemic glucocorticoids, immunosuppressive drugs, or anti-TNF therapy may be required. TNF inhibitors may reduce the frequency of attacks of uveitis in patients with ax-SpA. Cases of new or recurrent uveitis with use of a TNF inhibitor have been observed, especially with etanercept. Adalimumab is FDA approved to treat intermediate, posterior, or panuveitis. These presentations are rare in AS but not unusual in psoriatic or IBD-associated arthritis (see below). Anti-IL-17A agents have not been directly studied as treatment for SpA-associated uveitis, but secukinumab-treated AS patients showed no increased incidence of uveitis in clinical trials.

Spinal manipulation is strongly discouraged and can be particularly dangerous in patients with osteoporosis or structural lesions on x-ray.

Management of axial osteoporosis is similar to that used for primary osteoporosis because data specific for AS are not available.

REACTIVE ARTHRITIS

ReA refers to acute nonpurulent arthritis complicating an infection elsewhere in the body. In recent years, the term has been used primarily to refer to SpA following enteric or urogenital infections.

Other forms of reactive and infection-related arthritis not associated with B27 and showing a spectrum of clinical features different from SpA, such as Lyme disease, rheumatic fever, and poststreptococcal ReA, are discussed in Chaps. 186 and 359.

HISTORIC BACKGROUND

The association of acute arthritis with episodes of diarrhea or urethritis has been recognized for centuries. A high incidence during World

Wars I and II focused attention on the triad of arthritis, urethritis, and conjunctivitis, often with additional mucocutaneous lesions, which became known by eponyms that are now of historic interest only.

The identification of bacterial species triggering the clinical syndrome and the finding of an association with HLA-B27 led to the unifying concept of ReA as a clinical syndrome triggered by specific etiologic agents in a genetically susceptible host. A characteristic spectrum of clinical manifestations can be triggered by enteric infection with certain *Shigella*, *Salmonella*, *Yersinia*, and *Campylobacter* species; by genital infection with *Chlamydia trachomatis*; and by many other agents as well, apparently in some cases via nasopharyngeal infection with *Chlamydia pneumoniae* or other agents. The "classic triad" represents a small part of the clinical spectrum and is present only in a small minority of patients. For the purposes of this chapter, the use of the term *ReA* will be restricted to those cases of SpA with at least presumptive evidence for a related antecedent infection.

EPIDEMIOLOGY

In early reports, 60–85% of patients who developed ReA triggered by *Shigella*, *Yersinia*, or *Chlamydia* were HLA-B27-positive. However, a lower prevalence of B27 is found in ReA triggered by *Salmonella*, and little or no B27 association is seen in *Campylobacter*-induced ReA. Recent community-based or common-source epidemic studies showed an overall prevalence of B27 in ReA <50%. The most common age range is 18–40 years, but ReA can occur in children and older adults.

The reported attack rate of postenteric ReA ranges from 1% to about 30%, depending on the study and causative organism, whereas the attack rate of postchlamydial ReA is ~4–8%. The gender ratio following enteric infection is nearly 1:1, whereas venereally acquired ReA occurs mainly in men. The overall prevalence and incidence of ReA are difficult to assess because of lack of validated diagnostic criteria, variable prevalence and arthritogenic potential of the triggering microbes, and varying genetic susceptibility in different populations. In Scandinavia, an annual incidence of 10–28:100,000 has been reported. SpA was formerly almost unknown in sub-Saharan Africa. However, ReA and other peripheral SpAs became common in black Africans in the wake of the AIDS epidemic, without association to B27, which is rare in these populations. In Africans, ReA is often the first manifestation of HIV infection and often remits with disease progression. In contrast, Western white patients with HIV and SpA are usually B27-positive, and the arthritis flares as AIDS advances.

PATHOLOGY

Synovial histology is similar to that of other SpAs. Enthesitis shows increased vascularity and macrophage infiltration of fibrocartilage. Microscopic histopathologic evidence of inflammation mimicking IBD has routinely been demonstrated in the colon and ileum of patients with postenteric ReA and less commonly in postvenereal ReA. The skin lesions of keratoderma blennorrhagica, associated mainly with venereally acquired ReA, are histologically indistinguishable from pustular psoriasis.

ETIOLOGY AND PATHOGENESIS

Definite bacterial triggers of ReA include several *Salmonella* spp., *Shigella* spp., *Yersinia enterocolitica*, *Yersinia pseudotuberculosis*, *Campylobacter jejuni*, and *Chlamydia trachomatis*. These are all gram-negative bacteria containing lipopolysaccharide (LPS). All *Shigella* species have been implicated in cases of ReA, with *S. flexneri* and *S. sonnei* being the most common. *Yersinia* species in Europe and Scandinavia may have greater arthritogenic potential than elsewhere, and *C. trachomatis* appears to be a common trigger worldwide. The ocular serovars of *C. trachomatis* appear to be particularly, perhaps uniquely, arthritogenic.

There is also evidence implicating *Clostridium difficile*, *Campylobacter coli*, certain toxigenic *Escherichia coli*, *Ureaplasma urealyticum,* and *Mycoplasma genitalium* as potential triggers of ReA. *Chlamydia pneumoniae* can trigger ReA, but far less commonly so than *C. trachomatis*. There have been numerous isolated reports of acute arthritis following many other bacterial, viral, or parasitic infections, and arthritis following intravesicular bacillus Calmette-Guérin (BCG) treatment for bladder cancer is well documented.

It is not known whether there is a common pathogenic mechanism for triggering ReA that is shared by all of these microorganisms, nor has the mechanism been elucidated for any particular trigger. Many of the established triggers share a capacity to attack mucosal surfaces, to invade host cells, and to survive intracellularly. Antigens from *Chlamydia*, *Yersinia*, *Salmonella*, and *Shigella* have been found in synovium and/or synovial fluid leukocytes of patients with ReA for long periods following the acute attack. In ReA triggered by *Y. enterocolitica*, bacterial LPS and heat-shock protein antigens have been found in peripheral blood cells years after the triggering infection. *Yersinia* DNA and *C. trachomatis* DNA and RNA have been detected in synovial tissue from ReA patients, suggesting the presence of viable organisms despite uniform failure to culture organisms from these specimens. The specificity of these findings is unclear, however, since chromosomal bacterial DNA and 16S rRNA from a wide variety of bacteria have also been found in synovium in other rheumatic diseases, albeit less frequently.

Recent work has documented high levels of IL-17 in ReA synovial fluid, but the source has not been identified. HLA-B27 seems to be associated with more severe and chronic ReA, but its pathogenic role remains to be determined. HLA-B27 significantly prolongs the intracellular survival of *Y. enterocolitica* and *Salmonella enteritidis* in human and mouse cell lines. This may permit trafficking of infected leukocytes from the site of primary infection to joints, where an innate and/or adaptive immune response to persistent bacterial antigens may then promote arthritis.

A recent study using 16S ribosomal RNA gene sequencing of intestinal microbiota showed a higher abundance of *Erwinia* and *Pseudomonas* species and an increased prevalence of typical enteropathogens in ReA patients, compared with controls. Correlations were found between specific bacteria and disease manifestations, and there was an HLA correlation with microbiome diversity.

CLINICAL FEATURES

The clinical manifestations of ReA range from an isolated, transient monoarthritis or enthesitis to severe multisystem disease. A careful history will often elicit evidence of an antecedent infection 1–4 weeks before onset of symptoms of the reactive disease, particularly in postenteric ReA. However, in a sizable minority, no clinical or laboratory evidence of an antecedent infection can be found, particularly in the case of postchlamydial ReA. In cases of presumed venereally acquired reactive disease, there is often a history of a recent new sexual partner.

Constitutional symptoms are common, including fatigue, malaise, fever, and weight loss. The musculoskeletal symptoms are usually acute in onset. Arthritis is usually asymmetric and additive, with involvement of new joints occurring over a few days to 1–2 weeks. The joints of the lower extremities, especially the knee, ankle, subtalar, metatarsophalangeal, and toe interphalangeal joints, are most commonly involved, but the wrist and fingers may be involved. The arthritis is usually quite painful, and tense joint effusions are not uncommon, especially in the knee. Dactylitis, or "sausage digit," a diffuse swelling of a solitary finger or toe, is a distinctive feature of ReA and PsA, but can be seen in polyarticular gout and sarcoidosis. Tendinitis and fasciitis are particularly characteristic lesions, producing pain at multiple entheses, especially the Achilles insertion, the plantar fascia, and sites along the axial skeleton. Back and buttock pain are quite common and may be caused by insertional inflammation, muscle spasm, acute sacroiliitis, or, presumably, arthritis in intervertebral joints.

Urogenital lesions may occur throughout the course of the disease. In men, urethritis may be marked or relatively asymptomatic and may be either an accompaniment of the triggering infection or a result of the reactive phase of the disease; interestingly, it occurs in both postvenereal and postenteric ReA. Prostatitis is common. In women, cervicitis or salpingitis may be caused either by the infectious trigger or by the sterile reactive process.

Ocular disease is common, ranging from transient, asymptomatic conjunctivitis to an aggressive anterior uveitis that occasionally proves refractory to treatment and may result in blindness.

Mucocutaneous lesions are frequent. Oral ulcers tend to be superficial, transient, and often asymptomatic. The characteristic skin lesion,

keratoderma blennorrhagica, consists of vesicles and/or pustules that become hyperkeratotic, ultimately forming a crust before disappearing. They are most common on the palms and soles but may occur elsewhere as well. In patients with HIV infection, these lesions are often severe and extensive, sometimes dominating the clinical picture **(Chap. 202)**. Lesions on the glans penis, termed *circinate balanitis*, consist of vesicles that quickly rupture to form painless superficial erosions, which in circumcised individuals can form crusts similar to those of keratoderma blennorrhagica. Nail changes are common and consist of onycholysis, distal yellowish discoloration, and/or heaped-up hyperkeratosis.

Less frequent or rare manifestations of ReA include cardiac conduction defects, aortic insufficiency, central or peripheral nervous system lesions, and pleuropulmonary infiltrates.

In resolving cases, arthritis typically lasts for 3–5 months. Chronic joint symptoms persist in about 15% of patients, and in up to 60% of patients in hospital-based series. The chronic symptoms tend to be less severe than in the acute stage, but work disability or forced change in occupation is common. Chronic heel pain is often particularly distressing. Low-back pain, sacroiliitis, or even overt AS are common sequelae. Recurrences of the acute syndrome may occur. In most studies, HLA-B27–positive patients showed a worse outcome than B27-negative patients. Patients with *Yersinia*- or *Salmonella*-induced arthritis have less chronic disease than those whose initial episode follows epidemic shigellosis.

LABORATORY AND RADIOGRAPHIC FINDINGS

The ESR and acute-phase reactants are usually elevated during the acute phase of the disease, often markedly. Mild anemia may be present. Synovial fluid is nonspecifically inflammatory. In most ethnic groups, 30–50% of the patients are B27-positive. The triggering infection usually does not persist at the site of primary mucosal infection through the time of onset of the reactive disease, but it may be possible to culture the organism, for example, in the case of *Yersinia*- or *Chlamydia*-induced disease. Serologic evidence of exposure to a causative organism is nonspecific and of questionable utility. Polymerase chain reaction (PCR) for chlamydial DNA in first-voided urine specimens may have high sensitivity in the acute stage but is less useful with chronic disease.

In early or mild disease, radiographic changes may be absent or confined to juxtaarticular osteoporosis. With long-standing disease, radiographic features share those of PsA; marginal erosions and loss of joint space can be seen in affected joints. Periostitis with reactive new bone formation is characteristic, as in all the SpAs. Spurs at the insertion of the plantar fascia are common. Sacroiliitis and spondylitis may be seen as late sequelae. Sacroiliitis is more commonly asymmetric than in AS, and spondylitis can begin anywhere along the lumbar spine. The syndesmophytes are described as nonmarginal; they are coarse, asymmetric, and "comma"-shaped, arising from the middle of a vertebral body, a pattern less commonly seen in primary AS. Progression to spinal fusion is uncommon.

DIAGNOSIS

ReA is a clinical diagnosis with no definitively diagnostic laboratory test or radiologic finding. The diagnosis should be entertained in any patient with an acute inflammatory, asymmetric, additive arthritis or tendinitis. The evaluation should include thorough but tactful questioning regarding possible triggering events. On physical examination, attention must be paid to the distribution of the joint and tendon involvement and to possible sites of extraarticular involvement, including the eyes, mucous membranes, skin, nails, and genitalia. Synovial fluid analysis is usually necessary to exclude septic or crystal-induced arthritis. Culture, serology, or molecular methods may help identify a triggering infection, but they cannot be relied upon.

Although typing for B27 has low negative predictive value in ReA, it may have prognostic significance in terms of severity, chronicity, and the propensity for spondylitis and uveitis. Furthermore, if positive, it can be helpful diagnostically in atypical cases. HIV testing is often indicated and may be necessary in selecting therapy.

Both ReA and disseminated gonococcal disease **(Chap. 156)** can be venereally acquired and associated with urethritis. Unlike ReA, gonococcal arthritis and tenosynovitis tend to involve both upper and lower extremities equally, spare the axial skeleton, and be associated with characteristic vesicular skin lesions. A positive gonococcal culture from the urethra or cervix does not exclude ReA; however, culturing gonococci from blood, skin lesion, or synovium establishes the diagnosis of disseminated gonococcal disease. PCR assay for *Neisseria gonorrhoeae* and *C. trachomatis* may be helpful. Occasionally, only a therapeutic trial of antibiotics can distinguish ReA from disseminated gonococcal disease.

ReA shares many features with PsA. However, PsA is usually gradual in onset; the arthritis tends to affect primarily the upper extremities; and there are usually no associated mouth ulcers, urethritis, or bowel symptoms.

TREATMENT

Reactive Arthritis

Most patients with ReA benefit to some degree from high-dose NSAIDs, although acute symptoms are rarely completely ameliorated, and some patients fail to respond at all.

Prompt, appropriate antibiotic treatment of acute chlamydial urethritis or enteric infection may prevent the emergence of ReA but is not universally successful. Data regarding the potential benefit of antibiotic therapy initiated after onset of arthritis are conflicting; however, a systematic review and meta-analysis of 10 controlled trials suggested no benefit. One of these trials reported that a majority of patients with chronic ReA associated with *C. trachomatis* or *C. pneumoniae* benefited significantly from a 6-month course of rifampin plus either azithromycin or doxycycline. This 2010 study still awaits confirmation.

Multicenter trials have suggested that sulfasalazine, up to 3 g/d in divided doses, may be beneficial to patients with persistent ReA.[1] Patients with persistent disease may respond to azathioprine, 1–2 mg/kg per day, or to methotrexate, up to 20 mg per week; however, these regimens have never formally been studied. Anecdotal evidence from 30 patients supports the use of anti-TNF in severe chronic cases, and there are isolated reports of responses to anti-IL-17A or anti-IL-6 receptor therapy.[1]

Tendinitis and other enthesitic lesions may benefit from intralesional glucocorticoids. Uveitis may require aggressive treatment to prevent serious sequelae. Skin lesions ordinarily require only symptomatic topical treatment. In patients with HIV infection and ReA, many of whom have severe skin lesions, the skin lesions in particular respond to antiretroviral therapy. Cardiac complications are managed conventionally; management of neurologic complications is symptomatic.

Comprehensive management includes counseling patients to avoid sexually transmitted disease and exposure to enteropathogens, as well as appropriate use of physical therapy, vocational counseling, and continued surveillance for long-term complications such as AS. Patients with a history of ReA are at increased risk for recurrent attacks following repeat exposure.

[1]Azathioprine, methotrexate, sulfasalazine, pamidronate, anti-TNFα agents, anti-IL-17A agents, and anti-IL-6 receptor agents have not been approved for this purpose by the FDA at the time of publication.

PSORIATIC ARTHRITIS

Psoriatic arthritis refers to an inflammatory musculoskeletal disease that has both autoimmune and autoinflammatory features characteristically occurring in individuals with psoriasis.

HISTORIC BACKGROUND

The association between arthritis and psoriasis was noted in the nineteenth century. In the 1960s, it became clear that unlike RA, arthritis associated with psoriasis was usually seronegative, often involved the

distal interphalangeal (DIP) joints of the fingers and the spine and sacroiliac joints, had distinctive radiographic features, and showed considerable familial aggregation. In the 1970s, PsA was included in the broader category of spondyloarthritis because of features similar to those of AS and ReA.

EPIDEMIOLOGY

The prevalence of PsA appears to be increasing in parallel with disease awareness. Recent data suggest that up to 30% of patients with psoriasis develop PsA. Longer duration and greater severity of psoriasis increase the likelihood of developing PsA. In white populations, psoriasis is estimated to have a prevalence of 1–3%. In other races, psoriasis and PsA are less common in the absence of HIV infection, and the prevalence of PsA in individuals with psoriasis may be less common. First-degree relatives of PsA patients have an elevated risk for psoriasis, for PsA, and for other forms of SpA. Of patients with psoriasis, up to 30% have an affected first-degree relative. In monozygotic twins, the reported concordance for psoriasis varies from 35–72%, and for PsA from 10–30%. A variety of HLA associations have been found. HLA-C6 is directly associated with psoriasis, particularly familial juvenile-onset (type I) psoriasis. HLA-B27 is associated with psoriatic spondylitis (see below). HLA-DR7, -DQ3, and -B57 are associated with PsA because of linkage disequilibrium with C6. A recent study found additive associations of PsA with haplotypes containing HLA-B8, -C6, -B27, -B38, and -B39. A correlation was also found between different haplotype combinations and entheseal, synovial, or axial predominant phenotypes. Genome-wide analyses have identified associations of PsA with polymorphisms in the IL-23 receptor (*IL23R*), molecules involved in nuclear factor κB gene expression (*TNIP1, TRAF3IP2*) and signaling (*TNFAIP3, TYK2*), and cytokines *TNF*, *IL12A*, and *IL12B*. A specific *IL23R* SNP is associated with PsA distinct from psoriasis without arthritis. Overall genetic sharing of AS with psoriasis is 0.28, lower than with IBD (see below). Polymorphisms in *IL-23A* are associated with psoriasis and with PsA, but not with AS.

PATHOLOGY

The inflamed synovium in PsA resembles that of RA, although with somewhat less hyperplasia and cellularity than in RA. As noted with AS above, the synovial vascular pattern in PsA is generally greater and more tortuous than in RA, independent of disease duration. Some studies have indicated a higher tendency to synovial fibrosis in PsA. Unlike RA, PsA shows prominent enthesitis, with histology similar to other forms of SpA.

PATHOGENESIS

PsA presumably shares immunopathogenic mechanisms with psoriasis. PsA synovium is characterized by lining layer hyperplasia; diffuse infiltration with T cells, B cells, macrophages, and NK receptor–expressing cells, with upregulation of leukocyte homing receptors; and neutrophil proliferation with angiogenesis. Clonally expanded T-cell subpopulations are frequent and have been demonstrated both in the synovium and the skin. Plasmacytoid dendritic cells are thought to play a key role in psoriasis, and there is some evidence for their participation in PsA. Interferon γ, TNF, and IL-1β, 2, 6, 8, 10, 12, 13, 15, and 17A, and myeloid-related protein (S100A8/A9) are found in PsA synovium or synovial fluid. IL-23/17 pathway cytokines are critical drivers of PsA pathogenesis. Both T_H17 cells and type 3 innate lymphocytes (ILC3) have been identified in dermal extracts of psoriatic lesions and in synovial fluid of PsA patients. Consistent with the extensive bone remodeling in PsA, patients with PsA have been found to have a marked increase in osteoclastic precursors in peripheral blood and upregulation of receptor activator of nuclear factor κB ligand (RANKL) in the synovial lining layer. Increased serum levels of TNF, RANKL, leptin, and omentin positively correlate with these osteoclastic precursors.

CLINICAL FEATURES

In 70% of cases, psoriasis precedes joint disease. In 15% of cases, the two manifestations appear within 1 year of each other. In about 15% of cases, the arthritis precedes the onset of psoriasis and can present a diagnostic challenge. The frequency in men and women is almost equal, although the frequency of disease patterns differs somewhat in the two sexes. The disease can begin in childhood or late in life but typically begins in the fourth or fifth decade, at an average age of 37 years.

Many classification schemes have been proposed for the broad spectrum of arthropathy in PsA. Wright and Moll described five patterns: (1) arthritis of the DIP joints; (2) asymmetric oligoarthritis; (3) symmetric polyarthritis similar to RA; (4) axial involvement (spine and sacroiliac joints); and (5) arthritis mutilans, a highly destructive form of the disease. These patterns frequently coexist, and the pattern that persists chronically often differs from that of the initial presentation. A simpler scheme in recent use contains three patterns: oligoarthritis, polyarthritis, and axial arthritis.

Nail changes in the fingers or toes occur in most patients with PsA, compared with only a minority of psoriatic patients without arthritis, and pustular psoriasis is said to be associated with more severe arthritis. Dactylitis and enthesitis are common in PsA and help to distinguish it from other joint disorders. Dactylitis occurs in >30%; enthesitis and tenosynovitis are probably present in most patients, although often not appreciated on physical examination. Shortening of digits because of underlying osteolysis is particularly characteristic of PsA, and there is a much greater tendency than in RA for both fibrous and bony ankylosis of small joints. Rapid ankylosis of one or more proximal interphalangeal (PIP) joints early in the course of disease is not uncommon. Joint involvement tends to follow a "ray" distribution, with all of the joints of one finger involved, while sparing adjacent fingers entirely. Back and neck pain and stiffness are also common in PsA.

Arthropathy confined to the DIP joints occurs in ~5% of cases. Accompanying nail changes in the affected digits are almost always present. These joints are also often affected in the other patterns of PsA. Approximately 30% of patients have asymmetric oligoarthritis. This pattern commonly involves a knee or another large joint with a few small joints in the fingers or toes, often with dactylitis. Symmetric polyarthritis occurs in about 40% of PsA patients at presentation. It may be indistinguishable from RA in terms of the joints involved, but other features characteristic of PsA are usually also present. Almost any peripheral joint can be involved. Axial arthritis without peripheral involvement is found in ~5% of PsA patients. It may be clinically indistinguishable from idiopathic AS, although more neck involvement and less thoracolumbar spinal involvement are characteristic, and nail changes are not found in idiopathic AS. A small percentage of PsA patients have arthritis mutilans, in which there can be widespread shortening of digits ("telescoping"), sometimes coexisting with ankylosis and contractures in other digits.

Six patterns of nail involvement are identified: pitting, horizontal ridging, onycholysis, yellowish discoloration of the nail margins, dystrophic hyperkeratosis, and combinations of these findings. Extraarticular and extradermal manifestations are common. Eye involvement, either conjunctivitis or uveitis, is reported in 7–33% of PsA patients. Unlike uveitis associated with AS, the uveitis in PsA is more often insidious in onset, bilateral, chronic, and/or nonanterior. The prevalences of aortic valve insufficiency and heart block are apparently similar to those in AS.

Widely varying estimates of clinical outcome have been reported in PsA. At its worst, severe PsA with arthritis mutilans is potentially at least as crippling and ultimately fatal as severe untreated RA. Unlike RA, however, many patients with PsA experience temporary remissions. Overall, erosive disease develops in the majority of patients, progressive disease with deformity and disability is common, and in some large series, mortality was found to be significantly increased compared with the general population.

The psoriasis and associated arthropathy seen with HIV infection both tend to be severe and can occur in populations with low prevalence of psoriasis. Severe enthesitis, dactylitis, and rapidly progressive joint destruction are seen, but axial involvement is very rare. This condition is prevented by or responds well to antiretroviral therapy.

LABORATORY AND RADIOGRAPHIC FINDINGS

There are no laboratory tests diagnostic of PsA. ESR and CRP are elevated in only 30% of patients. A small percentage of patients may

have low titers of rheumatoid factor or ANAs. About 10% of patients have anti-CCP antibodies. Uric acid may be elevated in the presence of extensive psoriasis. HLA-B27 is found in 50–70% of patients with axial disease but in ≤20% of patients with only peripheral joint involvement.

Peripheral and axial arthritis in PsA show several radiographic features that distinguish them from RA and AS, respectively. Characteristics of peripheral PsA include DIP involvement, including the classic "pencil-in-cup" deformity; marginal erosions with adjacent bony proliferation ("whiskering"); small-joint ankylosis; osteolysis of phalangeal and metacarpal bone, with telescoping of digits; periostitis and proliferative new bone at sites of enthesitis; and a "ray" distribution of lesions. Characteristics of axial PsA that differ from idiopathic AS include asymmetric sacroiliitis; less facet joint arthritis; nonmarginal, bulky, "comma"-shaped syndesmophytes that tend to be fewer, less symmetric, and less delicate than the marginal syndesmophytes of AS; fluffy hyperperiostosis on anterior vertebral bodies; severe cervical spine involvement, with a tendency to atlantoaxial subluxation but relative sparing of the thoracolumbar spine; and paravertebral ossification. Ultrasound and MRI both readily demonstrate enthesitis and tendon sheath effusions that can be difficult to assess on physical examination. A recent MRI study of 68 PsA patients found sacroiliitis in 35%, unrelated to B27 but correlated with restricted spinal movement.

DIAGNOSIS

Classification criteria for PsA were published in 2006 (Classification of Psoriatic Arthritis [CASPAR] criteria) **(Table 362-2)**. The sensitivity and specificity of these criteria exceed 90%, and they are useful in clinical practice as a guide for early diagnosis. Diagnosis can be challenging when the arthritis precedes psoriasis, the psoriasis is undiagnosed or obscure, or the joint involvement closely resembles another form of arthritis. A high index of suspicion is needed in any patient with an undiagnosed inflammatory arthritis. The history should include inquiry about psoriasis in the patient and family members. Patients should be examined disrobed, and psoriasiform lesions should be sought in the scalp, ears, umbilicus, and gluteal folds in addition to more accessible sites; the fingernails and toenails should also be carefully examined. Axial symptoms or signs, dactylitis, enthesitis, ankylosis, the pattern of joint involvement, and characteristic radiographic changes can be helpful clues. The differential diagnosis includes all other forms of arthritis, which can occur coincidentally in individuals with psoriasis. The differential diagnosis of isolated DIP involvement is short. Osteoarthritis (Heberden's nodes) is usually not inflammatory; gout involving more than one DIP joint often involves other sites and may be accompanied by tophi; the very rare entity multicentric reticulohistiocytosis involves other joints and has characteristic small pearly periungual skin nodules; and the uncommon entity, inflammatory osteoarthritis, like the others, lacks the nail changes of PsA. Radiography can be helpful in all these cases, and in distinguishing between psoriatic spondylitis and idiopathic AS. A history of trauma to an affected joint preceding the onset of arthritis may occur more frequently in PsA than in other types of arthritis, perhaps reflecting the Koebner phenomenon in which psoriatic skin lesions arise at sites of skin trauma.

TABLE 362-2 The CASPAR (*Cla*ssification Criteria for *P*soriatic *A*rthritis) Criteria[a]

To meet the CASPAR criteria, a patient must have inflammatory articular disease (joint, spine, or entheseal) with ≥3 points from any of the following five categories:

1. Evidence of current psoriasis,[b,c] a personal history of psoriasis, or a family history of psoriasis[d]
2. Typical psoriatic nail dystrophy[e] observed on current physical examination
3. A negative test result for rheumatoid factor
4. Either current dactylitis[f] or a history of dactylitis recorded by a rheumatologist
5. Radiographic evidence of juxtaarticular new bone formation[g] in the hand or foot

[a]Specificity of 99% and sensitivity of 91%. [b]Current psoriasis is assigned 2 points; all other features are assigned 1 point. [c]Psoriatic skin or scalp disease present at the time of examination, as judged by a rheumatologist or dermatologist. [d]History of psoriasis in a first- or second-degree relative. [e]Onycholysis, pitting, or hyperkeratosis. [f]Swelling of an entire digit. [g]Ill-defined ossification near joint margins, excluding osteophyte formation.

TREATMENT

Psoriatic Arthritis

Ideally, coordinated therapy is directed at both the skin and joints in PsA, and biologic agents have dramatically facilitated this goal. This was first observed with anti-TNF agents, with prompt and dramatic resolution of both arthritis and skin lesions observed in large, randomized controlled trials of all five agents. Many of the responding patients had long-standing disease that was resistant to all previous therapy, as well as extensive skin disease. The clinical response is often more dramatic than in RA, and delay of disease progression has been demonstrated radiographically. The potential additive effect of methotrexate to anti-TNF agents in PsA remains uncertain. As noted above, anti-TNF therapy, paradoxically, has been reported to trigger exacerbation or de novo appearance of psoriasis, typically the palmoplantar pustular variety. In some cases, the therapy can nevertheless be continued.

Antagonists of the IL-23/IL-17 pathway show efficacy at least comparable to that of anti-TNF for PsA and in some cases superior for psoriasis. Approved agents include secukinumab and ixekizumab, monoclonal antibodies to IL-17A; and ustekinumab, a monoclonal antibody to the shared IL-23/IL-12p40 subunit. Three monoclonal antibodies to IL-23 (p19 subunit) that are approved for plaque psoriasis—guselkumab, risankizumab, and tildrakizumab—showed efficacy in PsA in clinical trials (Fig. 362-3).

Apremilast, an oral phosphodiesterase-4 inhibitor, is approved for both psoriasis and PsA. Although not quite as effective for PsA as the biologics, apremilast has a more favorable safety profile. It is not indicated in patients with radiographically evident joint damage or axial involvement.

The oral JAK inhibitor, tofacitinib, is approved for treatment of PsA. When directly compared, its efficacy was comparable to the anti-TNF agent adalimumab. At least five other JAK inhibitors are currently being studied in PsA clinical trials.

Older treatments for PsA have been based on drugs that have efficacy in RA and/or in psoriasis. Methotrexate in doses of 15–25 mg/week has moderate efficacy for psoriasis, and expert opinion favors its use in PsA not requiring biologics. Agents with efficacy in psoriasis reported to benefit PsA are cyclosporine, retinoic acid derivatives, and psoralens plus ultraviolet A light (PUVA). The pyrimidine synthetase inhibitor leflunomide has been shown to be beneficial in PsA, with modest benefit for psoriasis.

All these treatments require careful monitoring. Immunosuppressive therapy may be used cautiously in HIV-associated PsA if the HIV infection is well controlled.

UNDIFFERENTIATED AND JUVENILE SPONDYLOARTHRITIS

Many patients present with one or more SpA features but lack sufficient findings for one of the preceding diagnoses. These patients were formerly said to have *undifferentiated spondyloarthritis*, or simply *spondyloarthritis*, as defined by the 1991 European Spondyloarthropathy Study Group criteria. Some of these patients may have ReA in which the triggering infection remains clinically silent. In other cases, the patient may subsequently develop IBD or psoriasis. The diagnosis of undifferentiated SpA was commonly applied to patients with peripheral arthritis and/or enthesitis, and to patients with IBP and other SpA features who did meet radiographic criteria for AS. Many of these latter patients would now be classified as nr-axSpA (Table 362-1).

Comparable to the classification criteria for axial SpA, the ASAS has formulated criteria for peripheral SpA. This is intended to exclude patients with axial symptoms and thus to divide the universe of patients

TABLE 362-3 ASAS Criteria for Peripheral Spondyloarthritis[a]

ARTHRITIS[b] *OR* ENTHESITIS *OR* DACTYLITIS
PLUS EITHER
One or more of the following SpA features:
• Psoriasis
• Crohn's disease or ulcerative colitis
• Preceding infection
• Uveitis
• HLA-B27
• Sacroiliitis on imaging (radiographs or MRI)
OR two or more of the following SpA features:
• Arthritis
• Enthesitis
• Dactylitis
• Inflammatory back pain ever
• Family history for SpA

[a]Sensitivity 78%, specificity 82%. [b]Peripheral arthritis, usually predominantly lower limb and/or asymmetric. The various SpA features are as defined in Table 362-1. Preceding infection refers to preceding gastrointestinal or urogenital infection.

Source: M Rudawaleit et al: Ann Rheum Dis 70:25, 2011.

with SpA into predominantly axial and predominantly peripheral subsets. These criteria are shown in **Table 362-3**.

In juvenile SpA, which usually begins between ages 7 and 16 years, an asymmetric, predominantly lower-extremity oligoarthritis and enthesitis without extraarticular features is the typical mode of presentation. This condition is termed the *seronegative enthesitis and arthritis* (*SEA*) *syndrome*. There is male predominance (60–80%), and the prevalence of B27 is ~80%. Despite the absence of axial symptoms, active sacroiliitis by MRI has commonly been found at diagnosis. Many, but not all, of these patients go on to develop AS in late adolescence or adulthood.

Management of peripheral SpA is similar to that of the other spondyloarthritides. Biologic therapy is indicated in severe, persistent cases not responsive to other treatment.

Current pediatric literature should be consulted for information on management of juvenile SpA.

IBD-ASSOCIATED ARTHRITIS

HISTORIC BACKGROUND

The relationship between arthritis and IBD, first observed in the 1930s, was further defined by epidemiologic studies in the 1950s and 1960s, and included in the concept of the spondyloarthritides in the 1970s.

EPIDEMIOLOGY

Both common forms of IBD, ulcerative colitis (UC) and Crohn's disease (CD) **(Chap. 326)**, are associated with SpA. UC and CD both have an estimated prevalence of 0.1–0.2%, and the incidence of each is thought to have increased in recent decades. Both axial and peripheral SpA are associated with UC and CD. Wide variations have been reported in the estimated frequencies of these associations. In recent series, AS was diagnosed in 1–10%, and peripheral arthritis in 10–50% of patients with IBD. IBP and enthesitis are common, and many patients have sacroiliitis on imaging studies.

The prevalence of UC or CD in patients with AS is thought to be 5–10%, and a recent meta-analysis found the prevalence in patients with nr-axSpA to be 6.4%. However, investigation of unselected SpA patients by ileocolonoscopy has revealed that up to two-thirds of patients with AS have subclinical intestinal inflammation that is evident either macroscopically or histologically. These lesions have also been found in patients with undifferentiated SpA or ReA (both enterically and urogenitally acquired).

Both UC and CD show familial aggregation, more so for CD. HLA associations have been weak and inconsistent. HLA-B27 is found in up to 70% of patients with IBD and AS, but in ≤15% of patients with IBD and peripheral arthritis or IBD alone. Three alleles of the *NOD2/CARD15* gene have been found in approximately one-half of patients with CD. These alleles are not associated with SpA per se. In addition, more than 200 other genes have been found to be associated with CD, UC, or both. Many of the SNPs associated with AS are also associated with IBD, almost all with the same direction of association. Overall, the genetic correlation of AS is 0.49 with CD and 0.47 with UC.

PATHOLOGY

Available data for IBD-associated peripheral arthritis suggest a synovial histology similar to other forms of SpA. Association with arthritis does not affect the gut histology of UC or CD **(Chap. 326)**. The subclinical inflammatory lesions in the colon and distal ileum associated with SpA are classified as either acute or chronic. The former resembles acute bacterial enteritis, with largely intact architecture and neutrophilic infiltration in the lamina propria. The latter resemble the lesions of CD, with distortion of villi and crypts, aphthoid ulceration, and mononuclear cell infiltration in the lamina propria.

PATHOGENESIS

Both IBD and SpA are immune-mediated, and the shared genetics presumably reflect shared pathogenic mechanisms, but the specific connection between them remains obscure. Rodent models showing various immune perturbations manifest both IBD and arthritis. Resident innate immune cells and intestinal dysbiosis have been implicated in both conditions. Several lines of evidence indicate trafficking of leukocytes between the gut and the joint. Mucosal leukocytes from IBD patients have been shown to bind avidly to synovial vasculature through several different adhesion molecules. Macrophages expressing CD163 are prominent in the inflammatory lesions of both gut and synovium in the spondyloarthritides.

CLINICAL FEATURES

AS associated with IBD is clinically indistinguishable from idiopathic AS. It runs a course independent of the bowel disease, and in some patients, it precedes the onset of IBD. Peripheral arthritis may also begin before onset of overt bowel disease. The spectrum of peripheral arthritis includes acute self-limited attacks of oligoarthritis that often coincide with relapses of IBD, and more chronic and symmetric polyarticular arthritis that runs an independent course. The patterns of joint involvement are similar in UC and CD. In general, erosions and deformities are infrequent in IBD-associated peripheral arthritis. Isolated destructive hip arthritis is a rare complication of CD, apparently distinct from osteonecrosis and septic arthritis. Dactylitis and enthesopathy are occasionally found. In addition to the ~20% of IBD patients with SpA, a comparable percentage have arthralgias or fibromyalgia symptoms.

Other extraintestinal manifestations of IBD are seen in addition to arthritis, including uveitis, psoriasis, pyoderma gangrenosum, erythema nodosum, pulmonary nodules, and clubbing, all somewhat more commonly in CD than UC. The uveitis shares the features described above for PsA-associated uveitis.

LABORATORY AND RADIOGRAPHIC FINDINGS

Laboratory findings reflect the inflammatory and metabolic manifestations of IBD. Joint fluid is usually at least mildly inflammatory. Of patients with AS and IBD, 30–70% carry HLA-B27, compared with 80–90% of patients with AS alone and 50–70% of those with AS and psoriasis. Hence, definite or probable AS in a B27-negative individual in the absence of psoriasis should raise concern for occult IBD. Radiographic changes in the axial skeleton are the same as in uncomplicated AS. Erosions are uncommon in peripheral arthritis but may occur, particularly in the metatarsophalangeal joints.

DIAGNOSIS

Diarrhea and arthritis are both common conditions that can coexist for a variety of reasons. When etiopathogenically related, ReA and IBD-associated arthritis are the most common causes. Rare causes include celiac disease and Whipple's disease. Behcet's disease can mimic CD and cause arthritis. In most cases, diagnosis depends on investigation of the bowel disease.

TREATMENT

IBD-Associated Arthritis

Treatment of CD has been improved by anti-TNF agents. Infliximab, adalimumab, and certolizumab pegol are effective for induction and maintenance of clinical remission in CD, and infliximab is effective in fistulizing CD. IBD-associated arthritis also responds to these agents. Other biologics with efficacy in IBD that may have efficacy for peripheral arthritis include ustekinumab (anti-IL12/23) and risankizumab (anti-IL-23), but anti-IL-17 therapy is not indicated (Fig. 362-3). Tofacitinib is approved for treatment of UC. Other promising JAK inhibitors include upadacitinib and filgotinib. Other treatments for IBD include sulfasalazine and related drugs as well as systemic and local glucocorticoids. NSAIDs, especially COX-selective formulations, are helpful for arthritis and generally well tolerated, but they can precipitate IBD flares. As noted above for psoriasis, rare cases of IBD, either CD or UC, have apparently been precipitated by anti-TNF therapy. Vedolizumab is a gut-selective integrin inhibitor approved for both CD and UC. It is not given specifically for joint disease, but coexistent arthritis can improve during treatment of the IBD. However, there are many reports of de novo or flaring arthritis, either axial or peripheral, in IBD patients treated with vedolizumab.

SAPHO SYNDROME

The syndrome of synovitis, acne, pustulosis, hyperostosis, and osteitis (SAPHO) is characterized by a variety of skin and musculoskeletal manifestations. Dermatologic manifestations include palmoplantar pustulosis, acne conglobata, acne fulminans, and hidradenitis suppurativa. The main musculoskeletal findings are sternoclavicular and spinal hyperostosis, chronic recurrent foci of sterile osteomyelitis, and axial or peripheral arthritis. Cases with one or a few manifestations are probably the rule. The ESR and/or CRP are usually mildly to moderately elevated, occasionally dramatically. Bacteria, most often *Propionibacterium acnes*, have been cultured from bone biopsy specimens and occasionally other sites. IBD was coexistent in 8% of patients in one large series. No gene associations have been found, despite the resemblance to autoinflammatory syndromes. Radionuclide bone scan is very helpful diagnostically, often showing the classic "bull's head" sign involving the sternoclavicular joints and clavicles. High-dose NSAIDs may provide relief from bone pain. Uncontrolled series and case reports describe successful therapy with pamidronate or other bisphosphonates. Anecdotal benefit from biologic agents has been reported, including anti-TNF, anti-IL-17A, anti-IL-12/23, anti-IL-6, and anti-IL-1 agents. Successful prolonged antibiotic therapy has also been reported.

363 The Vasculitis Syndromes

Carol A. Langford, Anthony S. Fauci

DEFINITION

Vasculitis is a clinicopathologic process characterized by inflammation of and damage to blood vessels. The vessel lumen is usually compromised, and this is associated with ischemia of the tissues supplied by the involved vessel. A broad and heterogeneous group of syndromes may result from this process, since any type, size, and location of blood vessel may be involved. Vasculitis and its consequences may be the primary or sole manifestation of a disease; alternatively, vasculitis may be a secondary component of another disease. Vasculitis may be confined to a single organ, such as the skin, or it may simultaneously involve several organ systems.

CLASSIFICATION

A major feature of the vasculitic syndromes as a group is the fact that there is a great deal of heterogeneity at the same time as there is considerable overlap among them. Table 363-1 lists the major vasculitis

TABLE 363-1 Vasculitis Syndromes

PRIMARY VASCULITIS SYNDROMES	SECONDARY VASCULITIS SYNDROMES
Granulomatosis with polyangiitis	Vasculitis associated with probable etiology
Microscopic polyangiitis	Drug-induced vasculitis
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)	Hepatitis C virus–associated cryoglobulinemic vasculitis
IgA vasculitis (Henoch-Schönlein)	Hepatitis B virus–associated vasculitis
Cryoglobulinemic vasculitis	Cancer-associated vasculitis
Polyarteritis nodosa	Vasculitis associated with systemic disease
Kawasaki disease	Lupus vasculitis
Giant cell arteritis	Rheumatoid vasculitis
Takayasu arteritis	Sarcoid vasculitis
Behçet's disease	
Cogan's syndrome	
Single-organ vasculitis

syndromes. The distinguishing and overlapping features of these syndromes are discussed below.

PATHOPHYSIOLOGY AND PATHOGENESIS

Generally, most of the vasculitic syndromes are assumed to be mediated at least in part by immunopathogenic mechanisms that occur in response to certain antigenic stimuli. However, evidence supporting this hypothesis is for the most part indirect and may reflect epiphenomena as opposed to true causality. Furthermore, it is unknown why some individuals might develop vasculitis in response to certain antigenic stimuli, whereas others do not. It is likely that a number of factors are involved in the ultimate expression of a vasculitic syndrome. These include the genetic predisposition, environmental exposures, and the regulatory mechanisms associated with immune response to certain antigens. Although immune complex formation, antineutrophil cytoplasmic antibodies (ANCA), and pathogenic T lymphocyte responses **(Table 363-2)** have been among the prominent hypothesized mechanisms, it is likely that the pathogenesis of individual forms of vasculitis is complex and varied.

PATHOGENIC IMMUNE-COMPLEX FORMATION

Deposition of immune complexes was the first and most widely accepted pathogenic mechanism of vasculitis. However, the causal role of immune complexes has not been clearly established in most of the vasculitic syndromes. Circulating immune complexes need not result in deposition of the complexes in blood vessels with ensuing vasculitis, and many patients with active vasculitis do not have demonstrable circulating or deposited immune complexes. The actual antigen contained in the immune complex has only rarely been identified in vasculitic syndromes. In this regard, hepatitis B antigen has been identified in both the circulating and deposited immune complexes in a subset of patients who have features of a systemic vasculitis clinically similar to polyarteritis nodosa (see "Polyarteritis Nodosa"). Cryoglobulinemic vasculitis is strongly associated with hepatitis C virus infection; hepatitis C virions and hepatitis C virus antigen-antibody complexes have been identified in the cryoprecipitates of these patients (see "Cryoglobulinemic Vasculitis").

The mechanisms of tissue damage in immune complex–mediated vasculitis resemble those described for serum sickness. In this model, antigen-antibody complexes are formed in antigen excess and are deposited in vessel walls whose permeability has been increased by vasoactive amines such as histamine, bradykinin, and leukotrienes released from platelets or from mast cells as a result of IgE-triggered mechanisms. The deposition of complexes results in activation of complement components, particularly C5a, which is strongly chemotactic for neutrophils. These cells then infiltrate the vessel wall, phagocytose the immune complexes, and release their intracytoplasmic enzymes, which damage the vessel wall. As the process becomes subacute or chronic, mononuclear cells infiltrate the vessel wall. The common denominator of the resulting syndrome is compromise of the vessel lumen with ischemic changes in the tissues supplied by the involved vessel. Several variables may explain why only certain types of immune complexes cause vasculitis and why only certain vessels are affected in individual patients. These include the ability of the reticuloendothelial system to clear circulating complexes from the blood, the size and physicochemical properties of immune complexes, the relative degree of turbulence of blood flow, the intravascular hydrostatic pressure in different vessels, and the preexisting integrity of the vessel endothelium.

TABLE 363-2 Potential Mechanisms of Vessel Damage in Vasculitis Syndromes

Pathogenic immune-complex formation and/or deposition

ANTINEUTROPHIL CYTOPLASMIC ANTIBODIES

ANCA are antibodies directed against certain proteins in the cytoplasmic granules of neutrophils and monocytes. These autoantibodies are present in a high percentage of patients with active granulomatosis with polyangiitis and microscopic polyangiitis and in a lower percentage of patients with eosinophilic granulomatosis with polyangiitis (Churg-Strauss). Because these diseases share the presence of ANCA and small-vessel vasculitis, they have been grouped collectively as "ANCA-associated vasculitis." However, these diseases possess unique clinical phenotypes, such that they should continue to be viewed as separate entities.

There are two major categories of ANCA based on different targets for the antibodies. The terminology of *cytoplasmic ANCA* (cANCA) refers to the diffuse, granular cytoplasmic staining pattern observed by immunofluorescence microscopy when serum antibodies bind to indicator neutrophils. Proteinase-3, a 29-kDa neutral serine proteinase present in neutrophil azurophilic granules, is the major cANCA antigen. More than 90% of patients with active granulomatosis with polyangiitis have detectable antibodies to proteinase-3 (see below). The terminology of *perinuclear ANCA* (pANCA) refers to the more localized perinuclear or nuclear staining pattern of the indicator neutrophils. The major target for pANCA is the enzyme myeloperoxidase; other targets that can produce a pANCA pattern of staining include elastase, cathepsin G, lactoferrin, lysozyme, and bactericidal/permeability-increasing protein. However, only antibodies to myeloperoxidase have been convincingly associated with vasculitis. Antimyeloperoxidase antibodies have been reported to occur in variable percentages of patients with microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis (Churg-Strauss), isolated necrotizing crescentic glomerulonephritis, and granulomatosis with polyangiitis (see below). A pANCA pattern of staining that is not due to antimyeloperoxidase antibodies has been associated with nonvasculitic entities such as rheumatic and nonrheumatic autoimmune diseases, inflammatory bowel disease, certain drugs, and infections such as endocarditis and bacterial airway infections in patients with cystic fibrosis.

It is unclear why patients with these vasculitis syndromes develop antibodies to myeloperoxidase or proteinase-3 or what role these antibodies play in disease pathogenesis. There are a number of in vitro observations that suggest possible mechanisms whereby these antibodies can contribute to the pathogenesis of the vasculitis syndromes. Proteinase-3 and myeloperoxidase reside in the azurophilic granules and lysosomes of resting neutrophils and monocytes, where they are apparently inaccessible to serum antibodies. However, when neutrophils or monocytes are primed by tumor necrosis factor α (TNF-α) or interleukin 1 (IL-1), proteinase-3 and myeloperoxidase translocate to the cell membrane, where they can interact with extracellular ANCA. The neutrophils then degranulate and produce reactive oxygen species that can cause tissue damage. Furthermore, ANCA-activated neutrophils can adhere to and kill endothelial cells in vitro. Activation of neutrophils and monocytes by ANCA also induces the release of proinflammatory cytokines such as IL-1 and IL-8. Adoptive transfer experiments in genetically engineered mice provide further evidence for a direct pathogenic role of ANCA in vivo. In contradiction, however, a number of clinical and laboratory observations argue against a primary pathogenic role for ANCA. Patients may have active granulomatosis with polyangiitis in the absence of ANCA; the absolute height

of the antibody titers does not correlate well with disease activity; and patients with granulomatosis with polyangiitis in remission may continue to have high ANCA levels for years (see below).

PATHOGENIC T LYMPHOCYTE RESPONSES AND GRANULOMA FORMATION

The histopathologic feature of granulomatous vasculitis has provided evidence to support a role of pathogenic T lymphocyte responses and cell-mediated immune injury. Vascular endothelial cells can express human leukocyte antigen (HLA) class II molecules following activation by cytokines such as interferon (IFN) γ. This allows these cells to participate in immunologic reactions such as interaction with CD4+ T lymphocytes in a manner similar to antigen-presenting macrophages. Endothelial cells can secrete IL-1, which may activate T lymphocytes and initiate or propagate in situ immunologic processes within the blood vessel. In addition, IL-1 and TNF-α are potent inducers of endothelial-leukocyte adhesion molecule 1 (ELAM-1) and vascular cell adhesion molecule 1 (VCAM-1), which may enhance the adhesion of leukocytes to endothelial cells in the blood vessel wall.

APPROACH TO THE PATIENT

General Principles of Diagnosis

The diagnosis of vasculitis should be considered in any patient with an unexplained systemic illness. However, there are certain clinical abnormalities that when present alone or in combination should suggest a diagnosis of vasculitis. These include palpable purpura, pulmonary infiltrates and microscopic hematuria, chronic inflammatory sinusitis, mononeuritis multiplex, unexplained ischemic events, and glomerulonephritis with evidence of multisystem disease. A number of nonvasculitic diseases may also produce some or all of these abnormalities. Thus, the first step in the workup of a patient with suspected vasculitis is to exclude other diseases that produce clinical manifestations that can mimic vasculitis **(Table 363-3)**. It is particularly important to exclude infectious diseases with features that overlap those of vasculitis, especially if the patient's clinical condition is deteriorating rapidly and empirical immunosuppressive treatment is being contemplated.

Once diseases that mimic vasculitis have been excluded, the workup should follow a series of progressive steps that establish the diagnosis of vasculitis and determine, where possible, the category of the vasculitis syndrome **(Fig. 363-1)**. This approach is of considerable importance since several of the vasculitis syndromes require aggressive therapy with glucocorticoids and other immunosuppressive agents, whereas other syndromes usually resolve spontaneously and require symptomatic treatment only. The definitive diagnosis of vasculitis is usually made based on biopsy of involved tissue. The yield of "blind" biopsies of organs with no subjective or objective evidence of involvement is very low and should be avoided. When syndromes such as polyarteritis nodosa, Takayasu arteritis, or primary central nervous system (CNS) vasculitis are suspected, arteriogram of organs with suspected involvement should be performed.

GENERAL PRINCIPLES OF TREATMENT

Once a diagnosis of vasculitis has been established, a decision regarding therapeutic strategy must be made (Fig. 363-1). If an offending antigen that precipitates the vasculitis is recognized, the antigen should be removed where possible. If the vasculitis is associated with an underlying disease such as an infection, neoplasm, or connective tissue disease, the underlying disease should be treated. If the syndrome represents a primary vasculitic disease, treatment should be initiated according to the category of the vasculitis syndrome. Specific therapeutic regimens are discussed below for the individual vasculitis syndromes; however, certain general principles regarding therapy should be considered. Decisions regarding treatment should be based on the use of regimens for which there has been published literature supporting efficacy for that particular vasculitic disease. Since the potential toxic side effects of certain therapeutic regimens may be substantial, the risk-versus-benefit ratio of any therapeutic approach should be weighed carefully. Glucocorticoids and/or other immunosuppressive agents should be instituted immediately in diseases where irreversible organ system dysfunction and high morbidity and mortality rates have been clearly established. Granulomatosis with polyangiitis is the prototype of a severe systemic vasculitis requiring such a therapeutic approach (see below). Conversely, aggressive therapy should be avoided for vasculitic manifestations that rarely result in irreversible organ system dysfunction such as isolated idiopathic cutaneous vasculitis. Glucocorticoids should be initiated in those systemic vasculitides that cannot be specifically categorized or for which there is no established standard therapy, with other immunosuppressive agents being added if an adequate response does not result or if remission can only be achieved and maintained with an unacceptably toxic regimen of glucocorticoids. When remission is achieved, one should continually attempt to taper glucocorticoids and discontinue when possible. When using other immunosuppressive regimens, one should base the choice of agent upon the available therapeutic data supporting efficacy in that disease, the site and severity of organ involvement, and the toxicity profile of the drug.

Physicians should be thoroughly aware of the acute and long-term side effects associated with the agents that are commonly used to treat different forms of vasculitis **(Table 363-4)**.

Morbidity and mortality can occur as a result of treatment, and strategies to monitor for and prevent toxicity represent an essential part of patient care.

Addressing the risk of bone loss is important in all patients receiving glucocorticoids. Daily cyclophosphamide should be taken all at once in the morning with a large amount of fluid throughout the day to reduce the risk of bladder injury, and monitoring for bladder cancer should continue indefinitely.

Maintaining the white blood cell (WBC) count at >3000/μL and the neutrophil count at >1500/μL is essential to reduce the risk of life-threatening infections. Monitoring of the complete blood count every 1–2 weeks for as long as the patient receives cyclophosphamide can effectively prevent cytopenias. Methotrexate, azathioprine, and mycophenolate mofetil are also associated with bone marrow suppression, and complete blood counts should be obtained every 1–2 weeks for the first 1–2 months after their initiation and once a month thereafter. To lessen toxicity, methotrexate is often given together with folic acid, 1 mg daily, or folinic acid, 5–10 mg once a week 24 h following methotrexate. Methotrexate is eliminated by the kidney and contraindicated in renal insufficiency as this increases the risk for toxicity. Prior to initiation of azathioprine, thiopurine methyltransferase (TPMT), an enzyme involved in the metabolism of azathioprine, should be assayed because inadequate levels may result in severe cytopenia.

Rituximab can be associated with infusion reactions. In addition to administering this within a skilled infusion center, these reactions can be lessened by the use of premedications. There is a risk of hepatitis B reactivation with rituximab such that all patients should be screened for this infection prior to its use.

Tocilizumab is associated with cytopenias, hepatotoxicity, and hyperlipidemia. Laboratory monitoring for drug toxicity should be performed 4–8 weeks after start of therapy and every 3 months thereafter.

TABLE 363-4 Major Toxic Side Effects of Drugs Used in the Treatment of Vasculitis[a]

CONVENTIONAL IMMUNOSUPPRESSIVE AGENTS	
Glucocorticoids	
Osteoporosis	Growth suppression in children
Cataracts	Hypertension
Glaucoma	Avascular necrosis of bone
Diabetes mellitus	Myopathy
Electrolyte abnormalities	Alterations in mood
Metabolic abnormalities	Psychosis
Severe and opportunistic infections	Pseudotumor cerebri
Cushingoid features	Peptic ulcer diathesis
	Pancreatitis
Cyclophosphamide	
Bone marrow suppression	Hypogammaglobulinemia
Cystitis	Pulmonary fibrosis
Bladder carcinoma	Myelodysplasia
Gonadal suppression	Oncogenesis
Gastrointestinal intolerance	Teratogenicity
	Severe and opportunistic infections
Methotrexate	
Gastrointestinal intolerance	Pneumonitis
Stomatitis	Teratogenicity
Bone marrow suppression	Severe and opportunistic infections
Hepatotoxicity (may lead to fibrosis or cirrhosis)	
Azathioprine	
Gastrointestinal intolerance	Severe and opportunistic infections
Bone marrow suppression	Hypersensitivity
Hepatotoxicity	
Mycophenolate mofetil	
Bone marrow suppression	Severe and opportunistic infections
Gastrointestinal intolerance	Teratogenicity
BIOLOGIC AGENTS	
Rituximab (granulomatosis with polyangiitis and microscopic polyangiitis)	
Infusion reactions	Severe and opportunistic infections
Progressive multifocal leuko-encephalopathy	Hepatitis B reactivation
Mucocutaneous reactions	Tumor lysis syndrome
Hypogammaglobulinemia	Late-onset neutropenia
Tocilizumab (giant cell arteritis)	
Bone marrow suppression	Severe and opportunistic infections
Hepatotoxicity	Gastrointestinal perforation
Hyperlipidemia	Hypersensitivity reactions
Mepolizumab (eosinophilic granulomatosis with polyangiitis [Churg-Strauss])	
Hypersensitivity reactions	Opportunistic infections: herpes zoster
Apremilast (Behçet's disease; see Chap. 364)	
Diarrhea, nausea, and vomiting	Weight decrease
Depression	

[a]Consult the drug package insert for a full listing of side effects.

Infection represents a significant toxicity for all vasculitis patients treated with immunosuppressive therapy. Infections with *Pneumocystis jirovecii* and certain fungi can be seen even in the face of WBCs that are within normal limits, particularly in patients receiving glucocorticoids. All vasculitis patients who are receiving daily glucocorticoids in combination with another immunosuppressive

agent should receive trimethoprim-sulfamethoxazole (TMP-SMX) or another prophylactic therapy to prevent *P. jirovecii* infection.

In recent years, national and regional organizations have published treatment guidelines that can provide additional direction to clinicians. It should be emphasized that each patient is unique and requires individual decision-making. Information provided through guideline documents as well as this chapter should serve as a framework for the application of evidence-based approaches; however, flexibility should be practiced to provide maximal therapeutic efficacy with minimal toxic side effects in each patient.

GRANULOMATOSIS WITH POLYANGIITIS

DEFINITION

Granulomatosis with polyangiitis is a distinct clinicopathologic entity characterized by granulomatous vasculitis of the upper and lower respiratory tracts together with glomerulonephritis. In addition, variable degrees of disseminated vasculitis involving both small arteries and veins may occur.

INCIDENCE AND PREVALENCE

Granulomatosis with polyangiitis is an uncommon disease with an estimated prevalence of 3 per 100,000. It is extremely rare in blacks compared with whites; the male-to-female ratio is 1:1. The disease can be seen at any age; ~15% of patients are <19 years of age, but only rarely does the disease occur before adolescence; the mean age of onset is ~40 years.

PATHOLOGY AND PATHOGENESIS

The histopathologic hallmarks of granulomatosis with polyangiitis are necrotizing vasculitis of small arteries and veins together with granuloma formation, which may be either intravascular or extravascular **(Fig. 363-2)**. Lung involvement typically appears as multiple, bilateral, nodular cavitary infiltrates **(Fig. 363-3)**, which on biopsy can reveal necrotizing granulomatous vasculitis. Upper airway lesions, particularly those in the sinuses and nasopharynx, typically reveal inflammation, necrosis, and granuloma formation, with or without vasculitis.

In its earliest form, renal involvement is characterized by a focal and segmental glomerulitis that may evolve into a rapidly progressive crescentic glomerulonephritis. Granuloma formation is only rarely seen on renal biopsy. In contrast to other forms of glomerulonephritis, evidence of immune complex deposition is not found in the renal lesion of granulomatosis with polyangiitis. In addition to the classic triad of disease of the upper and lower respiratory tracts and kidney, virtually any organ can be involved with vasculitis, granuloma, or both.

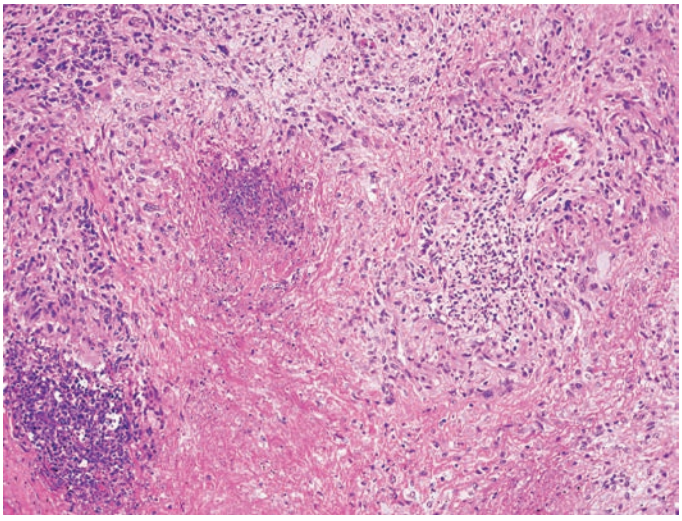

FIGURE 363-2 Lung histology in granulomatosis with polyangiitis. This area of geographic necrosis has a serpiginous border of histiocytes and giant cells surrounding a central necrotic zone. Vasculitis is also present with neutrophils and lymphocytes infiltrating the wall of a small arteriole (*upper right*). *(Courtesy of William D. Travis, MD; with permission.)*

FIGURE 363-3 Computed tomography scan of a patient with granulomatosis with polyangiitis. The patient developed multiple, bilateral, and cavitary infiltrates.

The immunopathogenesis of this disease is unclear, although the involvement of upper airways and lungs with granulomatous vasculitis suggests an aberrant cell-mediated immune response to an exogenous or even endogenous antigen that enters through or resides in the upper airway. Chronic nasal carriage of *Staphylococcus aureus* has been reported to be associated with a higher relapse rate of granulomatosis with polyangiitis; however, there is no evidence for a role of this organism in the pathogenesis of the disease.

Peripheral blood mononuclear cells obtained from patients with granulomatosis with polyangiitis manifest increased secretion of IFN-γ but not of IL-4, IL-5, or IL-10 compared to normal controls. In addition, TNF-α production from peripheral blood mononuclear cells and CD4+ T cells is elevated. Furthermore, monocytes from patients with granulomatosis with polyangiitis produce increased amounts of IL-12. These findings indicate an unbalanced T_H1-type T-cell cytokine pattern in this disease that may have pathogenic and perhaps ultimately therapeutic implications.

A high percentage of patients with granulomatosis with polyangiitis develop ANCA, and these autoantibodies may play a role in the pathogenesis of this disease (see above).

CLINICAL AND LABORATORY MANIFESTATIONS

Involvement of the upper airways occurs in 95% of patients with granulomatosis with polyangiitis. Patients often present with severe upper respiratory tract findings such as paranasal sinus pain and drainage and purulent or bloody nasal discharge, with or without nasal mucosal ulceration **(Table 363-5)**. Nasal septal perforation may follow, leading to saddle nose deformity. Serous otitis media may occur as a result of eustachian tube blockage. Subglottic stenosis resulting from active disease or scarring occurs in ~16% of patients and may result in severe airway obstruction.

Pulmonary involvement (85–90% of patients) may be clinically expressed as cough, hemoptysis, dyspnea, and chest discomfort, or active disease may be asymptomatic in up to 30% of cases. Endobronchial disease, either in its active form or as a result of fibrous scarring, may lead to obstruction with atelectasis.

Eye involvement (52% of patients) may range from a mild conjunctivitis to dacryocystitis, episcleritis, scleritis, granulomatous sclerouveitis, ciliary vessel vasculitis, and retroorbital mass lesions leading to proptosis.

Skin lesions (46% of patients) appear as papules, vesicles, palpable purpura, ulcers, or subcutaneous nodules; biopsy reveals vasculitis, granuloma, or both. Cardiac involvement (8% of patients) manifests as pericarditis, coronary vasculitis, or, rarely, cardiomyopathy. Nervous system manifestations (23% of patients) include cranial neuritis, mononeuritis multiplex, or, rarely, cerebral vasculitis and/or granuloma.

Renal disease (77% of patients) generally dominates the clinical picture and, if left untreated, accounts directly or indirectly for most of the mortality rate in this disease. Although it may smolder in some cases as a mild glomerulitis with proteinuria, hematuria, and red blood cell casts, it is clear that once clinically detectable renal functional

impairment occurs, rapidly progressive renal failure usually ensues unless appropriate treatment is instituted.

While the disease is active, most patients have nonspecific symptoms and signs such as malaise, weakness, arthralgias, anorexia, and weight loss. Fever may indicate activity of the underlying disease but more often reflects secondary infection, usually of the upper airway.

Characteristic laboratory findings include an elevated erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP), mild anemia and leukocytosis, mild hypergammaglobulinemia (particularly of the IgA class), and mildly elevated rheumatoid factor. Thrombocytosis may be seen as an acute-phase reactant. Approximately 90% of patients with active granulomatosis with polyangiitis have a positive antiproteinase-3 ANCA. However, in the absence of active disease, the sensitivity drops to ~60–70%. A small percentage of patients with granulomatosis with polyangiitis may have antimyeloperoxidase rather than antiproteinase-3 antibodies, and up to 20% may lack ANCA.

Patients with granulomatosis with polyangiitis have been found to have an increased incidence of venous thrombotic events. Although routine anticoagulation for all patients is not recommended, a heightened awareness for any clinical features suggestive of deep-vein thrombosis or pulmonary emboli is warranted.

DIAGNOSIS

The diagnosis of granulomatosis with polyangiitis can be established by the demonstration of necrotizing granulomatous vasculitis on tissue biopsy in a patient with compatible clinical features. Pulmonary tissue offers the highest diagnostic yield, almost invariably revealing granulomatous vasculitis. Biopsy of upper airway tissue usually reveals granulomatous inflammation with necrosis but may not show vasculitis. Renal biopsy can confirm the presence of pauci-immune glomerulonephritis.

The specificity of a positive antiproteinase-3 ANCA for granulomatosis with polyangiitis is very high, especially if active glomerulonephritis is present. However, the presence of ANCA should be viewed as adjunctive with tissue diagnosis being pursued when clinically inconsistent features are present or when ANCA is absent. False-positive ANCA has been reported in certain infectious and neoplastic diseases.

In its typical presentation, the clinicopathologic complex of granulomatosis with polyangiitis usually provides ready differentiation from other disorders. However, if all the typical features are not present at once, it needs to be differentiated from the other vasculitides, antiglomerular basement membrane disease (Goodpasture's syndrome) **(Chap. 314)**, relapsing polychondritis **(Chap. 366)**, tumors of the upper airway or lung, and infectious diseases such as histoplasmosis **(Chap. 212)**, endocarditis **(Chap. 128)**, mucocutaneous leishmaniasis **(Chap. 226)**, and rhinoscleroma **(Chap. 218)** as well as noninfectious granulomatous diseases.

Of particular note is the differentiation from other *midline destructive diseases*. These diseases lead to extreme tissue destruction and mutilation localized to the midline upper airway structures including the sinuses; erosion through the skin of the face commonly occurs, a feature that is extremely rare in granulomatosis with polyangiitis. Although blood vessels may be involved in the intense inflammatory reaction and necrosis, primary vasculitis is not seen. *Upper airway neoplasms* and specifically *extranodal natural killer (NK)/T-cell lymphoma (nasal type)* are important causes of midline destructive disease. These lesions are diagnosed based on histology, which reveals polymorphous atypical lymphoid cells with an NK cell immunophenotype, typically Epstein-Barr virus **(Chap. 194)**. Such cases are treated based on their degree of dissemination, and localized lesions have responded to irradiation. Upper airway lesions should never be irradiated in granulomatosis with polyangiitis. Cocaine-induced tissue injury can be another important mimic of granulomatosis with polyangiitis in patients who present with isolated midline destructive disease. ANCA that target human neutrophil elastase can be found in patients with cocaine-induced midline destructive lesions and can complicate the differentiation from granulomatosis with polyangiitis. This has been further confounded by the high frequency of levamisole adulteration of cocaine, which can result in cutaneous infarction and serologic changes that may mimic vasculitis. Granulocytopenia is a common finding in levamisole-induced disease that would not be associated with granulomatosis with polyangiitis.

Granulomatosis with polyangiitis must also be differentiated from *lymphomatoid granulomatosis*, which is an Epstein-Barr virus–positive B-cell proliferation that is associated with an exuberant T-cell reaction. Lymphomatoid granulomatosis is characterized by lung, skin, CNS, and kidney involvement in which atypical lymphocytoid and plasmacytoid cells infiltrate nonlymphoid tissue in an angioinvasive manner. In this regard, it clearly differs from granulomatosis with polyangiitis in that it is not an inflammatory vasculitis in the classic sense but an angiocentric perivascular infiltration of atypical mononuclear cells. Up to 50% of patients may develop a true malignant lymphoma.

TREATMENT

Granulomatosis with Polyangiitis

Prior to the introduction of effective therapy, granulomatosis with polyangiitis was universally fatal within a few months of diagnosis. Glucocorticoids alone led to some symptomatic improvement, with little effect on the ultimate course of the disease. The development

of treatment with cyclophosphamide dramatically changed patient outcome such that marked improvement was seen in >90% of patients, complete remission in 75% of patients, and 5-year patient survival was seen in >80%.

Despite the ability to successfully induce remission, 50–70% of remissions are later associated with one or more relapses. The determination of relapse should be based on objective evidence of disease activity, taking care to rule out other features that may have a similar appearance such as infection, medication toxicity, or chronic disease sequelae. Many patients who achieve remission continue to have a positive ANCA for years, and changes in ANCA should not be used as a measure of disease activity. Results from a large prospective study found that increases in ANCA were not associated with relapse and that only 43% of patients relapsed within 1 year of an increase in ANCA levels. Thus, a rise in ANCA by itself is not a harbinger of immediate disease relapse and should not lead to reinstitution or increase in immunosuppressive therapy. Reinduction of remission after relapse is almost always achieved; however, a high percentage of patients ultimately have some degree of damage from irreversible features of their disease, such as varying degrees of renal insufficiency, neurologic impairment, hearing loss, subglottic stenosis, saddle nose deformity, and chronic sinus dysfunction. Patients who developed irreversible renal failure but who achieved subsequent remission have undergone successful renal transplantation.

Treatment of granulomatosis with polyangiitis is currently viewed as having two phases: *induction*, where active disease is put into remission, followed by *maintenance*. The decision regarding which agents to use for induction and maintenance is guided by experience from published data, determination of disease severity, and individual patient factors that include contraindications, relapse history, and comorbidities.

Current induction regimens consist of glucocorticoids plus another immunosuppressive agent. For severe disease, glucocorticoids have historically been given as prednisone 1 mg/kg per day for the first month, followed by gradual tapering on an alternate-day or daily schedule. Recently, use of a reduced-dose glucocorticoid regimen was found to be noninferior to a standard-dose regimen in a randomized trial and was associated with a lower rate of serious infection. For patients with nonsevere disease, use of lower initial glucocorticoid doses can be considered.

In patients presenting with disease that is life-threatening, methylprednisolone 1000 mg daily for 3 days has been used. Adjunctive plasmapheresis was recently found to provide no added benefit in reducing the composite outcome of end-stage renal disease or death. Whether it may still play a role in selected patients with the most fulminant disease remains uncertain.

CYCLOPHOSPHAMIDE INDUCTION FOR SEVERE DISEASE

Daily cyclophosphamide combined with glucocorticoids was the first regimen proven to effectively induce remission and prolong survival. Cyclophosphamide is given in doses of 2 mg/kg per day orally, but because it is renally eliminated, dosage reduction should be considered in patients with renal insufficiency. Although we continue to favor the use of daily cyclophosphamide, some reports have indicated therapeutic success using IV cyclophosphamide. In a randomized trial, IV cyclophosphamide 15 mg/kg, three infusions given every 2 weeks, then every 3 weeks thereafter, was compared to cyclophosphamide 2 mg/kg daily given for 3 months followed by 1.5 mg/kg daily. Although IV cyclophosphamide was found to have a comparable rate of remission with a lower cumulative cyclophosphamide dose and occurrence of leukopenia, the use of a consolidation phase and an insufficient frequency of blood count monitoring may have negatively influenced the results in those who received daily cyclophosphamide. Of note in this study was that relapse occurred in 19% of those who received IV cyclophosphamide as compared to 9% who received daily oral administration.

RITUXIMAB INDUCTION FOR SEVERE DISEASE

Rituximab is a chimeric monoclonal antibody directed against CD20 present on normal and malignant B lymphocytes that is U.S. Food and Drug Administration (FDA) approved for the treatment of granulomatosis with polyangiitis and microscopic polyangiitis. In two randomized trials that enrolled ANCA-positive patients with severe active granulomatosis with polyangiitis or microscopic polyangiitis, rituximab 375 mg/m^2 once a week for 4 weeks in combination with glucocorticoids was found to be as effective as cyclophosphamide with glucocorticoids for inducing disease remission. In the trial that also enrolled patients with relapsing disease, rituximab was found to be statistically superior to cyclophosphamide. Although rituximab does not have the bladder toxicity or infertility concerns, as can occur with cyclophosphamide, in both of the randomized trials, the rate of adverse events was similar in the rituximab and cyclophosphamide arms.

The decision about whether to utilize cyclophosphamide or rituximab for remission induction must be individually based. Factors to consider include the severity of the disease, whether the patient has newly diagnosed or relapsing disease, medication contraindications, and individual patient factors particularly including fertility concerns. In patients with rapidly progressive glomerulonephritis with a creatinine >4.0 mg/dL or pulmonary hemorrhage requiring mechanical ventilation, daily cyclophosphamide and glucocorticoids are favored.

REMISSION MAINTENANCE

When cyclophosphamide is given for induction, it should be stopped after 3–6 months and switched to another agent for remission maintenance. Medications used in this setting with which there has been published experience from randomized trials are rituximab, azathioprine, methotrexate, and mycophenolate mofetil. A lower rate of relapse was seen with rituximab given at 500 mg for two doses followed by 500 mg every 6 months when compared to azathioprine 2 mg/kg per day. In a randomized trial comparing methotrexate to azathioprine for remission maintenance, similar rates of toxicity and relapse were seen. Methotrexate is administered orally or subcutaneously at a starting not to exceed 15 mg/week, which is increased by 2.5 mg every 2 weeks up to a dosage of 20–25 mg/week. In patients who are unable to receive methotrexate or azathioprine or who have experienced relapse on such treatment, mycophenolate mofetil 1000 mg twice a day may also sustain remission, but it is associated with a higher rate of relapse compared to azathioprine.

For patients who receive rituximab for remission induction, a recent randomized trial found that rituximab 1000 mg given every 4 months had a lower rate of relapse compared to azathioprine.

The optimal duration of maintenance therapy is uncertain. With regard to glucocorticoids, it has been unclear whether maintaining patients on prednisone 5 mg/d has greater risks or benefits compared to discontinuation after 6–9 months. Maintenance therapy with azathioprine, methotrexate, or mycophenolate mofetil is usually given for a minimum of 2 years. Because there is evidence that the risk of relapse is higher once maintenance medication has been stopped, the decision is individualized regarding whether to continue treatment or taper these agents over a 6- to 12-month period until discontinuation. Patients with significant organ damage or a history of relapse may benefit from longer-term maintenance therapy. Although rituximab has been found to have a lower relapse rate, its long-term safety remains uncertain such that the decision for how long to continue this agent beyond 2 years must be weighed in each patient.

REMISSION INDUCTION OF NONSEVERE DISEASE

For patients whose disease is not immediately organ- or life-threatening, methotrexate or mycophenolate mofetil together with glucocorticoids may be given to induce and then maintain remission. Treatment with cyclophosphamide is rarely if ever justified for the treatment of nonsevere granulomatosis with polyangiitis.

OTHER BIOLOGIC AGENTS AND SMALL MOLECULE INHIBITORS

Abatacept (CTLA4-Ig) was examined in an open-label pilot study of nonsevere relapsing disease with favorable results, but further investigation is needed before application to clinical practice. Etanercept, a dimeric fusion protein containing the 75-kDa TNF

receptor bound to human IgG1, was not found to sustain remission when used adjunctively to standard therapy and should not be used in the treatment of granulomatosis with polyangiitis. Belimumab (anti-B lymphocyte stimulator) was examined as an adjunctive therapy to azathioprine for remission maintenance but showed no added benefit in reducing the risk of relapse.

Avacopan (a C5a receptor inhibitor) was recently investigated in a randomized trial as an alternative to glucocorticoids in patients receiving induction with either cyclophosphamide or rituximab. At 52 weeks, sustained remission was higher in those who received avacopan as compared to prednisone with a similar rate of serious adverse events. Although glucocorticoids were given within the first few weeks to some patients receiving avacopan, glucocorticoid exposure remained markedly less than those randomized to the prednisone treatment arm. Based on these findings, avacopan holds promise in being able to reduce the need for glucocorticoids in the treatment of ANCA-associated vasculitis.

TRIMETHOPRIM-SULFAMETHOXAZOLE

Although certain reports have indicated that TMP-SMX may be of benefit in the treatment of granulomatosis with polyangiitis isolated to the sinonasal tissues, it should never be used alone to treat active granulomatosis with polyangiitis involving other organs. In a study examining the effect of TMP-SMX on relapse, decreased relapses were shown only with regard to upper airway disease, and no differences in major organ relapses were observed.

ORGAN-SPECIFIC TREATMENT

Not all manifestations of granulomatosis with polyangiitis require or respond to immunosuppressive therapy, and differentiation of active disease from damage is necessary. As sinus disease can disrupt the mucociliary barrier, patients should be instructed on the use of local care with moisturization and humidification. Subglottic stenosis can often scar and responds optimally to nonmedical intervention with dilation and glucocorticoid injection.

MICROSCOPIC POLYANGIITIS

DEFINITION

The term *microscopic polyarteritis* was introduced into the literature by Davson in 1948 in recognition of the presence of glomerulonephritis in patients with polyarteritis nodosa. In 1992, the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis adopted the term *microscopic polyangiitis* to connote a necrotizing vasculitis with few or no immune complexes affecting small vessels (capillaries, venules, or arterioles). Glomerulonephritis is very common in microscopic polyangiitis, and pulmonary capillaritis often occurs. The absence of granulomatous inflammation in microscopic polyangiitis is said to differentiate it from granulomatosis with polyangiitis.

INCIDENCE AND PREVALENCE

The incidence of microscopic polyangiitis is estimated to be 3–5/100,000. The mean age of onset is ~57 years, and males are slightly more frequently affected than females.

PATHOLOGY AND PATHOGENESIS

Microscopic polyangiitis has a predilection to involve capillaries and venules in addition to small- and medium-sized arteries. Immunohistochemical staining reveals a paucity of immunoglobulin deposition in the vascular lesion of microscopic polyangiitis, suggesting that immune-complex formation does not play a role in the pathogenesis of this syndrome. The renal lesion seen in microscopic polyangiitis is identical to that of granulomatosis with polyangiitis. Like granulomatosis with polyangiitis, microscopic polyangiitis is highly associated with ANCA, which may play a role in pathogenesis of this syndrome (see above).

CLINICAL AND LABORATORY MANIFESTATIONS

Because of its predilection to involve the small vessels, microscopic polyangiitis and granulomatosis with polyangiitis share similar clinical features. Disease onset may be gradual, with initial symptoms of fever, weight loss, and musculoskeletal pain; however, it is often acute. Glomerulonephritis occurs in at least 79% of patients and can be rapidly progressive, leading to renal failure. Hemoptysis may be the first symptom of alveolar hemorrhage, which occurs in 12% of patients. Other manifestations include mononeuritis multiplex and gastrointestinal tract and cutaneous vasculitis. Upper airway disease and pulmonary nodules are not typically found in microscopic polyangiitis and, if present, suggest granulomatosis with polyangiitis.

Features of inflammation may be seen, including an elevated ESR and/or CRP, anemia, leukocytosis, and thrombocytosis. ANCA are present in 75% of patients with microscopic polyangiitis, with antimyeloperoxidase antibodies being the predominant antigen association.

DIAGNOSIS

The diagnosis is based on histologic evidence of vasculitis or pauci-immune glomerulonephritis in a patient with compatible clinical features of multisystem disease. Although microscopic polyangiitis is strongly ANCA-associated, tissue biopsy should continue to be pursued in patients who do not have a clinically compatible picture.

TREATMENT

Microscopic Polyangiitis

The 5-year survival rate for patients with treated microscopic polyangiitis is 74%, with disease-related mortality occurring from alveolar hemorrhage or gastrointestinal, cardiac, or renal disease. Studies on treatment have come from trials that have included patients with granulomatosis with polyangiitis or microscopic polyangiitis. Currently, the treatment approach for microscopic polyangiitis is the same as is used for granulomatosis with polyangiitis (see "Granulomatosis with Polyangiitis" for a detailed description of this therapeutic regimen). Disease relapse has been observed in at least 34% of patients. Treatment for such relapses would be based on site and severity of disease.

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (CHURG-STRAUSS)

DEFINITION

Eosinophilic granulomatosis with polyangiitis (Churg-Strauss) was described in 1951 by Churg and Strauss and is characterized by asthma, peripheral and tissue eosinophilia, extravascular granuloma formation, and vasculitis of multiple organ systems.

INCIDENCE AND PREVALENCE

Eosinophilic granulomatosis with polyangiitis (Churg-Strauss) is an uncommon disease with an estimated annual incidence of 1–3 per million. The disease can occur at any age with the possible exception of infants. The mean age of onset is 48 years, with a female-to-male ratio of 1.2:1.

PATHOLOGY AND PATHOGENESIS

The necrotizing vasculitis of eosinophilic granulomatosis with polyangiitis (Churg-Strauss) involves small- and medium-sized muscular arteries, capillaries, veins, and venules. A characteristic histopathologic feature of eosinophilic granulomatosis with polyangiitis (Churg-Strauss) is granuloma that may be present in the tissues or even within the walls of the vessels themselves. These are usually associated with infiltration of the tissues with eosinophils. This process can occur in any organ in the body; lung involvement is predominant, with skin, cardiovascular system, kidney, peripheral nervous system, and gastrointestinal tract also commonly involved. Although the precise pathogenesis of this disease is uncertain, its strong association with asthma and its clinicopathologic manifestations, including eosinophilia, granuloma, and vasculitis, point to aberrant immunologic phenomena.

CLINICAL AND LABORATORY MANIFESTATIONS

Patients with eosinophilic granulomatosis with polyangiitis (Churg-Strauss) often exhibit nonspecific manifestations such as fever, malaise,

anorexia, and weight loss, which are characteristic of a multisystem disease. The pulmonary findings in eosinophilic granulomatosis with polyangiitis (Churg-Strauss) dominate the clinical picture with severe asthmatic attacks and the presence of pulmonary infiltrates. Mononeuritis multiplex is the second most common manifestation and occurs in up to 72% of patients. Allergic rhinitis and sinusitis develop in up to 61% of patients and are often observed early in the course of disease. Clinically recognizable heart disease with myocarditis, pericarditis, endocarditis, or coronary vasculitis occurs in ~14% of patients and is an important cause of mortality. Skin lesions occur in ~51% of patients and include purpura in addition to cutaneous and subcutaneous nodules. The renal disease in eosinophilic granulomatosis with polyangiitis (Churg-Strauss) is less common and generally less severe than that of granulomatosis with polyangiitis and microscopic polyangiitis.

The characteristic laboratory finding in virtually all patients with eosinophilic granulomatosis with polyangiitis (Churg-Strauss) is a striking eosinophilia, which reaches levels >1000 cells/μL in >80% of patients. Evidence of inflammation as evidenced by elevated ESR and/or CRP, fibrinogen, or α_2-globulins can be found in 81% of patients. The other laboratory findings reflect the organ systems involved. Approximately 48% of patients with eosinophilic granulomatosis with polyangiitis (Churg-Strauss) have circulating ANCA that is usually antimyeloperoxidase.

DIAGNOSIS

Although the diagnosis of eosinophilic granulomatosis with polyangiitis (Churg-Strauss) is optimally made by biopsy in a patient with the characteristic clinical manifestations (see above), histologic confirmation can be challenging because the pathognomonic features often do not occur simultaneously. In order to be diagnosed with eosinophilic granulomatosis with polyangiitis (Churg-Strauss), a patient should have evidence of asthma, peripheral blood eosinophilia, and clinical features consistent with vasculitis.

TREATMENT

Eosinophilic Granulomatosis with Polyangiitis (Churg-Strauss)

The prognosis of untreated eosinophilic granulomatosis with polyangiitis (Churg-Strauss) is poor, with a reported 5-year survival of 25%. With treatment, prognosis is favorable, with one study finding a 78-month actuarial survival rate of 72%. Myocardial involvement is the most frequent cause of death and is responsible for 39% of patient mortality. Echocardiography should be performed in all newly diagnosed patients because this may influence therapeutic decisions.

Glucocorticoids alone appear to be effective in many patients. Dosage tapering is often limited by asthma, and many patients require low-dose prednisone for persistent asthma many years after clinical recovery from vasculitis. In patients who present with fulminant multisystem disease, particularly cardiac involvement, the treatment of choice is a combined regimen of daily cyclophosphamide and prednisone followed by azathioprine or methotrexate (see "Granulomatosis with Polyangiitis" for a detailed description of this therapeutic regimen).

Mepolizumab (anti-IL-5 antibody) 300 mg given subcutaneously once a month was studied in a randomized trial and found to be more effective than placebo. Patients with life-threatening eosinophilic granulomatosis with polyangiitis (Churg-Strauss) were excluded from the mepolizumab trial and should continue to be treated with cyclophosphamide and glucocorticoids. As mepolizumab is FDA approved for both eosinophilic granulomatosis with polyangiitis (Churg-Straus) and severe eosinophilic asthma, it may have a particularly beneficial role in the setting of relapsing or resistant asthma requiring glucocorticoids.

Rituximab has been examined in retrospective series and may have a role in patients with active or relapsing vasculitis despite conventional agents or intolerance of these medications.

POLYARTERITIS NODOSA

DEFINITION

Polyarteritis nodosa was described in 1866 by Kussmaul and Maier. It is a multisystem, necrotizing vasculitis of small- and medium-sized muscular arteries in which involvement of the renal and visceral arteries is characteristic. Polyarteritis nodosa does not involve pulmonary arteries, although bronchial vessels may be involved; granulomas, significant eosinophilia, and an allergic diathesis are not observed.

INCIDENCE AND PREVALENCE

It is difficult to establish an accurate incidence of polyarteritis nodosa because previous reports have included polyarteritis nodosa and microscopic polyangiitis as well as other related vasculitides. Polyarteritis nodosa, as currently defined, is felt to be a very uncommon disease.

PATHOLOGY AND PATHOGENESIS

The vascular lesion in polyarteritis nodosa is a necrotizing inflammation of small- and medium-sized muscular arteries. The lesions are segmental and tend to involve bifurcations and branchings of arteries. They may spread circumferentially to involve adjacent veins. However, involvement of venules is not seen in polyarteritis nodosa and, if present, suggests microscopic polyangiitis (see below). In the acute stages of disease, polymorphonuclear neutrophils infiltrate all layers of the vessel wall and perivascular areas, which results in intimal proliferation and degeneration of the vessel wall. Mononuclear cells infiltrate the area as the lesions progress to the subacute and chronic stages. Fibrinoid necrosis of the vessels ensues with compromise of the lumen, thrombosis, infarction of the tissues supplied by the involved vessel, and, in some cases, hemorrhage. As the lesions heal, there is collagen deposition, which may lead to further occlusion of the vessel lumen. Aneurysmal dilations up to 1 cm in size along the involved arteries are characteristic of polyarteritis nodosa.

Multiple organ systems are involved, and the clinicopathologic findings reflect the degree and location of vessel involvement and the resulting ischemic changes. As mentioned above, pulmonary arteries are not involved in polyarteritis nodosa, and bronchial artery involvement is uncommon. The pathology in the kidney in polyarteritis nodosa is that of arteritis without glomerulonephritis. In patients with significant hypertension, typical pathologic features of glomerulosclerosis may be seen. In addition, pathologic sequelae of hypertension may be found elsewhere in the body.

The presence of a polyarteritis nodosa–like vasculitis in patients with hepatitis B together with the isolation of circulating immune complexes composed of hepatitis B antigen and immunoglobulin and the demonstration by immunofluorescence of hepatitis B antigen, IgM, and complement in the blood vessel walls strongly suggest the role of immunologic phenomena in the pathogenesis of this disease. A polyarteritis nodosa–like vasculitis has also been reported in patients with hepatitis C. Hairy cell leukemia can be associated with polyarteritis nodosa; the pathogenic mechanisms of this association are unclear.

A polyarteritis nodosa–like vasculitis has being described in conjunction with deficiency of adenosine deaminase type 2 (DADA2). Patients with DADA2 usually present in childhood with a variable pattern of clinical features and vascular pathology that is responsive to TNF inhibitors. As this differs from the usual treatment for polyarteritis nodosa, DADA2 should be considered in patients with suggestive clinical features, particularly those with early-onset disease.

CLINICAL AND LABORATORY MANIFESTATIONS

Nonspecific signs and symptoms are the hallmarks of polyarteritis nodosa. Fever, weight loss, and malaise are present in over one-half of cases. Patients usually present with vague symptoms such as weakness, malaise, headache, abdominal pain, and myalgias that can rapidly progress to a fulminant illness. Specific complaints related to the vascular involvement within a particular organ system may also dominate the presenting clinical picture as well as the entire course of the illness

TABLE 363-6 Clinical Manifestations Related to Organ System Involvement in Polyarteritis Nodosa

ORGAN SYSTEM	PERCENT INCIDENCE	CLINICAL MANIFESTATIONS
Renal	60	Renal failure, hypertension
Musculoskeletal	64	Arthritis, arthralgia, myalgia
Peripheral nervous system	51	Peripheral neuropathy, mononeuritis multiplex
Gastrointestinal tract	44	Abdominal pain, nausea and vomiting, bleeding, bowel infarction and perforation, cholecystitis, hepatic infarction, pancreatic infarction
Skin	43	Rash, purpura, nodules, cutaneous infarcts, livedo reticularis, Raynaud's phenomenon
Cardiac	36	Congestive heart failure, myocardial infarction, pericarditis
Genitourinary	25	Testicular, ovarian, or epididymal pain
Central nervous system	23	Cerebral vascular accident, altered mental status, seizure

(Table 363-6). In polyarteritis nodosa, renal involvement most commonly manifests as hypertension, renal insufficiency, or hemorrhage due to microaneurysms.

There are no diagnostic serologic tests for polyarteritis nodosa. In >75% of patients, the leukocyte count is elevated with a predominance of neutrophils. Eosinophilia is seen only rarely and, when present at high levels, suggests the diagnosis of eosinophilic granulomatosis with polyangiitis (Churg-Strauss). The anemia of chronic disease may be seen, and an elevated ESR and/or CRP is almost always present. Other common laboratory findings reflect the particular organ involved. Hypergammaglobulinemia may be present, and all patients should be screened for hepatitis B and C. ANCA are rarely found in patients with polyarteritis nodosa.

DIAGNOSIS

The diagnosis of polyarteritis nodosa is based on the demonstration of characteristic findings of vasculitis on biopsy material of involved organs. Biopsy of symptomatic organs such as nodular skin lesions, painful testes, and nerve/muscle provides the highest diagnostic yields. In the absence of easily accessible tissue for biopsy, the arteriographic demonstration of involved vessels, particularly in the form of aneurysms of small- and medium-sized arteries in the renal, hepatic, and visceral vasculature, is sufficient to make the diagnosis. This should consist of a catheter-directed dye arteriogram because magnetic resonance and computed tomography arteriograms do not have sufficient resolution at the current time to visualize the vessels affected in polyarteritis nodosa. Aneurysms of vessels are not pathognomonic of polyarteritis nodosa; furthermore, aneurysms need not always be present, and arteriographic findings may be limited to stenotic segments and obliteration of vessels.

TREATMENT

Polyarteritis Nodosa

The prognosis of untreated polyarteritis nodosa is extremely poor, with a reported 5-year survival rate between 10 and 20%. Death usually results from gastrointestinal complications, particularly bowel infarcts and perforation, and cardiovascular causes. Intractable hypertension often compounds dysfunction in other organ systems, such as the kidneys, heart, and CNS, leading to additional late morbidity and mortality in polyarteritis nodosa. The combination of prednisone and cyclophosphamide has been found to significantly improve the survival rate (see "Granulomatosis with Polyangiitis" for a detailed description of this therapeutic regimen). In less severe cases of polyarteritis nodosa, glucocorticoids alone have resulted in disease remission. In patients with hepatitis B or C who have a polyarteritis nodosa–like vasculitis, antiviral therapy represents an important part of management and has been used in combination with glucocorticoids and plasma exchange in some series. Careful attention to the treatment of hypertension can lessen the vascular complications of polyarteritis nodosa. Following successful treatment, relapse of polyarteritis nodosa has been estimated to occur in 10–20% of patients.

GIANT CELL ARTERITIS AND POLYMYALGIA RHEUMATICA

DEFINITION

Giant cell arteritis, historically referred to as *temporal arteritis*, is an inflammation of medium- and large-sized arteries. It characteristically involves one or more branches of the carotid artery, particularly the temporal artery. However, it is a systemic disease that can involve arteries in multiple locations, particularly the aorta and its main branches.

Giant cell arteritis is closely associated with *polymyalgia rheumatica*, which is characterized by stiffness, aching, and pain in the muscles of the neck, shoulders, lower back, hips, and thighs. Most commonly, polymyalgia rheumatica occurs in isolation, but it may be seen in 40–50% of patients with giant cell arteritis. In addition, ~10–20% of patients who initially present with features of isolated polymyalgia rheumatica later go on to develop giant cell arteritis. This strong clinical association together with data from pathophysiologic studies has increasingly supported that giant cell arteritis and polymyalgia rheumatica represent differing clinical spectrums of a single disease process.

INCIDENCE AND PREVALENCE

Giant cell arteritis occurs almost exclusively in individuals aged >50 years. It is more common in women than in men and is rare in blacks. The incidence of giant cell arteritis varies widely in different studies and in different geographic regions. A high incidence has been found in Scandinavia and in regions of the United States with large Scandinavian populations, compared to a lower incidence in southern Europe. The annual incidence rates in individuals aged ≥50 years range from 6.9 to 32.8 per 100,000 population. Familial aggregation has been reported, as has an association with HLA-DR4. In addition, genetic linkage studies have demonstrated an association of giant cell arteritis with alleles at the HLA-DRB1 locus, particularly HLA-DRB1*04 variants. In Olmsted County, Minnesota, the annual incidence of polymyalgia rheumatica in individuals aged ≥50 years is 58.7 per 100,000 population.

PATHOLOGY AND PATHOGENESIS

Although the temporal artery is most frequently involved in giant cell arteritis, patients often have a systemic vasculitis of multiple medium- and large-sized arteries, which may go undetected. Histopathologically, the disease is a panarteritis with inflammatory mononuclear cell infiltrates within the vessel wall with frequent giant cell formation. There is proliferation of the intima and fragmentation of the internal elastic lamina. Pathophysiologic findings in organs result from the ischemia related to the involved vessels.

Experimental data support that giant cell arteritis is an antigen-driven disease in which activated T lymphocytes, macrophages, and dendritic cells play a critical role in pathogenesis. Sequence analysis of the T-cell receptor of tissue-infiltrating T cells in lesions of giant cell arteritis indicates restricted clonal expansion, suggesting the presence of an antigen residing in the arterial wall. Giant cell arteritis is believed to be initiated in the adventitia where CD4+ T cells enter through the vasa vasorum, become activated, and orchestrate macrophage differentiation. T cells recruited to vasculitic lesions in patients with giant cell arteritis produce predominantly IL-2 and IFN-γ, and the latter has been suggested to be involved in the progression to arteritis. Laboratory-based data demonstrate that at least two separate lineages of CD4

T cells—IFN-γ-producing T_H1 cells and IL-17-producing T_H17 cells—participate in vascular inflammation and may have differing levels of responsiveness to glucocorticoids.

CLINICAL AND LABORATORY MANIFESTATIONS

Giant cell arteritis is most commonly characterized clinically by the complex of fever, anemia, high ESR and/or CRP, and headaches in a patient aged >50 years. Other phenotypic manifestations include features of systemic inflammation, including malaise, fatigue, anorexia, weight loss, sweats, arthralgias, polymyalgia rheumatica, or large-vessel disease.

In patients with involvement of the cranial arteries, headache is the predominant symptom and may be associated with a tender, thickened, or nodular artery, which may pulsate early in the disease but may become occluded later. Scalp pain and claudication of the jaw and tongue may occur. A well-recognized and dreaded complication of giant cell arteritis, particularly in untreated patients, is ischemic optic neuropathy, which may lead to serious visual symptoms, including sudden blindness in some patients. However, most patients have complaints relating to the head or eyes before visual loss. Attention to such symptoms with institution of appropriate therapy (see below) lessens the risk of this complication. Other cranial ischemic complications include strokes and scalp or tongue infarction.

Up to one-third of patients can have large-vessel disease that can be the primary presentation of giant cell arteritis or can emerge at a later point in patients who have had previous cranial arteritis features or polymyalgia rheumatica. Manifestations of large-vessel disease can include subclavian artery stenosis that can present as arm claudication or aortic aneurysms involving the thoracic and to a lesser degree the abdominal aorta, which carry risks of rupture or dissection.

Characteristic laboratory findings in addition to the elevated ESR and/or CRP include a normochromic or slightly hypochromic anemia. Liver function abnormalities are common, particularly increased alkaline phosphatase levels. Increased levels of IgG and complement have been reported.

DIAGNOSIS

The diagnosis of giant cell arteritis can often be suggested clinically by the demonstration of the complex of fever, anemia, and high ESR and/or CRP with or without symptoms of polymyalgia rheumatica in a patient >50 years old. The diagnosis can be confirmed by biopsy of the temporal artery but may not be positive in all patients due to patchy histologic findings. Since involvement of the vessel may be segmental, positive yield is increased by obtaining a biopsy segment of 3–5 cm together with serial sectioning of biopsy specimens. Ultrasonography of the temporal artery has been reported to be helpful in diagnosis and has been increasingly used by some physicians. Therapy should not be delayed pending the performance of diagnostic studies. In this regard, it has been reported that temporal artery biopsies may show vasculitis even after ~14 days of glucocorticoid therapy. A dramatic clinical response to a trial of glucocorticoid therapy can further support the diagnosis.

Large-vessel disease may be suggested by symptoms and findings on physical examination such as diminished pulses or bruits. It is confirmed by vascular imaging, most commonly through magnetic resonance or computed tomography. Positron emission tomography has become increasingly investigated, although its role in diagnosis and monitoring remains unclear.

Isolated polymyalgia rheumatica is a clinical diagnosis made by the presence of typical symptoms of stiffness, aching, and pain in the muscles of the hip and shoulder girdle, an increased ESR and/or CRP, the absence of clinical features suggestive of giant cell arteritis, and a prompt therapeutic response to low-dose prednisone. Polymyalgia rheumatica can be associated with a peripheral arthritis that can mimic rheumatoid arthritis (Chap. 358). Rheumatoid factor and anti-cyclic citrullinated peptide (CCP) shoulder be negative. In patients who develop a worsening pattern of peripheral arthritis, the potential for a seronegative rheumatoid arthritis or other inflammatory arthropathy should be considered. Levels of enzymes indicative of muscle damage such as serum creatine kinase are not elevated.

TREATMENT

Giant Cell Arteritis and Polymyalgia Rheumatica

Acute disease–related mortality directly from giant cell arteritis is uncommon, with fatalities occurring from cerebrovascular events or myocardial infarction. However, patients are at risk of late mortality from aortic aneurysm rupture or dissection as patients with giant cell arteritis are 18 times more likely to develop thoracic aortic aneurysms than the general population.

The goals of treatment in giant cell arteritis are to reduce symptoms and, most importantly, to prevent visual loss. The treatment approach for cranial and large-vessel disease in giant cell arteritis is currently the same. Giant cell arteritis and its associated symptoms are responsive to glucocorticoid therapy. Treatment should begin with prednisone 40–60 mg/d for ~1 month, followed by a gradual tapering. When ocular signs and symptoms occur, consideration should be given for the use of methylprednisolone 1000 mg daily for 3 days to protect remaining vision. Although the optimal duration of glucocorticoid therapy has not been established, most series have found that patients require treatment for ≥2 years. Symptom recurrence during prednisone tapering develops in 60–85% of patients with giant cell arteritis, requiring a dosage increase. The ESR and/or CRP can serve as a useful indicator of inflammatory disease activity in monitoring and tapering therapy and can be used to judge the pace of the tapering schedule. However, minor increases in the ESR and/or CRP can occur as glucocorticoids are being tapered and do not necessarily reflect an exacerbation of arteritis, particularly if the patient remains symptom-free. Under these circumstances, the tapering should continue with caution. Glucocorticoid toxicity occurs in 35–65% of patients and represents an important cause of patient morbidity.

Tocilizumab (anti-IL-6 receptor) was found to be effective in giant cell arteritis in a randomized trial and is FDA approved for this indication. The recommended dose of tocilizumab is 162 mg given subcutaneously once every week or once every other week in combination with a tapering course of glucocorticoids. The decision about when to use tocilizumab in giant cell arteritis is individually based, taking into account patient comorbidities, potential for glucocorticoid toxicity, and the side effects of tocilizumab. By nature of its mechanism of action, tocilizumab impacts laboratory parameters of ESR and CRP, which will eliminate the ability to utilize these in disease activity assessment.

The use of methotrexate as a glucocorticoid-sparing agent has been examined in two randomized placebo-controlled trials that reached conflicting conclusions. It may be considered in select patients with glucocorticoid toxicity who are unable to take or intolerant of tocilizumab.

Abatacept (CTLA4-Ig) was examined in a small randomized trial in giant cell arteritis and demonstrated greater efficacy than glucocorticoids alone. Infliximab, a monoclonal antibody to TNF, was studied in a randomized trial and was not found to provide benefit.

Aspirin 81 mg daily has been found to reduce the occurrence of cranial ischemic complications in giant cell arteritis and should be given in addition to glucocorticoids in patients who do not have contraindications.

Patients with isolated polymyalgia rheumatica respond promptly to prednisone, which can be started at a lower dose of 10–20 mg/d. Similar to giant cell arteritis, the ESR and/or CRP can serve as a useful indicator in monitoring and prednisone reduction. Recurrent polymyalgia symptoms develop in the majority of patients during prednisone tapering. One study of methotrexate found that the use of this drug reduced the prednisone dose on average by only 1 mg and did not decrease prednisone-related side effects. A randomized trial in polymyalgia rheumatica did not find infliximab to lessen relapse or glucocorticoid requirements.

TAKAYASU ARTERITIS

DEFINITION

Takayasu arteritis is an inflammatory and stenotic disease of medium- and large-sized arteries characterized by a strong predilection for the aortic arch and its branches.

INCIDENCE AND PREVALENCE

Takayasu arteritis is an uncommon disease with an estimated annual incidence rate of 1.2–2.6 cases per million. It is most prevalent in adolescent girls and young women. Although it is more common in Asia, it is neither racially nor geographically restricted.

PATHOLOGY AND PATHOGENESIS

The disease involves medium- and large-sized arteries, with a strong predilection for the aortic arch and its branches; the pulmonary artery may also be involved. The most commonly affected arteries seen by arteriography are listed in Table 363-7. The involvement of the major branches of the aorta is much more marked at their origin than distally. The disease is a panarteritis with inflammatory mononuclear cell infiltrates and occasionally giant cells. There are marked intimal proliferation and fibrosis, scarring and vascularization of the media, and disruption and degeneration of the elastic lamina. Narrowing of the lumen occurs with or without thrombosis. The vasa vasorum are frequently involved. Pathologic changes in various organs reflect the compromise of blood flow through the involved vessels.

Immunopathogenic mechanisms, the precise nature of which is uncertain, are suspected in this disease. As with several of the vasculitis syndromes, circulating immune complexes have been demonstrated, but their pathogenic significance is unclear.

CLINICAL AND LABORATORY MANIFESTATIONS

Takayasu arteritis is a systemic disease with generalized as well as vascular symptoms. The generalized symptoms include malaise, fever, night sweats, arthralgias, anorexia, and weight loss, which may occur months before vessel involvement is apparent. These symptoms may merge into those related to vascular compromise and organ ischemia. Pulses are commonly absent in the involved vessels, particularly the subclavian artery. The frequency of arteriographic abnormalities and the potentially associated clinical manifestations are listed in Table 363-7. Hypertension occurs in 32–93% of patients and contributes to renal, cardiac, and cerebral injury.

Characteristic laboratory findings include an elevated ESR and/or CRP, mild anemia, and elevated immunoglobulin levels.

TABLE 363-7 Frequency of Arteriographic Abnormalities and Potential Clinical Manifestations of Arterial Involvement in Takayasu Arteritis

ARTERY	PERCENTAGE OF ARTERIOGRAPHIC ABNORMALITIES	POTENTIAL CLINICAL MANIFESTATIONS
Subclavian	93	Arm claudication, Raynaud's phenomenon
Common carotid	58	Visual changes, syncope, transient ischemic attacks, stroke
Abdominal aorta[a]	47	Abdominal pain, nausea, vomiting
Renal	38	Hypertension, renal failure
Aortic arch or root	35	Aortic insufficiency, congestive heart failure
Vertebral	35	Visual changes, dizziness
Coeliac axis[a]	18	Abdominal pain, nausea, vomiting
Superior mesenteric[a]	18	Abdominal pain, nausea, vomiting
Iliac	17	Leg claudication
Pulmonary	10–40	Atypical chest pain, dyspnea
Coronary	<10	Chest pain, myocardial infarction

[a]Arteriographic lesions at these locations are usually asymptomatic but may potentially cause these symptoms.

Source: G Kerr et al: Ann Intern Med 120:919, 1994.

DIAGNOSIS

The diagnosis of Takayasu arteritis should be suspected strongly in a young woman who develops a decrease or absence of peripheral pulses, discrepancies in blood pressure, and arterial bruits. The diagnosis is confirmed by the characteristic pattern on arteriography, which includes irregular vessel walls, stenosis, poststenotic dilation, aneurysm formation, occlusion, and evidence of increased collateral circulation. Complete imaging of the aorta and its major branches by magnetic resonance or computed tomography arteriography should be obtained to fully delineate the distribution and degree of arterial disease. Because of the involvement of the large vessels, tissue is rarely available as a means of diagnosis and obtained only if vascular surgery is necessary. IgG4-related disease (Chap. 368) is a potential cause of aortitis and periaortitis that is histologically differentiated from Takayasu arteritis by a dense lymphoplasmacytic infiltrate rich in IgG4-positive plasma cells, a storiform pattern of fibrosis, and obliterative phlebitis.

TREATMENT

Takayasu Arteritis

The long-term outcome of patients with Takayasu arteritis has varied widely between studies. Although two North American reports found overall survival to be ≥94%, the 5-year mortality rate from other studies has ranged from 0 to 35%. Disease-related mortality most often occurs from congestive heart failure, cerebrovascular events, myocardial infarction, aneurysm rupture, or renal failure. Even in the absence of life-threatening disease, Takayasu arteritis can be associated with significant morbidity. The course of the disease is variable, and although spontaneous remissions may occur, Takayasu arteritis is most often chronic and relapsing. Although glucocorticoid therapy in doses of 40–60 mg prednisone per day alleviates symptoms, there are no convincing studies that indicate that it increases survival. The combination of glucocorticoid therapy for acute signs and symptoms and an aggressive surgical and/or arterioplastic approach to stenosed vessels has markedly improved outcome and decreased morbidity by lessening the risk of stroke, correcting hypertension due to renal artery stenosis, and improving blood flow to ischemic viscera and limbs. Unless it is urgently required, surgical correction of stenosed arteries should be undertaken only when the vascular inflammatory process is well controlled with medical therapy.

In individuals who are refractory to or unable to taper glucocorticoids, methotrexate in doses up to 25 mg per week has yielded encouraging results. Results from retrospective series with anti-TNF therapies have been encouraging, but these agents have not been studied through randomized trials to determine efficacy.

Abatacept was examined in the first randomized trial to be conducted in Takayasu arteritis but did not demonstrate efficacy beyond glucocorticoids alone. Tocilizumab has been investigated in a randomized trial where it did not reach its primary efficacy endpoint. In this study, it was found to have secondary benefits and encouraging results have also been seen in retrospective studies such that the utility of this agent remains an active question.

IgA VASCULITIS (HENOCH-SCHÖNLEIN)

DEFINITION

IgA vasculitis (Henoch-Schönlein) is a small-vessel vasculitis characterized by palpable purpura (most commonly distributed over the buttocks and lower extremities), arthralgias, gastrointestinal signs and symptoms, and glomerulonephritis.

INCIDENCE AND PREVALENCE

IgA vasculitis (Henoch-Schönlein) is usually seen in children ages 4–7 years; however, the disease may also be seen in infants and adults. It is not a rare disease; in one series, it accounted for between 5 and 24 admissions per year at a pediatric hospital. The male-to-female ratio is 1.5:1. A seasonal variation with a peak incidence in spring has been noted.

PATHOLOGY AND PATHOGENESIS

The presumptive pathogenic mechanism for IgA (Henoch-Schönlein) vasculitis is immune-complex deposition. A number of inciting antigens have been suggested including upper respiratory tract infections, various drugs, foods, insect bites, and immunizations. IgA is the antibody class most often seen in the immune complexes and has been demonstrated in the renal biopsies of these patients.

CLINICAL AND LABORATORY MANIFESTATIONS

In pediatric patients, palpable purpura is seen in virtually all patients; most patients develop polyarthralgias in the absence of frank arthritis. Gastrointestinal involvement, which is seen in almost 70% of pediatric patients, is characterized by colicky abdominal pain usually associated with nausea, vomiting, diarrhea, or constipation, and is frequently accompanied by the passage of blood and mucus per rectum; bowel intussusception may occur. Renal involvement occurs in 10–50% of patients and is usually characterized by mild glomerulonephritis leading to proteinuria and microscopic hematuria, with red blood cell casts in the majority of patients; it usually resolves spontaneously without therapy. Rarely, a progressive glomerulonephritis will develop. In adults, presenting symptoms are most frequently related to the skin and joints, while initial complaints related to the gut are less common. Although certain studies have found that renal disease is more frequent and more severe in adults, this has not been a consistent finding. However, the course of renal disease in adults may be more insidious and thus requires close follow-up. Myocardial involvement can occur in adults but is rare in children.

Laboratory studies generally show a mild leukocytosis, a normal platelet count, and occasionally eosinophilia. Serum complement components are normal, and IgA levels are elevated in about one-half of patients.

DIAGNOSIS

The diagnosis of IgA vasculitis (Henoch-Schönlein) is based on clinical signs and symptoms. Skin biopsy specimen can be useful in confirming leukocytoclastic vasculitis with IgA and C3 deposition by immunofluorescence. Renal biopsy is rarely needed for diagnosis but may provide prognostic information in some patients.

TREATMENT

IgA Vasculitis (Henoch-Schönlein)

The prognosis of IgA vasculitis (Henoch-Schönlein) is excellent. Mortality is exceedingly rare, and 1–5% of children progress to end-stage renal disease. Most patients recover completely, and some do not require therapy. When glucocorticoids are required, prednisone, 1 mg/kg per day and tapered according to clinical response, has been shown to be useful in decreasing tissue edema, arthralgias, and abdominal discomfort; however, it has not proved beneficial in the treatment of skin or renal disease and does not appear to shorten the duration of active disease or lessen the chance of recurrence. Patients with rapidly progressive glomerulonephritis have been anecdotally reported to benefit from glucocorticoids used in combination with another immunosuppressive agent. Disease recurrences have been reported in 10–40% of patients.

CRYOGLOBULINEMIC VASCULITIS

DEFINITION

Cryoglobulins are cold-precipitable monoclonal or polyclonal immunoglobulins. Cryoglobulinemia may be associated with a systemic vasculitis characterized by palpable purpura, arthralgias, weakness, neuropathy, and glomerulonephritis. The most common association has been with hepatitis C, although cryoglobulinemia can be observed in association with a variety of underlying disorders including multiple myeloma, lymphoproliferative disorders, connective tissue diseases, infection, and liver disease and can be idiopathic.

INCIDENCE AND PREVALENCE

The incidence of cryoglobulinemic vasculitis has not been established. It has been estimated that 5% of patients with chronic hepatitis C will develop cryoglobulinemic vasculitis.

PATHOLOGY AND PATHOGENESIS

Skin biopsies in cryoglobulinemic vasculitis reveal an inflammatory infiltrate surrounding and involving blood vessel walls, with fibrinoid necrosis, endothelial cell hyperplasia, and hemorrhage. Deposition of immunoglobulin and complement is common. Abnormalities of uninvolved skin including basement membrane alterations and deposits in vessel walls may be found. Membranoproliferative glomerulonephritis is responsible for 80% of all renal lesions in cryoglobulinemic vasculitis.

The association between hepatitis C and cryoglobulinemic vasculitis has been supported by the high frequency of documented hepatitis C infection, the presence of hepatitis C RNA and anti–hepatitis C antibodies in serum cryoprecipitates, evidence of hepatitis C antigens in vasculitic skin lesions, and the effectiveness of antiviral therapy. Current evidence suggests that in the majority of cases, cryoglobulinemic vasculitis occurs when an aberrant immune response to hepatitis C infection leads to the formation of immune complexes consisting of hepatitis C antigens, polyclonal hepatitis C–specific IgG, and monoclonal IgM rheumatoid factor. The deposition of these immune complexes in blood vessel walls triggers an inflammatory cascade that results in cryoglobulinemic vasculitis.

CLINICAL AND LABORATORY MANIFESTATIONS

The most common clinical manifestations of cryoglobulinemic vasculitis are cutaneous vasculitis, arthritis, peripheral neuropathy, and glomerulonephritis. Renal disease develops in 10–30% of patients. Life-threatening rapidly progressive glomerulonephritis or vasculitis of the CNS, gastrointestinal tract, or heart occurs infrequently.

The presence of circulating cryoprecipitates is the fundamental finding in cryoglobulinemic vasculitis. Rheumatoid factor is almost always found and may be a useful clue to the disease when cryoglobulins are not detected. Hypocomplementemia occurs in 90% of patients. An elevated ESR and/or CRP and anemia occur frequently. Evidence for hepatitis C infection must be sought in all patients by testing for hepatitis C antibodies and hepatitis C RNA.

TREATMENT

Cryoglobulinemic Vasculitis

Acute mortality directly from cryoglobulinemic vasculitis is uncommon, but the presence of glomerulonephritis is a poor prognostic sign for overall outcome. In such patients, 15% progress to end-stage renal disease, with 40% later experiencing fatal cardiovascular disease, infection, or liver failure. As indicated above, the majority of cases are associated with hepatitis C infection. In such patients, treatment with antiviral therapy (Chap. 341) is first-line therapy for hepatitis C–associated cryoglobulinemic vasculitis, particularly given the efficacy of current hepatitis C therapies. Clinical improvement with antiviral therapy is dependent on the virologic response. Patients who clear hepatitis C from the blood have objective improvement in their vasculitis along with significant reductions in levels of circulating cryoglobulins, IgM, and rheumatoid factor. While transient improvement can be observed with glucocorticoids, a complete response is seen in only 7% of patients. Plasmapheresis and cytotoxic agents have been used in anecdotal reports. These observations have not been confirmed, and such therapies carry significant risks. Randomized trials with rituximab in hepatitis C–associated cryoglobulinemic vasculitis have provided evidence of benefit such that this agent should be considered in patients with active vasculitis either in combination with antiviral therapy or alone in patients who have relapsed through, are intolerant to, or have contraindications to antiviral agents.

SINGLE-ORGAN VASCULITIS

Single-organ vasculitis has been defined as vasculitis in arteries or veins of any size in a single organ that has no features that indicate that it is a limited expression of a systemic vasculitis. Examples include isolated aortitis, testicular vasculitis, vasculitis of the breast, isolated cutaneous vasculitis, and primary CNS vasculitis. In some instances, this may be discovered at the time of surgery such as orchiectomy for a testicular mass where there is concern for neoplasm that is found instead to be vasculitis. Some patients originally diagnosed with single-organ vasculitis may later develop additional manifestations of a more systemic disease. In instances where there is no evidence of systemic vasculitis and the affected organ has been removed in its entirety, the patient may be followed closely without immunosuppressive therapy. In other instances, such as primary CNS vasculitis or some patients with isolated cutaneous vasculitis, medical intervention is warranted.

IDIOPATHIC CUTANEOUS VASCULITIS

DEFINITION

The term *cutaneous vasculitis* is defined broadly as inflammation of the blood vessels of the dermis. Because of its heterogeneity, cutaneous vasculitis has been described by a variety of terms including *hypersensitivity vasculitis* and *cutaneous leukocytoclastic angiitis*. However, cutaneous vasculitis is not one specific disease but a manifestation that can be seen in a variety of settings. In >70% of cases, cutaneous vasculitis occurs either as part of a primary systemic vasculitis or as a secondary vasculitis related to an inciting agent or an underlying disease (see "Secondary Vasculitis," below). In the remaining 30% of cases, cutaneous vasculitis occurs idiopathically.

INCIDENCE AND PREVALENCE

Cutaneous vasculitis represents the most commonly encountered vasculitis in clinical practice. The exact incidence of idiopathic cutaneous vasculitis has not been determined due to the predilection for cutaneous vasculitis to be associated with an underlying process and the variability of its clinical course.

PATHOLOGY AND PATHOGENESIS

The typical histopathologic feature of cutaneous vasculitis is the presence of vasculitis of small vessels. Postcapillary venules are the most commonly involved vessels; capillaries and arterioles may be involved less frequently. This vasculitis is characterized by a *leukocytoclasis*, a term that refers to the nuclear debris remaining from the neutrophils that have infiltrated in and around the vessels during the acute stages. In the subacute or chronic stages, mononuclear cells predominate; in certain subgroups, eosinophilic infiltration is seen. Erythrocytes often extravasate from the involved vessels, leading to palpable purpura. *Cutaneous arteritis* can also occur, which involves slightly larger-sized vessels within the dermis.

CLINICAL AND LABORATORY MANIFESTATIONS

The hallmark of idiopathic cutaneous vasculitis is the predominance of skin involvement. Skin lesions may appear typically as palpable purpura; however, other cutaneous manifestations of the vasculitis may occur, including macules, papules, vesicles, bullae, subcutaneous nodules, ulcers, and recurrent or chronic urticaria. The skin lesions may be pruritic or painful, with a burning or stinging sensation. Lesions most commonly occur in the lower extremities in ambulatory patients or in the sacral area in bedridden patients due to the effects of hydrostatic forces on the postcapillary venules. Edema may accompany certain lesions, and hyperpigmentation often occurs in areas of recurrent or chronic lesions.

There are no specific laboratory tests diagnostic of idiopathic cutaneous vasculitis. A mild leukocytosis with or without eosinophilia is characteristic, as is an elevated ESR and/or CRP. Laboratory studies should be aimed toward ruling out features to suggest an underlying disease or a systemic vasculitis.

DIAGNOSIS

The diagnosis of cutaneous vasculitis is made by the demonstration of vasculitis on biopsy. An important diagnostic principle in patients with cutaneous vasculitis is to search for an etiology of the vasculitis—be it an exogenous agent, such as a drug or an infection, or an endogenous condition, such as an underlying disease (Fig. 363-1). In addition, a careful physical and laboratory examination should be performed to rule out the possibility of systemic vasculitis. This should start with the least invasive diagnostic approach and proceed to the more invasive only if clinically indicated.

TREATMENT

Idiopathic Cutaneous Vasculitis

When an antigenic stimulus is recognized as the precipitating factor in the cutaneous vasculitis, it should be removed; if this is a microbe, appropriate antimicrobial therapy should be instituted. If the vasculitis is associated with another underlying disease, treatment of the latter often results in resolution of the former. In situations where disease is apparently self-limited, no therapy, except possibly symptomatic therapy, is indicated. When cutaneous vasculitis persists and when there is no evidence of an inciting agent, an associated disease, or an underlying systemic vasculitis, the decision to treat should be based on weighing the balance between the degree of symptoms and the risk of treatment. Some cases of idiopathic cutaneous vasculitis resolve spontaneously, whereas others remit and relapse. In patients with persistent vasculitis, a variety of therapeutic regimens have been tried with variable results. In general, the treatment of idiopathic cutaneous vasculitis has not been satisfactory. Fortunately, since the disease is generally limited to the skin, this lack of consistent response to therapy usually does not lead to a life-threatening situation. Agents with which there have been anecdotal reports of success include dapsone, colchicine, hydroxychloroquine, and nonsteroidal anti-inflammatory agents. Glucocorticoids are often used in the treatment of idiopathic cutaneous vasculitis. Therapy is usually instituted as prednisone 1 mg/kg per day, with rapid tapering where possible, either directly to discontinuation or by conversion to an alternate-day regimen followed by ultimate discontinuation. In cases that prove refractory to glucocorticoids, a trial of another immunosuppressive agent may be indicated. Patients with chronic vasculitis isolated to cutaneous venules rarely respond dramatically to any therapeutic regimen, and cytotoxic agents should be used only as a last resort in these patients. Methotrexate and azathioprine have been used in such situations in anecdotal reports. Although cyclophosphamide is the most effective therapy for the systemic vasculitides, it should almost never be used for idiopathic cutaneous vasculitis because of the potential toxicity.

PRIMARY CENTRAL NERVOUS SYSTEM VASCULITIS

Primary CNS vasculitis is an uncommon clinicopathologic entity characterized by vasculitis restricted to the vessels of the CNS without other apparent systemic vasculitis. The inflammatory process is usually composed of mononuclear cell infiltrates with or without granuloma formation.

Patients may present with headaches, altered mental function, and focal neurologic defects. Systemic symptoms are generally absent. Devastating neurologic abnormalities may occur depending on the extent of vessel involvement. The diagnosis can be suggested by abnormal magnetic resonance imaging of the brain, an abnormal lumbar puncture, and/or demonstration of characteristic vessel abnormalities on arteriography **(Fig. 363-4)**, but it is confirmed by biopsy of the brain parenchyma and leptomeninges. In the absence of a brain biopsy, care should be taken not to misinterpret as true primary vasculitis arteriographic abnormalities that might actually be related to another cause. An important entity in the differential diagnosis is reversible cerebral vasoconstrictive syndrome, which typically presents with "thunderclap" headache and is associated with arteriographic abnormalities that mimic primary CNS vasculitis that are reversible. Other diagnostic

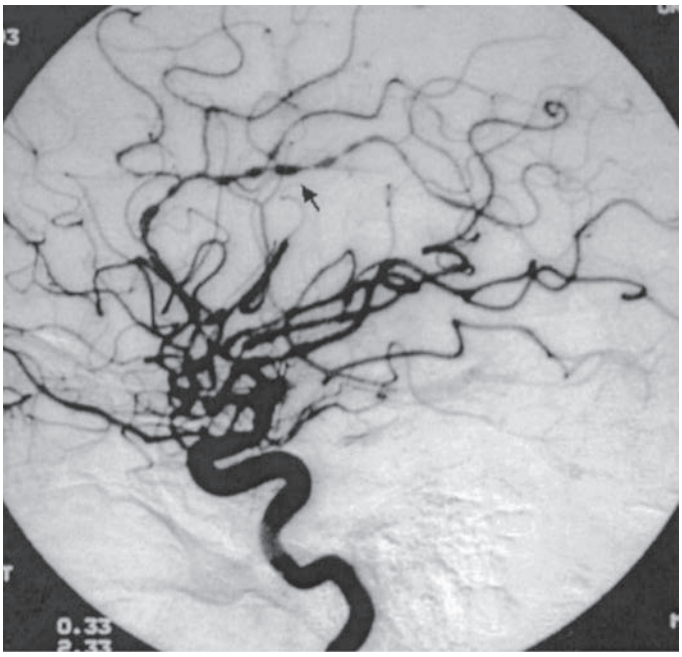

FIGURE 363-4 Cerebral arteriogram from a 32-year-old man with primary central nervous system vasculitis. Dramatic beading (*arrow*) typical of vasculitis is seen.

considerations include infection, atherosclerosis, emboli, connective tissue disease, sarcoidosis, malignancy, and drug-associated causes. The prognosis of granulomatous primary CNS vasculitis is poor; however, some reports indicate that glucocorticoid therapy, alone or together with cyclophosphamide administered as described above, has induced clinical remissions. Following disease remission, cyclophosphamide is switched to azathioprine or mycophenolate mofetil as these have good penetration into the CNS.

BEHÇET'S DISEASE

Behçet's disease is a clinicopathologic entity characterized by recurrent episodes of oral and genital ulcers, iritis, and cutaneous lesions. The underlying pathologic process is a leukocytoclastic venulitis, although vessels of any size and in any organ can be involved. **This disorder is described in detail in Chap. 364.**

COGAN'S SYNDROME

Cogan's syndrome is characterized by interstitial keratitis together with vestibuloauditory symptoms. It may be associated with a systemic vasculitis, particularly aortitis with involvement of the aortic valve. Glucocorticoids are the mainstay of treatment. Initiation of treatment as early as possible after the onset of hearing loss improves the likelihood of a favorable outcome.

KAWASAKI'S DISEASE

Kawasaki's disease is an acute, febrile, multisystem disease of children. Some 80% of cases occur prior to the age of 5, with the peak incidence occurring at ≤2 years. It is characterized by nonsuppurative cervical adenitis and changes in the skin and mucous membranes such as edema; congested conjunctivae; erythema of the oral cavity, lips, and palms; and desquamation of the skin of the fingertips. Although the disease is generally benign and self-limited, it is associated with coronary artery aneurysms in ~25% of cases, with an overall case-fatality rate of 0.5–2.8%. These complications usually occur between the third and fourth weeks of illness during the convalescent stage. Vasculitis of the coronary arteries is seen in almost all the fatal cases that have been autopsied and can cause complications into adulthood. There is typical intimal proliferation and infiltration of the vessel wall with mononuclear cells. Beadlike aneurysms and thromboses may be seen along the artery. Other manifestations include pericarditis, myocarditis, myocardial ischemia and infarction, and cardiomegaly.

Apart from the up to 2.8% of patients who develop fatal complications, the prognosis of this disease for uneventful recovery is excellent. High-dose IV γ-globulin (2 g/kg as a single infusion over 10 h) together with aspirin (100 mg/kg/d for 14 days followed by 3–5 mg/kg per day for several weeks) has been shown to be effective in reducing the prevalence of coronary artery abnormalities when administered early in the course of the disease. Surgery may be necessary for Kawasaki disease patients who have giant coronary artery aneurysms or other coronary complications. Surgical treatment most commonly includes thromboendarterectomy, thrombus clearing, aneurysmal reconstruction, and coronary artery bypass grafting.

Multisystem inflammatory syndrome (MIS-C), a serious condition that may resemble Kawasaki's disease, has been observed with infections due to the novel coronavirus, SARS-CoV-2 **(Chap. 199)**. Although clinical features consistent with Kawasaki's disease have been observed, these patients can also have manifestations atypical for Kawasaki's disease, including gastrointestinal symptoms, myocarditis, neurocognitive symptoms, and shock. Any patient who presents with a clinical picture suggestive of Kawasaki's disease should be tested for SARS-CoV-2 to guide care and management.

POLYANGIITIS OVERLAP SYNDROMES

Some patients with systemic vasculitis manifest clinicopathologic characteristics that do not fit precisely into any specific disease but have overlapping features of different vasculitides. The diagnostic and therapeutic considerations as well as the prognosis for these patients depend on the sites and severity of active vasculitis. Patients with vasculitis that could potentially cause irreversible damage to a major organ system should be treated as described under "Granulomatosis with Polyangiitis."

SECONDARY VASCULITIS

DRUG-INDUCED VASCULITIS

Vasculitis associated with drug reactions usually presents as palpable purpura that may be generalized or limited to the lower extremities or other dependent areas; however, urticarial lesions, ulcers, and hemorrhagic blisters may also occur **(Chap. 60)**. Signs and symptoms may be limited to the skin, although systemic manifestations such as fever, malaise, and polyarthralgias may occur. Although the skin is the predominant organ involved, systemic vasculitis may result from drug reactions. Drugs that have been implicated in vasculitis include allopurinol, thiazides, gold, sulfonamides, phenytoin, and penicillin **(Chap. 60)**.

An increasing number of drugs have been reported to cause vasculitis associated with ANCA. Of these, the best evidence of causality exists for hydralazine and propylthiouracil. The clinical manifestations in ANCA-positive drug-induced vasculitis can range from cutaneous lesions to glomerulonephritis and pulmonary hemorrhage. Outside of drug discontinuation, treatment should be based on the severity of the vasculitis. Patients with immediately life-threatening small-vessel vasculitis should initially be treated with glucocorticoids and cyclophosphamide as described for granulomatosis with polyangiitis. Following clinical improvement, consideration may be given for tapering such agents along a more rapid schedule.

SERUM SICKNESS AND SERUM SICKNESS–LIKE REACTIONS

These reactions are characterized by the occurrence of fever, urticaria, polyarthralgias, and lymphadenopathy 7–10 days after primary exposure and 2–4 days after secondary exposure to a heterologous protein (classic serum sickness) or a nonprotein drug such as penicillin or sulfa (serum sickness–like reaction). Most of the manifestations are not due to a vasculitis; however, occasional patients will have typical cutaneous venulitis that may progress rarely to a systemic vasculitis.

VASCULITIS ASSOCIATED WITH OTHER UNDERLYING DISEASES

Certain *infections* may directly trigger an inflammatory vasculitic process. For example, rickettsias can invade and proliferate in the endothelial cells of small blood vessels causing a vasculitis **(Chap. 187)**. In addition, the inflammatory response around blood vessels associated with certain systemic fungal diseases such as histoplasmosis **(Chap. 212)** may mimic a primary vasculitic process. A leukocytoclastic vasculitis predominantly involving the skin with occasional involvement of other organ systems may be a minor component of many other infections. These include *subacute bacterial endocarditis*, *Epstein-Barr virus infection*, *HIV infection*, and a number of other infections.

Vasculitis can be associated with certain *malignancies*, particularly lymphoid or reticuloendothelial neoplasms. Leukocytoclastic venulitis confined to the skin is the most common finding; however, widespread systemic vasculitis may occur. Of particular note is the association of *hairy cell leukemia* **(Chap. 110)** with polyarteritis nodosa.

A number of *connective tissue diseases* have vasculitis as a secondary manifestation of the underlying primary process. Foremost among these are *systemic lupus erythematosus* **(Chap. 356)**, *rheumatoid arthritis* **(Chap. 358)**, *inflammatory myositis* **(Chap. 365)**, *relapsing polychondritis* **(Chap. 366)**, and *Sjögren's syndrome* **(Chap. 361)**. The most common form of vasculitis in these conditions is the small-vessel venulitis isolated to the skin. However, certain patients may develop a fulminant systemic necrotizing vasculitis.

Secondary vasculitis has also been observed in association with *ulcerative colitis*, *congenital deficiencies of various complement components*, *sarcoidosis*, *primary biliary cirrhosis*, α_1*-antitrypsin deficiency*, and *intestinal bypass surgery*.

364 Behçet Syndrome

Yusuf Yazici

Behçet syndrome is a systemic vasculitis, first described by Hulusi Behçet, a Turkish dermatologist. It can present with skin and mucosal lesions, uveitis, arthritis, major arterial and venous vessel disease, and gastrointestinal and neurologic manifestations. These manifestations can be present in various combinations and sequences over time. Patients are most commonly from the Middle East, the Mediterranean region, and the Far East; it is most prevalent in Turkey, with a prevalence of 1 in 250 adults. It is relatively rare before the late teens and after age 50. Males and females are equally affected; however, males frequently have more severe disease and poorer outcomes. Some manifestations may show regional differences; for example, gastrointestinal involvement, rare in Turkey, is more common in Japan and is seen in ~30% of patients in the United States.

DIAGNOSIS

Behçet syndrome is diagnosed clinically. There are no specific laboratory, imaging, or histologic features that can help in the diagnosis of a patient with suggestive symptoms, and the diagnosis is based on a combination of clinical features in the setting of ruling out other potential causes. In this regard, some patients may require months to years to develop the array of symptoms that would lead to a definitive diagnosis, although a tentative diagnosis may be made well before. The most commonly used and best performing diagnostic criteria are the International Study Group (ISG) criteria (sensitivity ~95%, specificity ~96%); patients need to have recurrent oral ulcers plus two of the following four clinical manifestations: recurrent genital ulcers, skin lesions, eye lesions, or a positive pathergy test **(Table 364-1)**. Additional clinical manifestations may involve various organ systems, including the gastrointestinal, vascular, pulmonary, and central nervous systems. Up to 50–60% of patients, depending on where they are from, can be positive for HLA B*51; however, it is not used as a diagnostic test because it is also found in up to 20% of the normal population.

PATHOGENESIS

The pathogenesis and etiology of Behçet syndrome are unknown. Family studies show a possible genetic predisposition, and increased inflammation and immunologic mechanisms play a role. Both innate and adaptive immune systems may be involved. Unlike other autoimmune diseases, however, Behçet syndrome is not typically associated with autoantibodies, Raynaud's phenomenon, Sjögren's syndrome, thrombocytopenia, hemolytic anemia, sun hypersensitivity, serosal involvement, or an increased risk for other autoimmune diseases. On the other hand, features that separate it from autoinflammatory

TABLE 364-1 International Study Group Criteria for the Diagnosis of Behçet Syndrome

CRITERIA	FREQUENCY	COMMENTS
Oral ulcers	~98%	3 times in a 12-month period
Plus 2 out of 4 from below:		
Recurrent genital ulcers	~80%	Usually scarring
Skin lesions	~80%	Erythema nodosum, pseudofolliculitis, papulopastular or acneiform nodules (postadolescent, not receiving corticosteroids)
Eye lesions	~50%	Anterior/posterior uveitis cells in vitreous or retinal vasculitis
Pathergy	~50%	24–48 h, after dermal insertion of a 20-gauge needle

conditions include tendency to abate with time, absence of mutations associated with autoinflammatory diseases, and higher prevalence than typical autoinflammatory diseases such as familial Mediterranean fever (Chap. 369). There is neutrophil hyperreactivity; however, it is not clear whether this is primary or secondary to cytokine-directed activation. There is also evidence from retrospective patient cohort analyses that there may be different clusters of disease presentation; for example, acne lesions are more commonly seen with arthritis and associated with enthesitis, and each of these clusters may have a different pathogenesis.

CLINICAL PRESENTATION

The most common symptoms are associated with mucocutaneous tissues. Oral ulcers are seen in virtually all patients and are commonly the first manifestation. Commonly, like ordinary cancer sores, they are usually multiple. They last around 10 days but recur unless treated. Only the uncommon, major ulcers tend to scar. Beneficial effects of dental and periodontal therapies suggest that decreased oral health is associated with disease severity.

Genital ulcers are the most specific lesions, most commonly occurring on the scrotum or labia. They are larger and deeper and take longer to heal than oral ulcers and tend to form scars.

Acne-like or papulopustular lesions are indistinguishable from acne vulgaris in appearance and pathology. They are seen both at the usual acne sites as well as at uncommon sites such as lower extremities. Other skin findings are the nodular lesions, which are of two types: erythema nodosum lesions due to panniculitis and superficial vein thromboses. Superficial thrombophlebitis often occurs in men and is associated with deep-vein thrombosis; it should trigger workup for other vascular involvement, including pulmonary artery aneurysms.

Pathergy reaction is a nonspecific hyperreactivity of the skin to trauma. Typically, a papule or pustule forms in 24–48 h after a needle prick. It is rather unique for Behçet syndrome and is part of the ISG diagnostic criteria.

Arthralgia or arthritis is seen in about half of patients; it is usually a mono- or oligoarthritis in the lower extremities and does not usually cause deformity or erosions.

Eye involvement is seen in half of all patients and in ~70% of males. It is most commonly a bilateral panuveitis. A hypopyon, seen in ~10% of patients with eye disease, is an intense inflammation in the anterior chamber and is quite specific for Behçet syndrome. Ocular involvement develops usually in the first 2 years after fulfillment of diagnostic criteria and is most severe during the first few years and then tends to abate. Male gender, posterior involvement, frequent attacks (>3 per year), strong vitreous opacity, and macular edema are poor prognostic factors.

Vascular disease is seen in up to 40% of patients. It is associated with intensive thrombosis and runs a relapsing course. Several well-defined venous vascular associations are seen, and superficial and deep-vein thrombosis, Budd-Chiari syndrome, inferior vena cava syndrome, pulmonary artery involvement, intracardiac thrombosis, and cerebral venous sinus thrombosis frequently cluster in various combinations. Pulmonary artery aneurysms carry a 5-year mortality rate of 20–25%.

Prevalence of neurologic involvement is ~5%, with about three-quarters of patients presenting with parenchymal involvement, while the remaining cases present with cerebral venous sinus thrombosis. These two forms only rarely occur together. Parenchymal involvement usually affects the telencephalic-diencephalic junction, brainstem, and spinal cord. Patients may present with a subacute onset of severe headache, cranial nerve palsy, dysarthria, ataxia, and hemiparesis.

Prevalence of gastrointestinal involvement changes significantly across different populations (up to 50% in the Far East but rare in the Middle East). Clinical and endoscopic appearance of intestinal involvement can be similar to, and thus cannot easily be differentiated from, Crohn's disease. Ulcers tend to be single or less than five, are usually confined to the ileocecal area, are more likely to be deep and round, and are prone to perforate; perianal and rectal area involvement is rare. In practice, it is difficult to distinguish Behçet syndrome from Crohn's disease unless extraintestinal lesions are present.

TREATMENT

Behçet Syndrome

Treatment is guided by type and severity of involvement, with the goal of preventing long-term damage. Most new manifestations present within the first 5 years, and for most patients, the natural course is one of diminishing symptoms culminating in potential remission, frequently not requiring ongoing treatment with medications. Patient characteristics, such as being young and male, need to be kept in mind as these patients tend to have a worse prognosis. For most patients, tapering and/or stopping their medications in 2–3 years after the symptoms have improved should be attempted.

Oral ulcers can be managed with topical glucocorticoids and on an as-needed basis if mild. Lesions resistant to local measures may require systemic treatment with colchicine, oral glucocorticoids, immunosuppressants such as apremilast, azathioprine, or a tumor necrosis factor-α inhibitor such as infliximab. Apremilast has now been approved in the United States and Japan for the treatment of oral ulcers of Behçet syndrome. A similar treatment approach can be used for genital ulcers and other mucocutaneous manifestations. Patients may need a combination of medications, at least initially, to control disease activity.

Eye involvement, given its frequency and potential morbidity, requires early and aggressive treatment with brief courses of glucocorticoids and longer-term treatment with an immunosuppressant. Azathioprine is usually the preferred agent. Infliximab, adalimumab, or cyclosporine can also be used, in combination with systemic glucocorticoids and azathioprine, for control of disease activity. Monotherapy with interferon is another option. Glucocorticoids can be tapered in many patients after active disease has been controlled, whereas immunosuppressants are generally continued for at least 2 years.

Gastrointestinal involvement is treated with a glucocorticoid plus an immunosuppressant such as azathioprine alone or in combination with infliximab.

Venous thrombotic events are treated by controlling systemic inflammation with immunosuppressive medications (usually azathioprine or, for more severe cases, cyclophosphamide), rather than using anticoagulants. However, if venous thrombotic events occur, standard anticoagulation treatment can be given, provided there is a low risk of bleeding and there are no coexistent pulmonary artery aneurysms. For central nervous system involvement, the combination of azathioprine and a tumor necrosis factor inhibitor is usually the first choice.

365 Inflammatory Myopathies

Steven A. Greenberg, Anthony A. Amato

This chapter focuses on the major types of inflammatory myopathies (IMs), including dermatomyositis (DM), polymyositis (PM), immune-mediated necrotizing myopathy (IMNM), antisynthetase syndrome (AS), and inclusion body myositis (IBM) **(Table 365-1)**. Other IMs include those caused by infection, eosinophilic myositis, granulomatous myositis, and myositis triggered by checkpoint inhibitors. Of note, inflammatory cell infiltrates can also be occasionally seen in muscle biopsies in hereditary (e.g., muscular dystrophies, metabolic myopathies) and toxic myopathies.

Epidemiologic studies suggest that the incidence of IM grouped together is >4 cases per 100,000 with prevalence in the range of 14–32 per 100,000. Defining the actual incidence and prevalence of the individual myositides is limited, however, by the different diagnostic criteria employed in various epidemiologic studies, increasing recognition of AS, and frequent misdiagnosis of IBM and IMNM. Idiopathic PM without signs of an overlap syndrome is quite rare, while DM, IBM, and IMNM occur in roughly similar frequencies. DM can occur in children (juvenile DM), while IBM always occurs in adults and is the most common cause of myopathy in those aged >50. DM, PM, and AS are more common in women, while IBM is more common in men.

DIAGNOSTIC APPROACH AND DIFFERENTIAL DIAGNOSIS

The approach to patients with suspected myopathy is detailed in **Chap. 449**. In any patient presenting with weakness, the first step is to localize the site of the lesion by history and clinical findings **(Chap. 24)**. Weakness could be caused by a process in the cerebral hemispheres, spinal cord **(Chap. 442)**, anterior horn cell **(Chap. 437)**, peripheral nerve **(Chaps. 446-447)**, neuromuscular junction **(Chap. 448)**, or muscle **(Chap. 449)**. Past medical history, medication use, and family history, combined with a detailed clinical examination and an appreciation for the pattern of muscle involvement (e.g., what muscles are weak and atrophic or hypertrophic as well as the presence of scapular winging, early contractures, sensory abnormalities, fasciculations, or rash), help

TABLE 365-1 Inflammatory Myopathies: Clinical and Laboratory Features

DISORDER	SEX	AGE OF ONSET	RASH	PATTERN OF WEAKNESS	LABORATORY FEATURES	MUSCLE BIOPSY	CELLULAR INFILTRATE	RESPONSE TO IS THERAPY	COMMON ASSOCIATED CONDITIONS
DM	F > M	Childhood and adult	Yes	Proximal > distal	Normal or increased CK (up to 50× normal or higher); various MSAs (anti-MDA5, anti-TIF1, anti-Mi-2, anti-NXP2)	Perimysial and perivascular inflammation; IFN-1 regulated proteins (MHC-1, MxA), MAC deposition on capillaries	CD4+ dendritic cells; B cells; macrophages	Yes	Myocarditis, ILD, malignancy, vasculitis, other CTDs
PM	F > M	Adult	No	Proximal > distal	Increased CK (up to 50× normal or higher)	Endomysial and perivascular inflammation; ubiquitous expression of MHC-1	CD8+ T cells; macrophages; plasma cells	Yes	Myocarditis, ILD, other CTDs
NM	M = F	Children and adults	No	Proximal > distal	Elevated CK (>10× normal or higher); anti-HMGCR or anti-SRP antibodies	Necrotic muscle fibers; minimal inflammatory infiltrate	Macrophages in necrotic fibers undergoing phagocytosis	Yes	Malignancy, CTD, HMGCR antibody cases can be triggered by statin use
AS	F > M	Children and adults	Sometimes	Proximal > distal	Elevated CK (>10× normal or higher); antisynthetase antibodies	Perimysial and perivascular inflammation; perimysial fragmentation with alkaline phosphatase staining; perimysial muscle damage with necrosis	CD4+ dendritic cells; B cells; macrophages	Yes	Nonerosive arthritis, ILD, Raynaud's phenomenon, mechanic hands, and fever
IBM	M > F	Older adults (>50 years)	No	Proximal and distal; predilection for: finger/ wrist flexors, knee extensors	Normal or mildly increased CK (usually <10× normal); anti-cN-1A antibodies; large granular lymphocytes on flow cytometry and reduced CD4/CD8 ratio with increased CD8 count	Endomysial and perivascular inflammation; ubiquitous expression of MHC-1; rimmed vacuoles; p62, LC3, TDP-43 aggregates; EM: 15–18 nm tubulofilaments; ragged red and COX-negative fibers	CD8+ T cells; macrophages; plasma cells; myeloid dendritic cells; large granular lymphocytes	None or minimal	Granular lymphocytic leukemia/ lymphocytosis, sarcoidosis, sicca or Sjögren's syndrome

Abbreviations: CK, creatine kinase; cN-1A, cytosolic 5′-nucleotidase 1A; CTDs, connective tissue diseases; COX, cytochrome oxidase; DM, dermatomyositis; F, female; g, immunoglobulin; IBM, inclusion body myositis; IFN-1, type 1 interferon; ILD, interstitial lung disease; IS, immunosuppressive; M, male; MAC, membrane attack complex; MDA5, melanoma differentiation antigen; MHC-1, major histocompatibility antigen 1; MSA, myositis-specific autoantibodies; NCP2, nuclear matrix protein 2 (NXP2); NM, necrotizing myopathy; PM, polymyositis; TIF1, transcriptional intermediary factor 1.

differentiate myopathies from other neuromuscular disorders and the different types of myopathies from each other (see Chap. 449). For example, atrophy with fasciculations suggests a neurogenic process such as amyotrophic lateral sclerosis, fatigable weakness on examination points to a neuromuscular junction defect such as myasthenia gravis, and concomitant sensory symptoms suggest a central process such as a spinal cord disorder or a polyneuropathy. Scapular winging, calf hypertrophy or atrophy, and early contractures before significant weakness develops would strongly suggest a muscular dystrophy, particularly if there is a positive family history. A heliotrope rash combined with Gottron papules and dilated nailfold capillaries is diagnostic for DM. The presence of atrophy and weakness of the flexor forearm muscles and quadriceps in a person aged >50 years is most likely IBM.

When the site of the lesion cannot be localized based on history and clinical examination alone, laboratory testing is required. Serum creatine kinase (CK) is the most sensitive laboratory marker of muscle destruction. Not all myopathies are associated with elevated CK levels, but a markedly elevated CK (e.g., >2000 U/L) is almost always due to a myopathy. A slightly elevated CK can also be seen in neurogenic disorders, however. Myositis-associated and myositis-specific antibodies (MSAs) help to distinguish subtypes of IM, as discussed below. Electromyography (EMG) and nerve conductions studies (NCS) are useful in localizing the site of the lesion but are less specific in helping to determine the actual cause of a myopathy. EMG can be useful at times in guiding what muscle to biopsy, especially if muscles typically biopsied are normal on clinical examination. Imaging skeletal muscle can be helpful in assessing muscle involvement and revealing fatty replacement, atrophy, or edema within muscle or surrounding fascia.

A muscle biopsy is usually required to definitively distinguish one myopathy from another. The different forms of IM can have distinctive histopathologic abnormalities as discussed below. In a patient with a classic DM rash, a muscle or skin biopsy can be performed, but an argument can also be made that biopsy is unnecessary—particularly if the patient also has an MSA specific for DM. However, a muscle biopsy should be performed in every case of suspected PM to exclude IBM (if not clinically apparent) and other causes of myopathy. Diagnosis of IMNM is by definition based upon histologic findings. It is important to biopsy a muscle that is clinically affected but not too weak (e.g., Medical Research Council grade 4 out of 5 in strength); otherwise, one may just see end-stage muscle. A biopsy should always be coordinated with an experienced muscle histopathology laboratory.

Patients with severe muscle pain, subjective weakness, and fatigue with normal strength and function on examination are not likely to have an IM. Polymyalgia rheumatica should be considered in older individuals with an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) but normal CK and EMG. Fibromyalgia is likely in patients with a normal laboratory workup. In general, a muscle biopsy is not indicated unless there is objective weakness, an abnormal EMG, or elevated CK.

SPECIFIC DISORDERS

DERMATOMYOSITIS

Clinical Features DM manifests with symmetric, proximal greater than distal weakness along with a characteristic rash that includes the heliotrope rash (erythematous discoloration of eyelids with periorbital edema), Gottron sign (erythematous rash over the extensor surfaces of joints such as the knuckles, elbows, knees, and ankles), Gottron papules (raised erythematous rash over knuckles) (Fig. 365-1), V-sign (rash on the sun-exposed anterior neck and chest), shawl sign over the back of the neck and shoulders, nail bed telangiectasias, and subcutaneous calcium deposits. The weakness and rash usually accompany one another but can be separated by several months. Furthermore, there is a spectrum of involvement such that some patients continue to manifest only with a rash (amyopathic DM), while others may present mainly with weakness and little or no visible skin changes. Patients can also complain of myalgias, arthralgias, dysphagia, and dysarthria. Cutaneous disease activity is highly relevant in DM; in comparison to other debilitating skin diseases including cutaneous lupus erythematosus, psoriasis, and atopic dermatitis, skin symptoms in DM patients are associated with an overall reduction in life quality. Pruritus can be especially debilitating. Dyspnea can occur from ventilatory muscle weakness or intrinsic pulmonary problems including interstitial lung disease (ILD), bronchopneumonia, and alveolitis. Pulmonary manifestations are often associated with antisynthetase antibodies; myositis associated with the AS can be considered a distinct disorder (discussed below). DM can present in children (juvenile DM) or in adults. There is a higher risk for malignancy in adult-onset cases, ~15% within the first 2–3 years.

FIGURE 365-1 Cutaneous manifestations of dermatomyositis. ***A.*** Macular erythema plaques (Gottron sign) and erythematous papules (Gottron papules) on extensor surface of fingers and ***B.*** elbow. ***C.*** Macular erythema plaques over anterior neck and chest (V-sign) and ***D.*** the posterior neck, shoulder, and upper back (Shawl sign). ***E.*** Nail bed changes with dilated capillaries.

Laboratory Features Serum CK levels are elevated in 70–80% of patients; in 10% of those with normal CK, serum aldolase may be increased. Antinuclear antibodies can be positive but are a nonspecific finding. DM is associated with several MSA targeting melanoma differentiation antigen 5 (MDA5), transcriptional intermediary factor 1 (TIF1), Mi-2, and

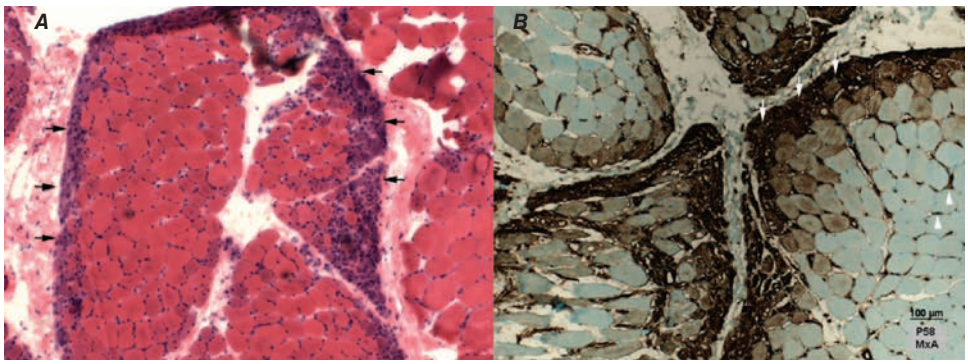

FIGURE 365-2 Perifascicular atrophy and myxovirus resistance protein A (MxA) expression in dermatomyositis. ***A.*** Perifascicular myofibers (*black arrows*) bordering on disrupted perimysial connective tissue are atrophic and basophilic on hematoxylin and eosin (H&E) stains. ***B.*** Perifascicular myofibers (*white arrows*) show intense staining for MxA protein along a gradient from superficial to deep; all capillaries show intense MxA expression (*white arrowheads*).

nuclear matrix protein 2 (NXP2). These antibodies are usually associated with characteristic clinical features. For example, anti-MDA5 antibodies are associated with amyopathic DM with severe palmar rash, digital ulcers, and rapidly progressive ILD. Anti-TIF1 (or p155) antibodies and anti-NXP2 antibodies are associated with an increased risk of cancer, while anti-Mi-2 antibodies are often associated with more benign DM and a favorable response to treatment.

EMG of weak muscles shows increased insertional and spontaneous activity in the form of positive sharp waves and fibrillation potentials, or complex repetitive discharges along with early recruitment of small amplitude, short duration, polyphasic motor units. These findings are nonspecific and can be seen in other myopathies. Skeletal muscle magnetic resonance imaging (MRI muscle) reveals edema in affected muscles and sometimes more specific findings of abnormalities of fascia suggesting fasciitis.

Histopathology and Pathogenesis The characteristic histopathologic abnormality on muscle biopsy is perifascicular atrophy **(Fig. 365-2*A*)**; however, this is present in perhaps only 50% of patients. Immunohistochemical staining for myxovirus resistance protein A (MxA) is diagnostically more sensitive and highly specific **(Fig. 365-2*B*)**. The inflammatory cell infiltrate is predominantly perivascular and located in the perimysium and is composed primarily of macrophages, B cells, and plasmacytoid dendritic cells (PDCs). Skin biopsies reveal cell-poor interface dermatitis, which is analogous to the perifascicular atrophy in that the basal layer of keratinocytes is most damaged; the inflammatory infiltrate is typically absent or minimal and, when present, is located mainly at the border zone of the dermis and epidermis.

The pathogenesis of DM was traditionally attributed to an antibody-mediated attack on endothelial cells, followed by complement-mediated destruction of capillaries and watershed ischemia of muscle fibers. However, recent studies suggest that this is not likely the case. Immunoglobulin deposition is largely absent on endothelial cells, and complement deposition may be a secondary phenomenon. There is increasing evidence that the microvasculopathy and skin and muscle damage associated with DM are primarily due to toxicity from type I interferon (IFN)–mediated pathways, most likely IFN-β.

Prognosis In the absence of malignancy, prognosis is generally favorable in patients with DM, with 5-year survival rates ranging from 70 to 93%. Poor prognostic features are increased age, associated ILD, cardiac disease, and late or previous inadequate treatment.

POLYMYOSITIS

Clinical Features PM is a heterogenous group of disorders that usually presents with symmetric and proximal weakness that worsens over several weeks to months. As with DM, there can be associated heart, lung, and joint involvement as well as an increased risk of cancer. Some epidemiologic studies suggest that the risk of cancer in PM is less than that in DM, but these older series likely included patients with IBM and dystrophies with inflammation who were misdiagnosed as having PM.

Laboratory Features CK levels are always elevated in uncontrolled PM. A normal CK should alert clinicians to the possibility of IBM. As in DM, EMG and skeletal muscle imaging can be abnormal, but the findings are not specific **(Fig. 365-3)**.

Histopathology and Pathogenesis Because PM is a heterogeneous category, muscle pathology varies substantially. Most often, patients with nonspecific inflammatory cells present in perimysial more often than endomysial locations have been categorized as PM. A small minority of patients have mononuclear inflammatory infiltrate that surrounds fibers with sarcolemmal major histocompatibility (MHC-I) expression **(Fig. 365-4)**. There is debate as to whether true invasion of myofibers occurs in PM, or rather always indicates IBM. The inflammatory infiltrate predominantly consists of CD8+ T cells and macrophages located in the endomysial, perimysial, and perivascular regions. As PM is heterogeneous, its varied forms of pathogenesis are poorly understood.

Prognosis Most patients with PM improve with immunotherapies but usually require lifelong treatment. Some retrospective studies suggest that PM does not respond as well as DM to these therapies. However, many of these older series of "PM" likely included patients who actually had IMNM, IBM, or other myopathies (including muscular dystrophies) that do not respond to immunotherapies. As in DM, poor prognostic features are cancer, increased age, lung or cardiac involvement, and late or previously inadequate treatment.

OVERLAP SYNDROMES

The term *overlap syndrome* is applied when DM or PM is associated with other well-defined connective tissue diseases (CTDs) such as scleroderma, mixed connective tissue disease (MCTD), Sjögren's syndrome, systemic lupus erythematosus (SLE), or rheumatoid arthritis.

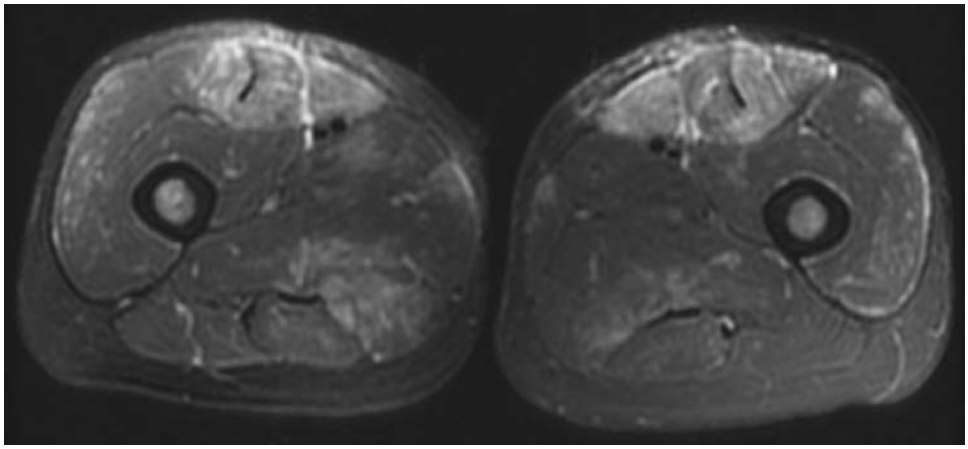

FIGURE 365-3 Skeletal muscle MRI with short T1 inversion recovery (STIR) imaging in polymyositis. MRI of the thigh demonstrates bright signal indicative of edema/inflammation, particularly in the rectus femoris muscle. This contrasts with MRI in IBM in which there is more selective involvement of the vastus lateralis and medialis with relative sparing of the rectus femoris (see Fig. 365-7*F* and *G*).

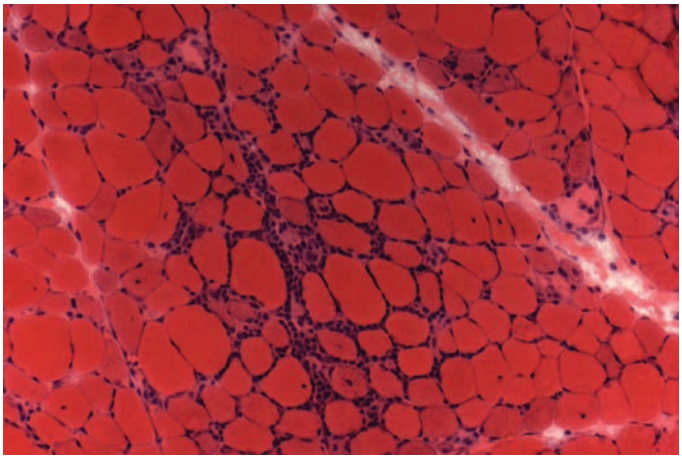

FIGURE 365-4 Pathology of polymyositis. Muscle biopsy demonstrates endomysial infiltrates surrounding nonnecrotic muscle fibers.

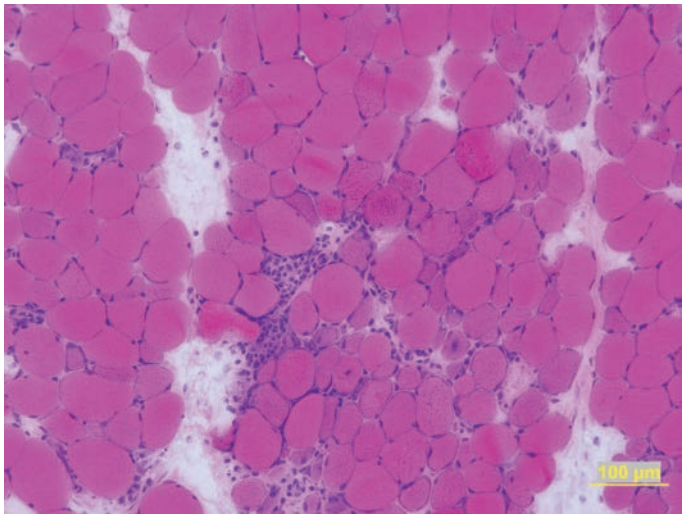

FIGURE 365-5 Pathology of immune-mediated necrotizing myopathy. Muscle biopsy demonstrates scattered necrotic fibers with inflammatory infiltrate confined to those fibers undergoing myophagocytosis along with a few regenerating fibers.

As in DM and PM, the myositis associated with these overlap syndromes is usually responsive to immunotherapies.

IMMUNE-MEDIATED NECROTIZING MYOPATHY

Clinical Features IMNM, or autoimmune necrotizing myopathy, is characterized by the acute or insidious onset of symmetric, proximal more than distal weakness. Dysphagia, dysarthria, or myalgia may occur. Patients may have an underlying CTD (usually scleroderma or MCTD) or cancer (paraneoplastic necrotizing myopathy), or the condition may be idiopathic. There are at least two distinct forms of IMNM associated with specific autoantibodies (anti-3-hydroxy-3-methyl-glutaryl-coenzyme reductase [HMGCR] and anti-signal recognition particle [SRP]). Anti-HMGCR myopathy can be seen in patients receiving statins, inhibitors of HMGCR, particularly in patients aged >50 years. However, anti-HMGCR myopathy can develop in children and young adults without a history of statin use and can mimic a limb girdle muscular dystrophy. Unlike the more common "toxic" myopathy associated with statin use, anti-HMGCR myopathy does not improve when statins are discontinued. Anti-SRP myopathies are notable for the presence of anti-SRP antibodies and a typically subacute, aggressive, and relatively refractory course.

Laboratory Features CK levels are markedly elevated (usually >10 × normal) in IMNM. As mentioned, IMNM can be associated with anti-HMGCR or anti-SRP antibodies. EMG often shows increased insertional and spontaneous activity, including myotonic discharges. Skeletal muscle imaging findings are nonspecifically abnormal.

Histopathology and Pathogenesis Muscle biopsies reveal multifocal necrotic and regenerating muscle fibers with a paucity of inflammatory cells (Fig. 365-5). However, some patients with anti-HMGCR myopathy have endomysial, macrophage-predominant infiltrates similar to what is seen in PM. Overexpression of MHC-I and membrane attack complex (MAC) may be evident on sarcolemma of nonnecrotic fibers and MAC deposition on capillaries. The pathogenesis of IMNM is not completely understood but may be complement mediated.

Prognosis IMNM is generally much more difficult to treat than either DM or PM, and aggressive immunotherapy is usually required. The progressive course despite immunotherapy and marked weakness with atrophy can lead to a misdiagnosis of a limb girdle muscular dystrophy. There may be an increased incidence of cancer in patients with anti-HMGCR myopathy; thus, patients should undergo a malignancy workup.

ANTISYNTHETASE SYNDROME

Clinical Features The presence of myositis, nonerosive arthritis, ILD, Raynaud's phenomenon, mechanic hands, and fever associated with antibodies against aminoacyl-tRNA synthetase constitute the AS. Some patients have an erythematous rash, and muscle biopsies share histopathologic features of DM, which likely accounts for many of these patients being classified as having DM.

Laboratory Features Antibodies against aminoacyl-tRNA synthetases are the most common MSA, present in 25–35% of patients with myositis. The most common aminoacyl-tRNA synthetase antibody is anti-Jo-1. CK is usually elevated in patients with AS and myositis. Those with ILD demonstrate reduced forced vital capacity and diffusion capacity on pulmonary function tests. Spiral chest CT scans are best at demonstrating the honeycomb pattern of ILD. Skeletal muscle MRI and EMG show abnormalities similar to DM, PM, and IMNM.

Histopathology and Pathogenesis Muscle biopsies demonstrate a predilection for perimysial damage including perimysial fragmentation and staining with alkaline phosphatase (Fig. 365-6), PDCs and macrophages in the perimysium and around blood vessels, and MAC deposition on capillaries. Also similar to DM, there is perifascicular muscle fiber damage, but with AS, there is more perifascicular muscle fiber necrosis compared to DM, in which perifascicular atrophy is more prominent. MHC-I and MAC deposits on muscle fibers may be seen on sarcolemma of perifascicular muscle fibers.

Prognosis Most patients respond to treatment, although responses are less complete than for DM and PM; ILD can be particularly refractory to treatment. Unlike DM, PM, and IMNM, there does not appear to be an increased risk of malignancy.

INCLUSION BODY MYOSITIS

Clinical Features IBM usually manifests in patients over the age of 50 years and is slightly more common in men than women. It is associated with slowly progressive weakness and muscle atrophy that has a predilection for early involvement of the wrist and finger flexors in the arms and quadriceps in the legs (Fig. 365-7). Weakness is often asymmetric. Dysphagia is common and rarely can be the presenting feature. These clinical features can help distinguish IBM from PM and other forms of myopathy. The mean duration from onset of symptoms to use of wheelchair or scooter is ~15 years. There is no known increased risk of malignancy.

Laboratory Features CK levels can be normal or only slightly elevated (usually <10 times normal). Antibodies targeting cytosolic 5′-nucleotidase 1A (cN-1A) are detected in the blood in a third to more than two-thirds of IBM patients and are a highly specific diagnostic biomarker for IBM among patients with myopathy. Other blood biomarkers for IBM include the presence of an abnormal population of large granular lymphocytes on flow cytometry and a reduced CD4/CD8 ratio with an increased CD8 count. Needle EMG may demonstrate large-amplitude, long-duration motor unit potentials that can be

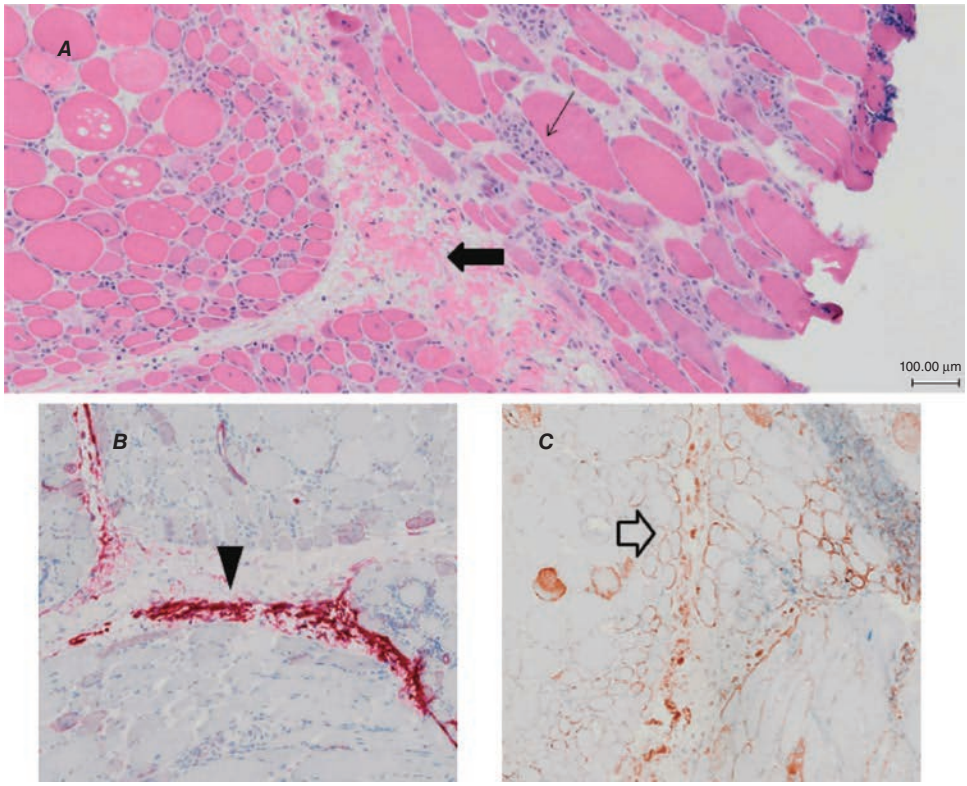

FIGURE 365-6 Pathology of myositis with anti-Jo-1 antibodies (antisynthetase syndrome). ***A.*** Perifascicular/perimysial muscle fiber atrophy and necrosis (*thin arrow*) associated with perimysial connective tissue is edematous and fragmented in appearance (*thick arrow*), hematoxylin and eosin stain. ***B.*** The perimysial connective tissue intensely stains red with alkaline phosphatase stain (*arrowhead*). ***C.*** Immunostaining demonstrates deposition of membrane attack complex (MAC) deposits on the sarcolemma of nonnecrotic perifascicular muscle fibers (*open arrow*).

misinterpreted as neurogenic but reflect the chronicity of the myopathy. Muscle MRI may show a predilection for involvement of the flexor digitorum profundus in the arms and the vastus medialis and lateralis muscles with sparing of the rectus femoris muscle.

Histopathology and Pathogenesis Muscle biopsies demonstrate endomysial inflammatory infiltrates predominantly composed of CD8+ T cells and macrophages surrounding and invading nonnecrotic muscle fibers, MHC-1 expression on the sarcolemma, fibers with rimmed vacuoles, cytochrome oxidase (COX)–negative fibers, and inclusions on light or electron microscopy (Fig. 365-8). The inclusions contain beta-sheet misfolded proteins (amyloid) but are difficult to appreciate with routine Congo red stain (they are seen on frozen but not paraffin sections). Immunostaining for p62 appears to be the most sensitive stain for detection of these inclusions. Importantly, rimmed vacuoles may not be seen in as many as 20–30% of muscle biopsies. In such cases, the presence of mitochondrial abnormalities (ragged red and COX-negative fibers) and immunostaining demonstrating p62 inclusions are helpful in distinguishing IBM from PM (aside from the clinical pattern of muscle weakness).

The pathogenesis of IBM is poorly understood. The marked adaptive immune system abnormalities related to T-cell inflammation and the presence of a relatively specific autoantibody against a muscle protein indicate an autoimmune attack on muscle. The chronic and highly inflammatory environment within muscles in IBM may alter protein synthesis and degradation pathways in part via aberrant immunoproteasome expression. Additional histologic features, typically referred to as "degenerative," include aggregation of various proteins including markers of endoplasmic reticulum (ER) stress and autophagy (e.g., p62 and LC3). Involvement of ER stress and autophagy has also been observed in other autoimmune diseases, such as primary biliary cholangitis (PBC), inflammatory bowel disease, and ankylosing spondylitis, some of which can be highly refractory to immunotherapy.

Prognosis The myopathy is slowly progressive and is not typically responsive to immunotherapies. Most patients require a scooter or wheelchair within 10–15 years of onset of symptoms.

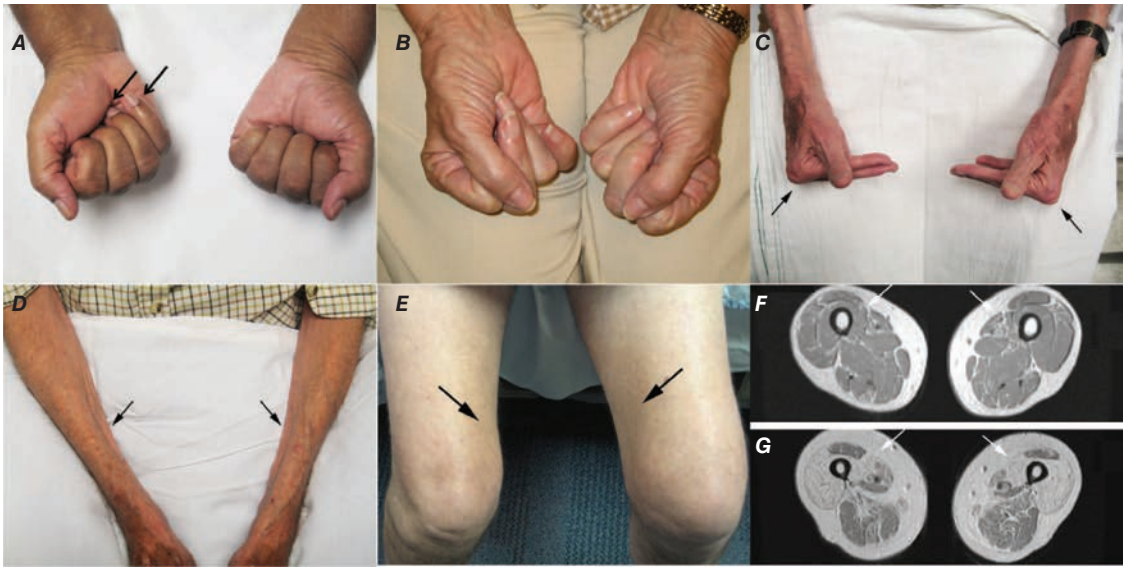

FIGURE 365-7 Muscle manifestations of inclusion body myositis (IBM; *A–C*). Finger flexor weakness can be (***A***) subtle and multifocal (*black arrows*), (***B***) moderate, or (***C***) severe. Note that even with complete paralysis of deep and superficial finger flexors, metacarpophalangeal joint flexion (*arrows*) is often maintained due to preservation of lumbricals. ***D.*** Ventral forearm atrophy (*arrows*). ***E.*** Atrophy of medial thighs due to loss of vastus medialis (*arrows*). ***F.*** Early IBM, with relatively preserved vastus medialis (*arrows*), in contrast to (***G***) advanced IBM with marked fibrous replacement of vastus medialis (*arrows*).

TREATMENT OF THE IM (TABLE 365-2)

DM, PM, AS, and IMNM are typically responsive to immunotherapy. High-dose glucocorticoids (i.e., starting dose of prednisone 0.75–1.0 mg/kg per day) are considered the first-line treatment. There is uncertainty regarding when to start second-line agents (e.g., methotrexate, azathioprine, mycophenolate, immunoglobulin, or rituximab). The clinician must weigh with the patient the increased risks of immunosuppression versus possible benefits (e.g., faster improvement, steroid-sparing effect, and/or avoidance of the morbidities associated with long-term glucocorticoid use). We usually start a second-line agent (typically methotrexate) with glucocorticoids in patients with severe weakness or other organ system involvement (e.g., myocarditis, ILD), those with increased risk of steroid complications (e.g., diabetics, osteoporosis, or postmenopausal women), and patients with IMNM who are known to have difficult-to-treat myositis. In those in whom we initiate treatment with prednisone alone, a second-line agent is added in patients who fail to significantly improve after 2–4 months of treatment or in those who cannot be tapered to a low dose of prednisone.

Most patients with IMNM do not respond to prednisone alone or even prednisone plus a second-line agent in combination. Many require triple therapy with prednisone, methotrexate, and intravenous immunoglobulin (IVIG) and, if this fails, rituximab. Recent reports suggest that anti-HMGCR myopathy may respond to monotherapy with IVIG, and a large multicenter clinical trial to test this approach is underway. Additionally, muscle biopsies demonstrate deposition of membrane attack complexes on sarcolemma of nonnecrotic fibers in IMNM, suggesting that muscle destruction is complement mediated. In this regard, there is an ongoing international trial investigating the safety and efficacy of a complement inhibitor in anti-HMGCR and anti-SRP myopathies.

Unfortunately, IBM does not typically respond to any known immunotherapies. The mainstay of treatment is physical and occupational therapy to improve function and swallowing therapy (and sometimes esophageal dilation or cricopharyngeal myotomy) in those with dysphagia.

GENERAL GUIDELINES FOR USE OF SPECIFIC IMMUNOTHERAPIES

Glucocorticoids Treatment is initiated with prednisone (0.75–1.5 mg/kg up to 100 mg) administered as a daily morning single dose (the most common dose used in adults is 60 mg daily). In patients with severe weakness or comorbidities (e.g., ILD, myocarditis), treatment with a short course of intravenous methylprednisolone (1 g daily for 3 days) is recommended prior to starting oral glucocorticoids. Patients are generally maintained on high-dose prednisone until strength normalizes or until improvement in strength has reached a plateau (usually 3–6 months). Subsequently, prednisone can be tapered by 5 mg every 2–4 weeks. Once the dose is reduced to 20 mg every day or every other day, the taper is slowed to 2.5 mg every 2–4 weeks. The goal is to taper prednisone to ≤10 mg daily. Although most patients improve, the response may not be complete and many will require at least a small dose of prednisone or a second-line agent to have a sustained remission. Serum CK levels are monitored; however, dose adjustments of prednisone and other immunotherapies are primarily based on the objective clinical examination and not the CK levels or the patients' subjective response. When no response is noted after an adequate trial of high-dose prednisone, alternative diagnoses (e.g., IBM or an inflammatory muscular dystrophy) and a repeat muscle biopsy should be considered.

Relapse of the myositis needs to be distinguished from steroid myopathy. Features suggesting a steroid myopathy include weakness developing while on high dosage, a normal serum CK, clinical features of steroid excess such as ecchymoses and "moon facies," and absence of muscle membrane irritability on EMG. By contrast, patients experiencing relapse of myositis may become weaker during the prednisone taper, have increasing serum CK levels, and display abnormal spontaneous activity on EMG.

SECOND-LINE THERAPIES

Methotrexate Methotrexate is usually the second-line treatment of choice because most authorities believe it works faster than other

TABLE 365-2 Immunotherapies for Inflammatory Myopathies

THERAPY	ROUTE	DOSE	SIDE EFFECTS	MONITOR
Prednisone	Oral	0.75–1.5 mg/kg per day to start	Hypertension, fluid and weight gain, hyperglycemia, hypokalemia, cataracts, gastric irritation, osteoporosis, infection, aseptic femoral necrosis	Weight, blood pressure, serum glucose/potassium, cataract formation
Methylprednisone	Intravenous	1 g in 100 mL/normal saline over 1–2 h, daily or every other day for 3–6 doses	Arrhythmia, flushing, dysgeusia, anxiety, insomnia, fluid and weight gain, hyperglycemia, hypokalemia, infection	Heart rate, blood pressure, serum glucose/potassium
Azathioprine	Oral	2–3 mg/kg per day; single a.m. dose	Flu-like illness, hepatotoxicity, pancreatitis, leukopenia, macrocytosis, neoplasia, infection, teratogenicity	Blood count, liver enzymes
Methotrexate	Oral	7.5–20 mg weekly, single or divided doses; 1 day a week dosing	Hepatotoxicity, pulmonary fibrosis, infection, neoplasia, infertility, leukopenia, alopecia, gastric irritation, stomatitis, teratogenicity	Liver enzymes, blood count
	Subcutaneously	20–50 mg weekly; 1 day a week dosing	Same as oral	Same as oral
Cyclophosphamide	Oral Intravenous	1.5–2 mg/kg per day; single a.m. dose 0.5–1.0 g/m^2 per month × 6–12 months	Bone marrow suppression, infertility, hemorrhagic cystitis, alopecia, infections, neoplasia, teratogenicity	Blood count, urinalysis
Cyclosporine	Oral	4–6 mg/kg per day, split into two daily doses	Nephrotoxicity, hypertension, infection, hepatotoxicity, hirsutism, tremor, gum hyperplasia, teratogenicity	Blood pressure, creatinine/BUN, liver enzymes, cyclosporine levels
Tacrolimus	Oral	0.1–0.2 mg/kg per day in two divided doses	Nephrotoxicity, hypertension, infection, hepatotoxicity, hirsutism, tremor, gum hyperplasia, teratogenicity	Blood pressure, creatinine/BUN, liver enzymes, tacrolimus levels
Mycophenolate mofetil	Oral	Adults (1–1.5 g BID) Children (600 mg/m^2 per dose BID) (no >1 g/d in patients with renal failure)	Bone marrow suppression, hypertension, tremor, diarrhea, nausea, vomiting, headache, sinusitis, confusion, amblyopia, cough, teratogenicity, infection, neoplasia	Blood count
Intravenous immunoglobulin	Intravenous	2 g/kg over 2–5 days; then 1 g/kg every 4–8 weeks as needed	Hypotension, arrhythmia, diaphoresis, flushing, nephrotoxicity, headache, aseptic meningitis, anaphylaxis, stroke	Heart rate, blood pressure, creatinine/BUN
Rituximab	Intravenous	A course is typically 750 mg/m^2 (up to 1 g) and repeated in 2 weeks Courses are then repeated usually every 6–18 months	Infusion reactions (as per IVIG), infection, progressive multifocal leukoencephalopathy	Some check B-cell count prior to subsequent courses (but this may not be warranted)

Abbreviations: BUN, blood urea nitrogen; IVIG, intravenous immunoglobulin.

agents. An oral dose of 5 or 7.5 mg/week is initiated and then gradually increased as needed up to 25 mg/week. If there is no improvement after 1 month of 25 mg/week of oral methotrexate, a switch to weekly parenteral (usually subcutaneous) methotrexate is the next step, with dose escalation by 5 mg weekly; only rarely is a dose >35 mg/week used. The major side effects of methotrexate are alopecia, stomatitis, ILD, teratogenicity, oncogenicity, risk of infection, and pulmonary fibrosis, along with bone marrow, renal, and liver toxicity. Patients are concomitantly treated with folate or folinic acid.

Azathioprine A recommended initial dose is 50 mg/d in adults, which can be increased by 50 mg every 2 weeks up to 2–3 mg/kg per day. Approximately 12% of patients develop a systemic reaction characterized by fever, abdominal pain, nausea, vomiting, and anorexia that requires discontinuation of the drug. The major practical limitation of azathioprine is that 6–18 months of treatment are usually required before benefit can be seen. Patients can be prescreened for thiopurine methyltransferase (TPMT) deficiency that is associated with severe bone marrow toxicity from this drug.

Mycophenolate Mofetil This drug inhibits the proliferation of T and B lymphocytes by blocking purine synthesis. It appears to be effective in different forms of myositis and is the second-line treatment of choice for myositis patients with ILD. The starting dose is 1.0 g twice daily and can be increased to 3 g daily in divided doses, if necessary. Mycophenolate is excreted through the kidneys; therefore, the dose should be decreased (no >1 g/d total dose) in patients with renal insufficiency. An advantage of mycophenolate compared to other immunosuppressive agents is the lack of renal or hepatic toxicity.

Intravenous Immunoglobulin IVIG is used in patients refractory to prednisone and at least one second-line immunosuppressive agent, although recent reports suggest that it may be the treatment of choice and effective as a monotherapy in anti-HMGCR myopathy. A dose of 2 g/kg is divided over 2–5 days, and repeat infusions are given at monthly intervals for at least 3 months. Subsequently, intervals can be lengthened or dosage decreased: 2 g/kg every 2 months or 1 g/kg per month.

Rituximab Rituximab is a monoclonal antibody directed against CD20+ B cells. A large randomized controlled trial found no benefit, but there were flaws in the study design. Most authorities feel that rituximab can be beneficial in some patients who are refractory to prednisone and at least one of the other second-line agents. The typical dosage is 750 mg/m^2 (up to 1 g) IV with a second infusion 2 weeks later and with repeat courses (375 mg/m^2 as a single infusion or with a second infusion 2 weeks apart) every 6–18 months as needed.

MYOSITIS ASSOCIATED WITH CHECKPOINT INHIBITORS

Autoimmune neurologic complications, including inflammatory neuropathy, myasthenia gravis, and myositis, can occur with use of immune checkpoint inhibitors (anti-CTLA-4, anti-PD-1, and anti-PD-L1) to treat various cancers **(see Chaps. 447 and 448)**. Patients with myositis often develop muscle pain and weakness (axial musculature and proximal limbs) after one or two cycles. Myocarditis can also develop. Additionally, diplopia with extraocular weakness along with dysphagia and dysarthria suggesting the co-occurrence of myasthenia gravis (MG) may be present. In such cases, an elevated CK level helps support the diagnosis of myositis, while acetylcholine receptor antibodies or

decremental response on slow repetitive nerve stimulation can establish the diagnosis of MG. Endomysial inflammatory cell infiltrates composed of macrophages expressing PD-L1 and CD8+ lymphocytes expressing PD-1, overexpression of MHC-I on sarcolemma of muscle fibers, and scattered necrotic and regenerating fibers can be found on muscle biopsies.

The immune checkpoint inhibitor should be discontinued, but most patients require concurrent treatment with glucocorticoids or IVIG. Patients generally improve over several months, during which time immunotherapy can be tapered. There are rare reports of patients with mild myositis who were able to be successfully re-treated with an immune checkpoint inhibitor.

MYOSITIS ASSOCIATED WITH COVID-19 INFECTION

Early series of patients hospitalized with COVID-19 report that as many as 44% of patients experienced muscle pain or fatigue and 33% have elevated CK levels. Rare cases are complicated by myoglobinuria. Histopathology can demonstrate inflammatory cell infiltration and necrotic muscle fibers. A major concern during this pandemic is whether or not patients with inflammatory myopathies treated with various immunotherapies are more susceptible to infection with COVID-19 or at greater risk for severe complications. We strongly encourage our patients to wear masks and maintain social distancing.

GLOBAL ISSUES

There is a lack of epidemiologic data with regard to the incidence and prevalence of various subtypes of IM throughout the world. Complicating the issue is disease awareness and the inability to obtain and process muscle biopsies and MSAs, particularly in less developed countries. Nevertheless, each of these disorders occurs throughout the world. The specific environmental triggers and genetic risk factors are likely variable. Interestingly, a report from Japan found that 28% of IBM patients had evidence of exposure to hepatitis C, which was much higher than seen in the Western Hemisphere and also more common than seen in PM and healthy population controls in Japan. HIV-associated PM and IBM are more commonly encountered in areas endemic for HIV, and recent studies suggest most of these "PM" patients turn out to have IBM and can develop symptoms at an earlier age (e.g., in the 30s). Pyomyositis and parasitic myositis are clearly more common in the tropics. The prevalence of different types of cancers varies in different parts of the world, an important consideration with respect to paraneoplastic myositis seen in DM, PM, and IMNM. For example, nasopharyngeal cancer is particularly common in Asia; thus, assessment for this type of cancer should be considered in the workup of patients from high-risk regions.

366 Relapsing Polychondritis

Carol A. Langford

Relapsing polychondritis is an uncommon disorder of unknown cause characterized by inflammation of cartilage predominantly affecting the ears, nose, and laryngotracheobronchial tree. Multisystem disease occurs commonly and can also involve noncartilaginous tissues and organs. Relapsing polychondritis has been estimated to have an annual incidence of 3.5 per million. The peak age of onset is between 40 and 50 years, but the disease can be seen in all ages with both sexes being equally affected. Approximately 30% of patients with relapsing polychondritis will have another rheumatologic disorder, most frequently systemic vasculitis, rheumatoid arthritis, or systemic lupus erythematosus (SLE). Nonrheumatic disorders have also been associated with relapsing polychondritis **(Table 366-1)**. In most cases, these disorders antedate the appearance of relapsing polychondritis, usually by months or years; however, in other instances, the onset of relapsing polychondritis can accompany disease presentation.

PATHOLOGY AND PATHOPHYSIOLOGY

The earliest abnormality of hyaline and elastic cartilage noted histologically is a focal or diffuse loss of basophilic staining indicating depletion of proteoglycan from the cartilage matrix. Inflammatory infiltrates are found adjacent to involved cartilage and consist predominantly of mononuclear cells and occasional plasma cells. In acute disease,

TABLE 366-1 Disorders Associated with Relapsing Polychondritis[a]

Primary biliary cirrhosis
Pulmonary fibrosis
Hashimoto's thyroiditis
Graves' disease
Crohn's disease
Ulcerative colitis
Myelodysplastic syndrome

[a]Systemic vasculitis is the most common association, followed by rheumatoid arthritis and systemic lupus erythematosus.

Source: Modified from CJ Michet et al: Ann Intern Med 104:74, 1986.

polymorphonuclear white cells may also be present. Destruction of cartilage begins at the outer edges and advances centrally. There is lacunar breakdown and loss of chondrocytes. Degenerating cartilage is replaced by granulation tissue and later by fibrosis and focal areas of calcification. Small loci of cartilage regeneration may be present. Extracellular granular material observed in the degenerating cartilage matrix by electron microscopy has been interpreted to be enzymes, immunoglobulins, or proteoglycans.

The available data suggest that both humoral and cell-mediated immunity play an important role in the pathogenesis of relapsing polychondritis. Immunoglobulin and complement deposits are found at sites of inflammation. In addition, antibodies to type II collagen and to matrilin-1 and immune complexes are detected in the sera of some patients. The possibility that an immune response to type II collagen may be important in the pathogenesis is supported experimentally by the occurrence of auricular chondritis in rats immunized with type II collagen. Antibodies to type II collagen are found in the sera of these animals, and immune deposits are detected at sites of ear inflammation. Humoral immune responses to type IX and type XI collagen, matrilin-1, and cartilage oligomeric matrix protein have been demonstrated in some patients. Matrilin-1 is a noncollagenous protein present in the extracellular matrix in cartilage. It is present in high concentrations in the trachea and is also present in the nasal septum but not in articular cartilage. In one study, rats immunized with matrilin-1 were found to develop severe inspiratory stridor and swelling of the nasal septum but without involvement of the joint or ear cartilage. The rats had severe inflammation with erosions of the involved cartilage, which was characterized by increased numbers of CD4+ and CD8+ T cells in the lesions, and all had IgG antibodies to matrilin-1. A subsequent study demonstrated serum anti-matrilin-1 antibodies in ~13% of patients with relapsing polychondritis; ~70% of these patients had respiratory symptoms. Cell-mediated immunity may also be operative in causing tissue injury, since lymphocyte transformation can be demonstrated when lymphocytes of patients are exposed to cartilage extracts. T cells specific for type II collagen have been found in some patients, and CD4+ T cells have been observed at sites of cartilage inflammation. Genetic background may also play a role in disease development. A significantly higher frequency of HLA-DR4 has been found in patients with relapsing polychondritis than in healthy individuals, although a predominant subtype allele(s) was not found.

CLINICAL MANIFESTATIONS

The onset of relapsing polychondritis is frequently abrupt, with the appearance of one or two sites of cartilaginous inflammation. The pattern of cartilaginous involvement and the frequency of episodes vary widely among patients. Noncartilaginous presentations may also occur. Systemic inflammatory features such as fever, fatigue, and weight loss commonly occur and may precede other clinical signs. Relapsing polychondritis may go unrecognized for several months or even years in patients who only initially manifest intermittent joint pain and/or swelling or who have unexplained eye inflammation, hearing loss, valvular heart disease, or pulmonary symptoms. Recent studies have suggested that relapsing polychondritis may present in different subgroups that vary in time to diagnosis, clinical and radiologic characteristics, and disease-related complications. Although further investigation will be necessary to determine how these subgroups may impact treatment and outcome, recognition of disease patterns beyond cartilaginous involvement may facilitate diagnosis.

Auricular chondritis is the most frequent presenting manifestation of relapsing polychondritis, occurring in 40% of patients and eventually affecting ~85% of patients **(Table 366-2)**. One or both ears are involved, either sequentially or simultaneously. Patients experience the sudden onset of pain, tenderness, and swelling of the cartilaginous portion of the ear. This typically involves the pinna of the ears, sparing the earlobes because they do not contain cartilage. The overlying skin has a beefy red or violaceous color. Prolonged or recurrent episodes lead to cartilage destruction and result in a droopy ear. Swelling may close off the eustachian tube or the external auditory meatus, either of which can impair hearing. Inflammation of the internal auditory artery or its cochlear branch produces hearing loss, vertigo, ataxia, nausea, and vomiting. Vertigo is almost always accompanied by hearing loss.

TABLE 366-2 Clinical Manifestations of Relapsing Polychondritis

CLINICAL FEATURE	PRESENTING	CUMULATIVE
	Frequency, %	
Auricular chondritis	43	89
Arthritis	32	72
Nasal chondritis	21	61
Ocular inflammation	18	59
Laryngotracheal symptoms	23	55
Reduced hearing	7	40
Saddle nose deformity	11	25
Cutaneous	4	25
Laryngotracheal stricture	15	23
Vasculitis	2	14
Elevated creatinine	7	13
Aortic or mitral regurgitation	0	12

Source: Reproduced with permission from PD Kent et al: Relapsing polychondritis. Curr Opin Rheumatology 16:56, 2004. *https://pubmed.ncbi.nlm.nih.gov/14673390/.*

Approximately 61% of patients will develop nasal involvement, with 21% having this at the time of presentation. Patients may experience nasal congestion, rhinorrhea, and epistaxis. The bridge of the nose and surrounding tissue become red, swollen, and tender and may collapse, producing a saddle nose deformity **(Fig. 366-1)**. In some patients, nasal deformity develops insidiously without overt inflammation. Saddle nose is observed more frequently in younger patients, especially in women.

Joint involvement is the presenting manifestation in relapsing polychondritis in approximately one-third of patients and may be present for several months before other features appear. Eventually, more than one-half of the patients will have arthralgias or arthritis. The arthritis

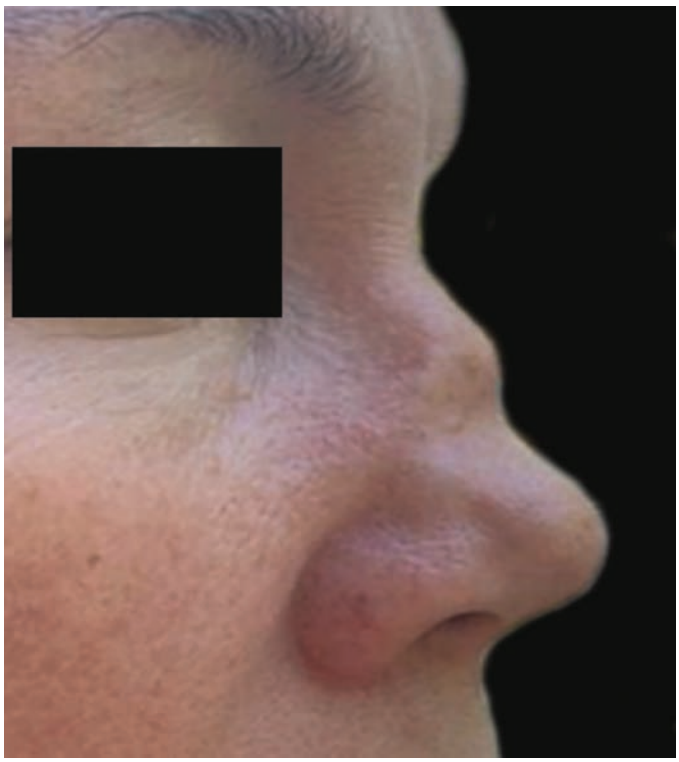

FIGURE 366-1 Saddle nose resulting from destruction and collapse of the nasal cartilage. *(Image courtesy of Marcela Ferrada, MD)*

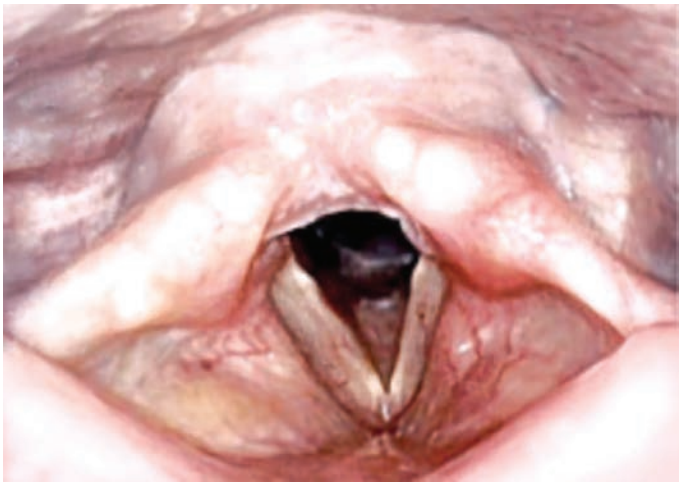

FIGURE 366-2 Narrowing of the subglottis occurring as a result of laryngotracheal involvement in relapsing polychondritis. *(Image courtesy of Marcela Ferrada, MD)*

is usually asymmetric and oligo- or polyarticular, and it involves both large and small peripheral joints. An episode of arthritis lasts from a few days to several weeks and resolves spontaneously without joint erosion or deformity. Attacks of arthritis may not be temporally related to other manifestations of relapsing polychondritis. Joint fluid has been reported to be noninflammatory. In addition to peripheral joints, inflammation may involve the costochondral, sternomanubrial, and sternoclavicular cartilages. Destruction of these cartilages may result in a pectus excavatum deformity or even a flail anterior chest wall.

Eye manifestations occur in more than one-half of patients and include conjunctivitis, episcleritis, scleritis, iritis, uveitis, and keratitis. Ocular inflammation can be severe and visually threatening. Other manifestations include eyelid and periorbital edema, proptosis, optic neuritis, extraocular muscle palsies, retinal vasculitis, and renal vein occlusion.

Laryngotracheobronchial involvement occurs in ~50% of patients and is among the most serious manifestations of relapsing polychondritis **(Fig. 366-2)**. Symptoms include hoarseness, a nonproductive cough, and tenderness over the larynx and proximal trachea. Mucosal edema, strictures, and/or collapse of laryngeal or tracheal cartilage may cause stridor and life-threatening airway obstruction necessitating tracheostomy. Involvement can extend into the lower airways resulting in tracheobronchomalacia. Collapse of cartilage in bronchi leads to pneumonia and, when extensive, to respiratory insufficiency.

Cardiac valvular regurgitation occurs in ~5–10% of patients and is due to progressive dilation of the valvular ring or to destruction of the valve cusps. Aortic regurgitation occurs in ~7% of patients, with the mitral and other heart valves being affected less often. Other cardiac manifestations include pericarditis, myocarditis, coronary vasculitis, and conduction abnormalities. Aneurysms of the proximal, thoracic, or abdominal aorta may occur even in the absence of active chondritis and occasionally rupture.

Renal disease occurs in ~10% of patients. The most common renal lesions include mesangial expansion or segmental necrotizing glomerulonephritis, which often have small amounts of electron-dense deposits in the mesangium where there is also faint deposition of C3 and/or IgG or IgM. Tubulointerstitial disease and IgA nephropathy have also been reported.

Approximately 25% of patients have skin lesions, which can include purpura, erythema nodosum, erythema multiforme, angioedema/urticaria, livedo reticularis, and panniculitis.

Features of vasculitis are seen in up to 25% of patients and can affect any size vessel. Large vessel vasculitis may present with aortic aneurysms, and medium vessel disease may affect the coronary, hepatic, mesenteric, or renal arteries or vessel-supplying nerves. Cutaneous vasculitis can also occur. A variety of primary vasculitides have also been reported to occur in association with relapsing polychondritis **(Chap. 363)**. One specific overlap is the "MAGIC" syndrome (*m*outh *a*nd *g*enital ulcers with *i*nflamed *c*artilage) in which patients present with features of both relapsing polychondritis and Behçet's disease **(Chap. 364)**.

Relapsing polychondritis has also been found to be associated with VEXAS syndrome (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic). VEXAS syndrome should be considered in male patients with relapsing polychondritis who have hematologic abnormalities often in the spectrum of myelodysplastic syndrome, fevers, venous thrombotic events, pulmonary infiltrates, cutaneous lesions, or treatment resistant disease. VEXAS syndrome is strongly suggested by its clinical features and the finding of vacuoles within bone marrow precursor cells. It is proven by genetic testing for myeloid-restricted somatic missense mutations in UBA1, the major E1 enzyme that initiates ubiquitylation.

LABORATORY FINDINGS AND DIAGNOSTIC IMAGING

There are no laboratory features that are diagnostic for relapsing polychondritis. Mild leukocytosis and normocytic, normochromic anemia are often present. Eosinophilia is observed in 10% of patients. The erythrocyte sedimentation rate and C-reactive protein are usually elevated. Rheumatoid factor and antinuclear antibody tests are occasionally positive in low titers, and complement levels are normal. Antibodies to type II collagen are present in fewer than one-half of patients and are not specific. Circulating immune complexes may be detected, especially in patients with early active disease. Elevated levels of γ globulin may be present. Antineutrophil cytoplasmic antibodies (ANCA), either cytoplasmic (cANCA) or perinuclear (pANCA), are found in some patients with active disease. However, on target antigen–specific testing, there are only occasional reports of positive myeloperoxidase-ANCA, and proteinase 3-ANCA are very rarely found in relapsing polychondritis.

The upper and lower airways can be evaluated by imaging techniques such as computed tomography (CT) and magnetic resonance (MR). Dynamic inspiratory and expiratory CT imaging can be useful in assessing airway involvement. Bronchoscopy provides direct visualization of the airways but can be a high-risk procedure in patients with airway compromise. Pulmonary function testing with flow-volume loops can show inspiratory and/or expiratory obstruction.

Imaging can also be useful to detect extracartilaginous disease. Arteriography by CT or MR should be pursued if features are present suggesting aortic or other large vessel involvement. Electrocardiography and echocardiography can be useful in further evaluating for cardiac features of disease. A number of reports have described the use of positron emission tomography in relapsing polychondritis, but it is currently unclear if this is useful and for what features.

DIAGNOSIS

Diagnosis is based on recognition of the typical clinical features. Biopsies of the involved cartilage from the ear, nose, or respiratory tract can confirm the diagnosis but are only necessary when clinical features are not typical and may be difficult to obtain. Diagnostic criteria were suggested in 1976 by McAdam et al and included biopsy evidence combined with three of the following: (1) recurrent chondritis of both auricles; (2) nonerosive inflammatory arthritis; (3) chondritis of nasal cartilage; (4) inflammation of ocular structures, including conjunctivitis, keratitis, scleritis/episcleritis, and/or uveitis; (5) chondritis of the laryngeal and/or tracheal cartilages; and (6) cochlear and/or vestibular damage manifested by neurosensory hearing loss, tinnitus, and/or vertigo. In 1979, Damiani and Levine suggested that the diagnosis could be made when one or more of the above features and a positive biopsy were present, when two or more separate sites of cartilage inflammation were present that responded to treatment, or when three or more of the above features were present.

The differential diagnosis of relapsing polychondritis is centered around its sites of clinical involvement. Patients with granulomatosis with polyangiitis may have a saddle nose and tracheal involvement but can be distinguished by the primary inflammation occurring in the mucosa at these sites, the absence of auricular involvement, and the presence of pulmonary parenchymal disease. Patients with

Cogan's syndrome have interstitial keratitis and vestibular and auditory abnormalities, but this syndrome does not involve the respiratory tract or ears. Reactive arthritis may initially resemble relapsing polychondritis because of oligoarticular arthritis and eye involvement, but it is distinguished by the occurrence of urethritis and typical mucocutaneous lesions and the absence of nose or ear cartilage involvement. Rheumatoid arthritis may initially suggest relapsing polychondritis because of arthritis and eye inflammation, although the arthritis is erosive and symmetric. In addition, rheumatoid factor titers are usually high compared with those in relapsing polychondritis, and anti-cyclic citrullinated peptide is usually not seen. Bacterial infection of the pinna may be mistaken for relapsing polychondritis but differs by usually involving only one ear, including the earlobe. Auricular cartilage may also be damaged by trauma or frostbite. Nasal destructive disease and auricular abnormalities can also be seen in patients using cocaine adulterated with levamisole. Ear involvement in this setting differs from relapsing polychondritis by typically manifesting as purpuric plaques with necrosis extending to the earlobe, which does not contain cartilage.

TREATMENT

Relapsing Polychondritis

In patients with active chondritis, prednisone, 40–60 mg/d, is often effective in suppressing disease activity; it is tapered gradually once disease is controlled. In some patients, prednisone can be stopped, whereas in others, low doses in the range of 5–10 mg/d are required for continued suppression of disease. Other immunosuppressive drugs such as cyclophosphamide, methotrexate, azathioprine, mycophenolate mofetil, or cyclosporine should be used in patients who have severe organ-threatening disease, fail to respond to prednisone, or require high doses to control disease activity. There has been significant interest in the use of biologic agents to treat relapsing polychondritis. Tumor necrosis factor inhibitors have been the most widely examined therapies to date, and although benefit has been suggested, this has come solely from retrospective cases and series. Other agents with which there have been published reports include anakinra, rituximab, tocilizumab, and abatacept, but reports are too few in number to assess efficacy. Dapsone has also been used in selected settings but has largely been supplanted by other approaches and should not be used for severe disease. Heart valve replacement or repair of an aortic aneurysm may be necessary. When airway obstruction is severe, tracheostomy is required. Stents may be necessary in patients with tracheobronchial collapse.

PATIENT OUTCOME, PROGNOSIS, AND SURVIVAL

The course of relapsing polychondritis is highly variable. Some patients experience inflammatory episodes lasting from a few days to several weeks that then subside spontaneously or with treatment. Attacks may recur at intervals varying from weeks to months. In other patients, the disease has a chronic, smoldering course that may be severe. In one study, the 5-year estimated survival rate was 74%, and the 10-year survival rate was 55%. About one-half of the deaths could be attributed to relapsing polychondritis or complications of treatment. Airway complications accounted for 10% of all fatalities, although higher rates have been reported in other series. In general, patients with more widespread disease have a worse prognosis.

367 Sarcoidosis

Robert P. Baughman, Elyse E. Lower

DEFINITION

Sarcoidosis is an inflammatory disease characterized by the presence of noncaseating granulomas. The disease is often multisystemic and requires the presence of involvement in two or more organs for a specific diagnosis. The finding of granulomas is not specific for sarcoidosis, and other conditions known to cause granulomas must be ruled out. These conditions include mycobacterial and fungal infections, malignancy, and environmental agents such as beryllium. Although sarcoidosis can affect virtually every organ of the body, the lung is most commonly affected. Other organs commonly affected are the liver, skin, and eye. The clinical outcome of sarcoidosis varies, with remission occurring in over one-half of patients within a few years of diagnosis; however, the remaining patients may develop chronic disease that lasts for decades.

ETIOLOGY

Despite multiple investigations, the cause of sarcoidosis remains unknown. Currently, the most likely etiology is an infectious or noninfectious environmental agent that triggers an inflammatory response in a genetically susceptible host. Among the possible infectious agents, careful studies have shown a much higher incidence of *Propionibacterium acnes* in the lymph nodes of sarcoidosis patients compared to controls. An animal model has shown that *P. acnes* can induce a granulomatous response in mice similar to sarcoidosis. Others have demonstrated the presence of a mycobacterial protein (*Mycobacterium tuberculosis* catalase-peroxidase [mKatG]) in the granulomas of some sarcoidosis patients. This protein is very resistant to degradation and may represent the persistent antigen in sarcoidosis. Immune response to this and other mycobacterial proteins has been documented by another laboratory. These studies suggest that a *Mycobacterium* similar to *M. tuberculosis* could be responsible for sarcoidosis. The mechanism exposure/infection with such agents has been the focus of other studies. Environmental exposures to insecticides and mold have been associated with an increased risk for disease. In addition, health care workers appear to have an increased risk. Also, sarcoidosis in a donor organ has occurred after transplantation into a sarcoidosis patient. Some authors have suggested that sarcoidosis is not due to a single agent but represents a particular host response to multiple agents. Some studies have been able to correlate environmental exposures to genetic markers. These studies have supported the hypothesis that a genetically susceptible host is a key factor in the disease.

INCIDENCE, PREVALENCE, AND GLOBAL IMPACT

Sarcoidosis is seen worldwide, with the highest prevalence reported in the Nordic population. In the United States, the disease has been reported more commonly in African Americans than whites, with the ratio of African Americans to whites ranging from 3:1 to 17:0. In the United States, women are more susceptible than men. The higher incidence in African Americans may have been influenced by the fact that African Americans seem to develop more extensive and chronic pulmonary disease. Because most sarcoidosis clinics are run

by pulmonologists, a selection bias may have occurred. Worldwide, the prevalence of the disease varies from 20–60 per 100,000 for many groups such as Japanese, Italians, and American whites. Higher rates occur in Ireland and Nordic countries. In one closely observed community in Sweden, the lifetime risk for developing sarcoidosis was 3%.

Sarcoidosis often occurs in young, otherwise healthy adults. It is uncommon to diagnose the disease in someone aged <18 years. However, it has become clear that a second peak in incidence develops around age 60. In a study of nearly 30,000 sarcoidosis patients in the United States, the median age at diagnosis was 55.

Although most cases of sarcoidosis are sporadic, a familial form of the disease exists. At least 5% of patients with sarcoidosis will have a family member with sarcoidosis. Sarcoidosis patients who are Irish or African American seem to have a two to three times higher rate of familial disease.

PATHOPHYSIOLOGY AND IMMUNOPATHOGENESIS

The granuloma is the pathologic hallmark of sarcoidosis. A distinct feature of sarcoidosis is the local accumulation of inflammatory cells. Extensive studies in the lung using bronchoalveolar lavage (BAL) have demonstrated that the initial inflammatory response is an influx of T helper cells. In addition, there is an accumulation of activated monocytes. **Figure 367-1** is a proposed model for sarcoidosis. Using the HLA-CD4 complex, antigen-presenting cells present an unknown antigen to the helper T cell. Studies have clarified that specific human leukocyte antigen (HLA) haplotypes such as HLA-DRB1*1101 are associated with an increased risk for developing sarcoidosis. In addition, different HLA haplotypes are associated with different clinical outcomes.

The macrophage/helper T-cell cluster leads to activation with the increased release of several cytokines. These include interleukin (IL) 2 released from the T cell and interferon γ and tumor necrosis factor (TNF) released by the macrophage. The T cell is a necessary part of the initial inflammatory response. In advanced, untreated HIV infection, patients who lack helper T cells rarely develop sarcoidosis. In contrast, several reports confirm that sarcoidosis becomes unmasked as HIV-infected individuals receive antiretroviral therapy, with subsequent restoration of their immune system. In contrast, treatment of established pulmonary sarcoidosis with cyclosporine, a drug that downregulates helper T-cell responses, seems to have little impact on sarcoidosis.

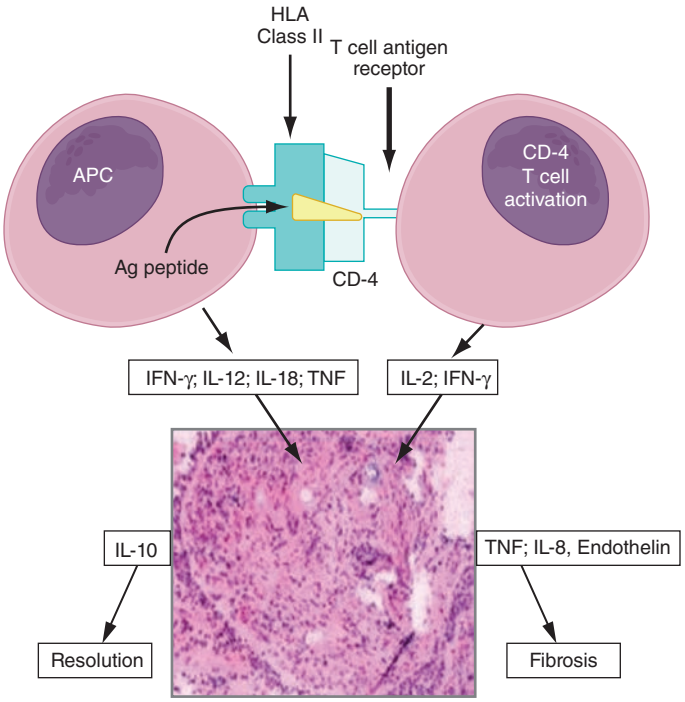

FIGURE 367-1 Schematic representation of initial events of sarcoidosis. The antigen-presenting cell and helper T-cell complex leads to the release of multiple cytokines. This forms a granuloma. Over time, the granuloma may resolve or lead to chronic disease, including fibrosis. APC, antigen-presenting cell; HLA, human leukocyte antigen; IFN, interferon; IL, interleukin; TNF, tumor necrosis factor.

The granulomatous response of sarcoidosis can resolve with or without therapy. However, in at least 20% of patients with sarcoidosis, a chronic form of the disease develops. This persistent form of the disease is associated with increased levels in blood and/or BAL of IL-8, IL-17, and CXCL9. Also, studies have reported that patients with this chronic form of disease release excessive amounts of TNF in areas of inflammation. Specific gene signatures have been associated with more severe disease, such as cardiac, neurologic, and fibrotic pulmonary disease.

At diagnosis, the natural history of the disease may be difficult to predict. One form of the disease, *Löfgren's syndrome*, consists of erythema nodosum and hilar adenopathy on chest roentgenogram. In some cases, periarticular arthritis may be identified without erythema nodosum. Löfgren's syndrome is associated with a good prognosis, with >90% of patients experiencing disease resolution within 2 years. Recent studies have demonstrated that the HLA-DRB1*03 was found in two-thirds of Scandinavian patients with Löfgren's syndrome. More than 95% of those patients who were HLA-DRB1*03 positive had resolution of their disease within 2 years, whereas nearly one-half of the remaining patients had disease for >2 years. It remains to be determined whether these observations can be applied to a non-Scandinavian population.

CLINICAL MANIFESTATIONS

The presentation of sarcoidosis ranges from patients who are asymptomatic to those with organ failure. It is unclear how often sarcoidosis is asymptomatic. In countries where routine chest roentgenogram screening is performed, 20–30% of pulmonary cases are detected in asymptomatic individuals. The inability to screen for other asymptomatic forms of the disease would suggest that as many as one-third of sarcoidosis patients are asymptomatic.

Respiratory complaints including cough and dyspnea are the most common presenting symptoms. In many cases, the patient presents with a 2- to 4-week history of these symptoms. Unfortunately, due to the nonspecific nature of pulmonary symptoms, the patient may see physicians for up to a year before a diagnosis is confirmed. For these patients, the diagnosis of sarcoidosis is usually only suggested when a chest roentgenogram is performed.

Symptoms related to cutaneous and ocular disease are the next two most common complaints. Skin lesions are often nonspecific. However, because these lesions are readily observed, the patient and treating physician are often led to a diagnosis. In contrast to patients with pulmonary disease, patients with cutaneous lesions are more likely to be diagnosed within 6 months of symptoms.

Nonspecific constitutional symptoms include fatigue, fever, night sweats, and weight loss. Fatigue is perhaps the most common constitutional symptom that affects these patients. Given its insidious nature, patients are usually not aware of the association with their sarcoidosis until their disease resolves.

The overall incidence of sarcoidosis at the time of diagnosis and eventual common organ involvement are summarized in **Table 367-1**. Over time, skin, eye, and neurologic involvement seem more apparent. In the United States, the frequency of specific organ involvement appears to be affected by age, race, and gender. For example, eye disease is more common among African Americans. Under the age of 40, it occurs more frequently in women. However, in those diagnosed over the age of 40, eye disease is more common in men.

LUNG

Lung involvement occurs in >90% of sarcoidosis patients. The most commonly used method for detecting lung disease is still the chest roentgenogram. **Figure 367-2** illustrates the chest roentgenogram from a sarcoidosis patient with bilateral hilar adenopathy. Although the CT scan has changed the diagnostic approach to interstitial lung disease, it is not usually considered a monitoring tool for patients with sarcoidosis except for those with pulmonary fibrosis. **Figure 367-3** demonstrates some of the characteristic CT features, including peribronchial thickening and reticular nodular changes, which are predominantly

TABLE 367-1 Frequency of Common Organ Involvement and Lifetime Risk[a]

	PRESENTATION, %[b]	FOLLOW-UP, %[c]
Lung	95	94
Skin	24	43
Eye	12	29
Extrathoracic lymph node	15	16
Liver	12	14
Spleen	7	8
Neurologic	5	16
Cardiac	2	3

[a]Patients could have more than one organ involved. [b]From ACCESS study of 736 patients evaluated within 6 months of diagnosis. [c]From follow-up of 1024 sarcoidosis patients seen at the University of Cincinnati Interstitial Lung Disease and Sarcoidosis Clinic from 2002 to 2006.

subpleural. The peribronchial thickening seen on CT seems to explain the high yield of granulomas from bronchial biopsies performed for diagnosis.

Although the CT scan is more sensitive, the standard scoring system described by Scadding in 1961 for chest roentgenograms remains the preferred method of characterizing chest involvement. Stage 1 is hilar adenopathy alone (Fig. 367-2), often with right paratracheal involvement. Stage 2 is a combination of adenopathy plus infiltrates, whereas stage 3 reveals infiltrates alone. Stage 4 consists of fibrosis. Usually the infiltrates in sarcoidosis are predominantly an upper lobe process. Only in a few noninfectious diseases is an upper lobe predominance noted. In addition to sarcoidosis, the differential diagnosis of upper lobe disease includes hypersensitivity pneumonitis, silicosis, and Langerhans cell histiocytosis. For infectious diseases, tuberculosis and *Pneumocystis* pneumonia can often present as upper lobe diseases.

Lung volumes, mechanics, and diffusion are all useful in evaluating interstitial lung diseases such as sarcoidosis. The diffusion of carbon monoxide (DL_{CO}) is the most sensitive test for interstitial lung disease. Reduced lung volumes are a reflection of the restrictive lung disease seen in sarcoidosis. However, a third of the patients presenting with sarcoidosis still have lung volumes within the normal range, despite abnormal chest roentgenograms and dyspnea.

Approximately one-half of sarcoidosis patients present with obstructive disease, reflected by a reduced ratio of forced expiratory volume in 1 s to forced vital capacity (FEV_1/FVC). Cough is a very common symptom. Airway involvement causing varying degrees of obstruction underlies the cough in most sarcoidosis patients. Airway

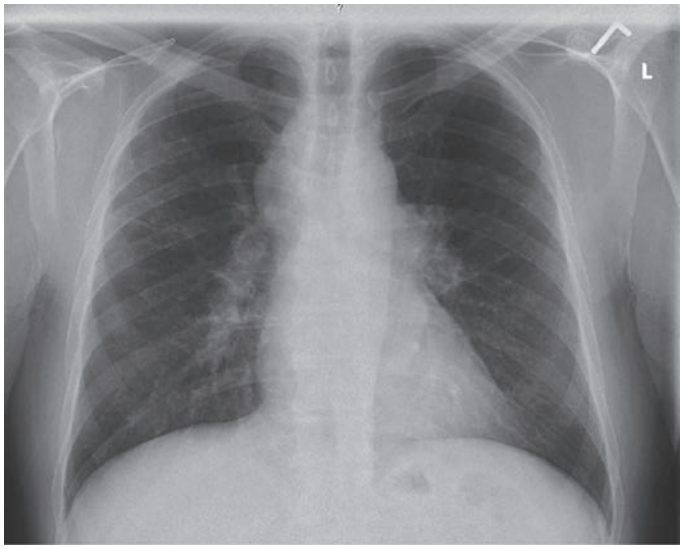

FIGURE 367-2 Posterior-anterior chest roentgenogram demonstrating bilateral hilar adenopathy, stage 1 disease.

FIGURE 367-3 High-resolution CT scan of the chest demonstrating patchy reticular nodularity, including areas of confluence.

hyperreactivity, as determined by methacholine challenge, will be positive in some of these patients. A few patients with cough will respond to traditional bronchodilators as the only form of treatment. In some cases, high-dose inhaled glucocorticoids alone are useful. Airway obstruction can be due to large airway stenosis, which can become fibrotic and unresponsive to anti-inflammatory therapy.

Pulmonary arterial hypertension is reported in at least 5% of sarcoidosis patients. Either direct vascular involvement or the consequence of fibrotic changes in the lung can lead to pulmonary arterial hypertension. In sarcoidosis patients with end-stage fibrosis awaiting lung transplant, 70% will have pulmonary arterial hypertension. This is a much higher incidence than that reported for other fibrotic lung diseases. In less advanced but still symptomatic patients, pulmonary arterial hypertension has been noted in up to 50% of cases. Because sarcoidosis-associated pulmonary arterial hypertension may respond to therapy, evaluation for this should be considered in persistently dyspneic patients.

SKIN

Skin involvement is eventually identified in over a third of patients with sarcoidosis. The classic cutaneous lesions include erythema nodosum, maculopapular lesions, hyper- and hypopigmentation, keloid formation, and subcutaneous nodules. A specific complex of involvement of the bridge of the nose, the area beneath the eyes, and the cheeks is referred to as *lupus pernio* **(Fig. 367-4)** and is diagnostic for a chronic form of sarcoidosis.

In contrast, erythema nodosum is a transient rash that can be seen in association with hilar adenopathy and uveitis (Löfgren's syndrome). Erythema nodosum is more common in women and in certain self-described demographic groups including whites and Puerto Ricans. In the United States, the other manifestations of skin sarcoidosis, especially lupus pernio, are more common in African Americans than whites.

The maculopapular lesions from sarcoidosis are the most common chronic form of the disease **(Fig. 367-5)**. These are often overlooked by the patient and physician because they are chronic and not painful. Initially, these lesions are usually purplish papules and are often indurated. They can become confluent and infiltrate large areas of the skin. With treatment, the color and induration may fade. Because these lesions are caused by noncaseating granulomas, the diagnosis of sarcoidosis can be readily made by a skin biopsy.

EYE

The frequency of ocular manifestations for sarcoidosis varies depending on race. In Japan, >70% of sarcoidosis patients develop ocular disease, whereas in the United States, only 30% have eye disease, with

FIGURE 367-4 Chronic inflammatory lesions around the nose, eyes, and cheeks, referred to as *lupus pernio.*

problems more common in African Americans than whites. Although the most common manifestation is anterior uveitis, over a quarter of patients will have inflammation at the posterior of the eye, including retinitis and pars planitis. Although symptoms such as photophobia, blurred vision, and increased tearing can occur, some asymptomatic patients still have active inflammation. Initially asymptomatic patients with ocular sarcoidosis can eventually develop blindness. Therefore, it is recommended that all patients with sarcoidosis receive a dedicated ophthalmologic examination. Sicca is seen in over one-half of chronic sarcoidosis patients. Dry eyes appear to be a reflection of prior lacrimal gland disease. Although the patient may no longer have active inflammation, dry eyes may require natural tears or other lubricants.

LIVER

Using biopsies to detect granulomatous disease, liver involvement can be identified in over one-half of sarcoidosis patients. However, using liver function studies, only 20–30% of patients will have evidence of liver involvement. The most common abnormality of liver function is an elevation of the alkaline phosphatase level, consistent with an obstructive pattern. In addition, elevated transaminase levels can occur. An elevated bilirubin level is a marker for more advanced liver disease. Overall, only 5% of sarcoidosis patients have sufficient symptoms from their liver disease to require specific therapy. Although symptoms can be due to hepatomegaly, more frequently symptoms result from extensive intrahepatic cholestasis leading to portal hypertension. In this case, ascites and esophageal varices can occur. It is rare that a sarcoidosis patient will require a liver transplant because even the patient with cirrhosis due to sarcoidosis can respond to systemic therapy.

BONE MARROW AND SPLEEN

One or more bone marrow manifestations can be identified in many sarcoidosis patients. The most common hematologic problem is lymphopenia, which is a reflection of sequestration of the lymphocytes into the areas of inflammation. Anemia occurs in 20% of patients, and leukopenia is less common. A bone marrow examination will reveal granulomas in about a third of patients. Although splenomegaly can be detected in 5–10% of patients, splenic biopsy reveals granulomas in 60% of patients. The CT scan can be relatively specific for sarcoidosis involvement of the spleen **(Fig. 367-6)**. Both bone marrow and spleen involvement are more common in African Americans than whites. Although these manifestations alone are rarely an indication for therapy, on rare occasion, splenectomy may be indicated for massive symptomatic splenomegaly or profound pancytopenia. Nonthoracic lymphadenopathy can occur in up to 20% of patients.

CALCIUM METABOLISM

Hypercalcemia and/or hypercalciuria occur in ~10% of sarcoidosis patients. It is more common in whites than African Americans and in men. The mechanism of abnormal calcium metabolism is increased production of 1,25-dihydroxyvitamin D by the granuloma itself. The 1,25-dihydroxyvitamin D causes increased intestinal absorption of calcium, leading to hypercalcemia with a suppressed parathyroid hormone (PTH) level **(Chap. 410)**. Increased exogenous vitamin D from diet or sunlight exposure may exacerbate this problem. Serum calcium should be determined as part of the initial evaluation of all sarcoidosis patients, and a repeat determination may be useful during the summer months with increased sun exposure. In patients with a history of renal calculi, a 24-h urine calcium measurement should be obtained. If a sarcoidosis patient with a history of renal calculi is to be placed on calcium supplements, a follow-up 24-h urine calcium level should be measured.

FIGURE 367-5 Maculopapular lesions on the trunk of a sarcoidosis patient.

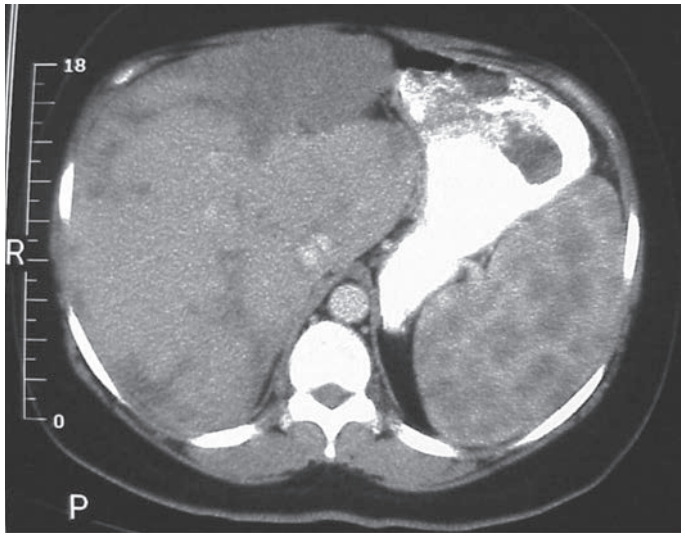

FIGURE 367-6 CT scan of the abdomen after oral and intravenous contrast. The stomach is compressed by the enlarged spleen. Within the spleen, areas of hypo- and hyperdensity are identified.

RENAL DISEASE

Direct kidney involvement occurs in <5% of sarcoidosis patients. It is associated with granulomas in the kidney itself and can lead to nephritis. However, hypercalcemia is the most likely cause of sarcoidosis-associated renal disease. In 1–2% of sarcoidosis patients, acute renal failure may develop as a result of hypercalcemia. Successful treatment of hypercalcemia with glucocorticoids and other therapies often improves but usually does not totally resolve renal dysfunction.

NERVOUS SYSTEM

Neurologic disease is reported in 5–10% of sarcoidosis patients and appears to be of equal frequency across all ethnic groups. Any part of the central or peripheral nervous system can be affected. The presence of granulomatous inflammation is often visible on MRI studies. MRI with gadolinium enhancement may demonstrate space-occupying lesions, but the MRI can be negative due to small lesions or the effect of systemic therapy in reducing the inflammation. Cerebral spinal fluid (CSF) findings include lymphocytic meningitis with a mild increase in protein. The CSF glucose level is usually normal but can be low. Certain areas of the nervous system are more commonly affected in neurosarcoidosis. These include cranial nerve involvement, basilar meningitis, myelopathy, and anterior hypothalamic disease with associated diabetes insipidus **(Chap. 381)**. Seizures and cognitive changes also occur. Of the cranial nerves, seventh nerve paralysis can be transient and mistaken for Bell's palsy (idiopathic seventh nerve paralysis). Because this form of neurosarcoidosis often resolves within weeks and may not recur, it may have occurred prior to a definitive diagnosis of sarcoidosis. Optic neuritis is another cranial nerve manifestation of sarcoidosis. This manifestation is more chronic and usually requires long-term systemic therapy. It can be associated with both anterior and posterior uveitis. Differentiating between neurosarcoidosis and multiple sclerosis can be difficult at times. Optic neuritis can occur in both diseases. In some patients with sarcoidosis, multiple enhancing white matter abnormalities may be detected by MRI, suggesting multiple sclerosis. In such cases, the presence of meningeal enhancement or hypothalamic involvement suggests neurosarcoidosis, as does evidence of extraneurologic disease such as pulmonary or skin involvement, which also suggests sarcoidosis. Because the response of neurosarcoidosis to glucocorticoids and cytotoxic therapy is different from that of multiple sclerosis, differentiating between these disease entities is important.

CARDIAC

The presence of cardiac involvement is influenced by race. Although over a quarter of Japanese sarcoidosis patients develop cardiac disease, only 5% of sarcoidosis patients in the United States and Europe develop symptomatic cardiac disease. However, there is no apparent racial predilection between whites and African Americans. Cardiac disease, which usually presents as either congestive heart failure or cardiac arrhythmias, results from infiltration of the heart muscle by granulomas. Diffuse granulomatous involvement of the heart muscle can lead to profound dysfunction with left ventricular ejection fractions of <10%. Even in this situation, improvement in the ejection fraction can occur with systemic therapy. Arrhythmias can also occur with diffuse infiltration or with more patchy cardiac involvement. If the atrioventricular (AV) node is infiltrated, heart block can occur, which can be detected by routine electrocardiography. Ventricular arrhythmias and ventricular tachycardia are common causes of death. Arrhythmias are best detected using 24-h ambulatory monitoring, and electrophysiology studies may be negative. Other screening tests for cardiac disease include routine electrocardiography and echocardiography. The confirmation of cardiac sarcoidosis is usually performed with either MRI or positron emission tomography (PET) scanning. Because ventricular arrhythmias are usually multifocal due to patchy multiple granulomas in the heart, ablation therapy is not useful. Patients with significant ventricular arrhythmias should be considered for an implanted defibrillator, which appears to have reduced the rate of death in cardiac sarcoidosis. Although systemic therapy can be useful in treating arrhythmias, patients may still have malignant arrhythmias up to 6 months after starting successful treatment, and the risk for recurrent arrhythmias occurs whenever medications are tapered.

MUSCULOSKELETAL SYSTEM

Direct granulomatous involvement of bone and muscle can be documented by radiography (x-ray, MRI, PET scan **[Fig. 367-7]**, or gallium scan) or confirmed by biopsy in ~10% of sarcoidosis patients. However, a larger percentage of sarcoidosis patients complain of myalgia and arthralgia. These complaints are similar to those reported by patients with other inflammatory diseases, including chronic infections such as mononucleosis. Fatigue associated with sarcoidosis may be overwhelming for many patients. A link between fatigue and small peripheral nerve fiber disease in sarcoidosis has been described.

OTHER ORGAN INVOLVEMENT

Although sarcoidosis can affect any organ of the body, rarely does it involve the breast, testes, ovary, or stomach. Because of the rarity of involvement, a mass in one of these areas requires a biopsy to rule out other diseases, including cancer. For example, in a study of breast problems in female sarcoidosis patients, a breast lesion was more likely to be a granuloma from sarcoidosis than from breast cancer. However, findings on the physical examination or mammogram cannot reliably differentiate between these lesions. More importantly, as women with sarcoidosis age, breast cancer becomes more common. Therefore, it is recommended that routine screening including mammography be performed along with other imaging studies (ultrasound, MRI) or biopsy as clinically indicated.

COMPLICATIONS

Sarcoidosis is usually a self-limited, non-life-threatening disease. However, organ-threatening disease can occur. These complications can include blindness, paraplegia, or renal failure. Death from sarcoidosis occurs in ~5% of patients seen in sarcoidosis referral clinics. The usual causes of death related to sarcoidosis are from lung, cardiac, neurologic, or liver involvement. In respiratory failure, an elevation of the right atrial pressure is a poor prognostic finding. Lung complications can also include infections such as mycetoma, which can subsequently lead to massive bleeding. In addition, the use of immunosuppressive agents can increase the incidence of serious infections.

FIGURE 367-7 Positron emission tomography and CT scan merged, demonstrating increased activity in the spleen, ribs, and spine of a patient with sarcoidosis.

LABORATORY FINDINGS

The chest roentgenogram remains the most commonly used tool to assess lung involvement in sarcoidosis. As noted above, the chest roentgenogram classifies involvement into four stages, with stages 1 and 2 having hilar and paratracheal adenopathy. The CT scan has been used increasingly in evaluating interstitial lung disease. In sarcoidosis, the presence of adenopathy and a nodular infiltrate is not specific for sarcoidosis. Adenopathy up to 2 cm can be seen in other inflammatory lung diseases such as idiopathic pulmonary fibrosis. However, adenopathy >2 cm in the short axis supports the diagnosis of sarcoidosis over other interstitial lung diseases.

The PET scan has increasingly replaced gallium-67 scanning to identify areas of granulomatous disease in the chest and other parts of the body (Fig. 367-7). Both tests can be used to identify potential areas for biopsy. Cardiac PET scanning has also proved useful in assessing cardiac sarcoidosis. The identification of hypermetabolic activity may be due to the granulomas from sarcoidosis and not to disseminated malignancy.

MRI has also proved useful in the assessment of extrapulmonary sarcoidosis. Gadolinium enhancement has been demonstrated in areas of inflammation in the brain, heart, and bone. MRI scans may detect asymptomatic lesions. Like the PET scan, MRI changes appear similar to those seen with malignancy and infection. In some cases, biopsy may be necessary to determine the cause of the radiologic abnormality.

Serum levels of angiotensin-converting enzyme (ACE) can be helpful in the diagnosis of sarcoidosis. However, the test has somewhat low sensitivity and specificity. Elevated levels of ACE are reported in 60% of patients with acute disease and only 20% of patients with chronic disease. Although there are several causes for mild elevation of ACE, including diabetes, elevations of >50% of the upper limit of normal are seen in only a few conditions including sarcoidosis, leprosy, Gaucher's disease, hyperthyroidism, and disseminated granulomatous infections such as miliary tuberculosis. Because the ACE level is determined by a biologic assay, the concurrent use of an ACE inhibitor such as lisinopril will lead to a very low ACE level.

DIAGNOSIS

The diagnosis of sarcoidosis requires both compatible clinical features and pathologic findings. Because the cause of sarcoidosis remains elusive, the diagnosis cannot be made with 100% certainty. Nevertheless, the diagnosis can be made with reasonable certainty based on history and physical features along with laboratory and pathologic findings.

Patients are usually evaluated for possible sarcoidosis based on two scenarios **(Fig. 367-8)**. In the first scenario, a patient may undergo a biopsy revealing a noncaseating granuloma in either a pulmonary or an extrapulmonary organ. If the clinical presentation is consistent with sarcoidosis and there is no alternative cause for the granulomas identified, the patient is felt to have sarcoidosis.

In the second scenario, signs or symptoms suggesting sarcoidosis such as the presence of bilateral adenopathy may be present in an otherwise asymptomatic patient or a patient with uveitis or a rash consistent with sarcoidosis. At this point, a diagnostic procedure should be performed. For the patient with a compatible skin lesion, a skin biopsy should be considered. Other biopsies to consider could include liver, extrathoracic lymph node, or muscle. In some cases, a biopsy of the affected organ may not be easy to perform (such as a brain or spinal cord lesion). In other cases, such as an endomyocardial biopsy, the likelihood of a positive biopsy is low. Because of the high rate of pulmonary involvement in these cases, the lung may be easier to approach by bronchoscopy. During the bronchoscopy, a transbronchial biopsy, bronchial biopsy, or transbronchial needle aspirate can be performed. The endobronchial ultrasonography-guided (EBUS) transbronchial needle aspirate can assist in diagnosing sarcoidosis in patients with mediastinal adenopathy (stage 1 or 2 radiographic pulmonary disease), whereas transbronchial biopsy has a higher diagnostic yield for those with only parenchymal lung disease (stage 3). These tests are complementary and may be performed together.

If the biopsy reveals granulomas, an alternative diagnosis such as infection or malignancy must be excluded. Bronchoscopic washings can be sent for cultures for fungi and tuberculosis. For the pathologist,

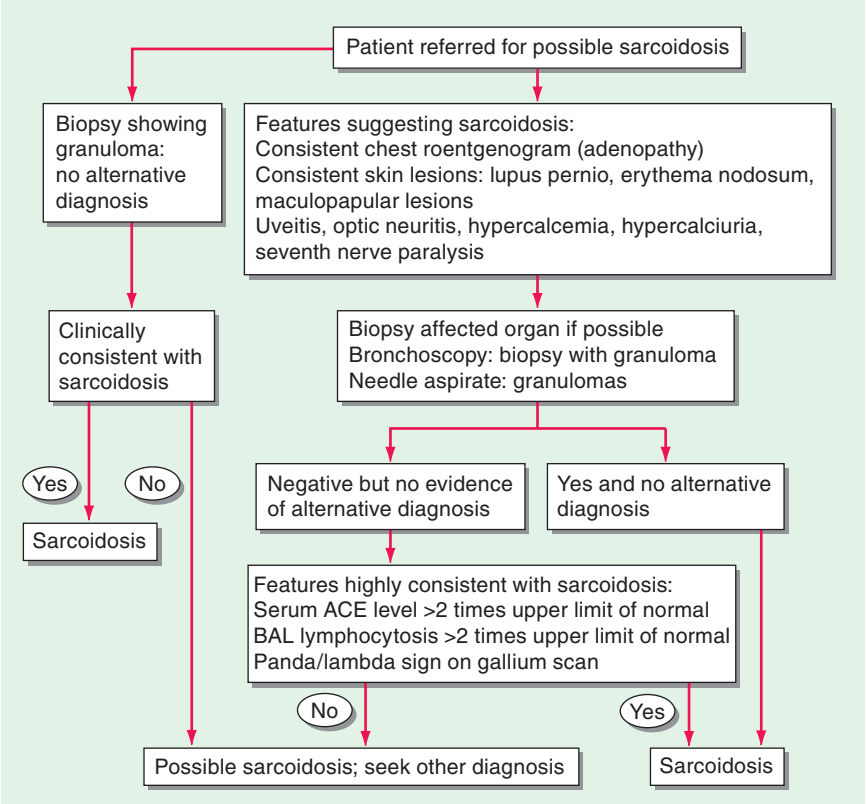

FIGURE 367-8 Proposed approach to management of a patient with possible sarcoidosis. Presence of one or more of the following features supports the diagnosis of sarcoidosis: uveitis, optic neuritis, hypercalcemia, hypercalciuria, seventh cranial nerve paralysis, and/or diabetes insipidus. ACE, angiotensin-converting enzyme; BAL, bronchoalveolar lavage.

the more tissue that is provided, the more comfortable is the diagnosis of sarcoidosis. A needle aspirate may be adequate in an otherwise classic case of sarcoidosis but may be insufficient in a patient in whom lymphoma or fungal infection is a likely alternative diagnosis. Because granulomas can be seen on the edge of a lymphoma, the presence of a few granulomas from a needle aspirate may not be sufficient to clarify the diagnosis. Mediastinoscopy provides a larger sample to confirm the presence or absence of lymphoma in the mediastinum. Alternatively, for most patients, evidence of extrathoracic disease (e.g., eye involvement) may further support the diagnosis of sarcoidosis.

For patients with negative pathology, positive supportive tests may increase the likelihood of the diagnosis of sarcoidosis. These tests include an elevated ACE level, which can also be elevated in other granulomatous diseases but not in malignancy. A positive PET scan can support the diagnosis if multiple organs are affected. BAL is often performed during the bronchoscopy. An increase in the percentage of lymphocytes supports the diagnosis of sarcoidosis. The lymphocyte markers CD4 and CD8 can be used to determine the CD4/CD8 ratio of these increased lymphocytes in the BAL fluid. A ratio of >3.5 is strongly supportive of sarcoidosis but is less sensitive than an increase in lymphocytes alone. Although in general an increase in BAL lymphocytes is supportive of the diagnosis, other conditions must be considered.

Supportive findings, when combined with commonly associated but nondiagnostic clinical features of the disease, improve the diagnostic probability of sarcoidosis. These clinical features include uveitis, renal stones, hypercalcemia, seventh cranial nerve paralysis, and erythema nodosum. A sarcoidosis diagnostic score has been developed that incorporates the cumulative information from multiorgan involvement and allows one to quantitate the likelihood of sarcoidosis.

Because the diagnosis of sarcoidosis can never be certain, over time, other features may arise that lead to an alternative diagnosis. Conversely, evidence for new organ involvement may eventually confirm the diagnosis of sarcoidosis.

PROGNOSIS

The risk of death or loss of organ function remains low in sarcoidosis. Poor outcomes usually occur in patients who present with advanced disease in whom treatment seems to have little impact. In these cases, irreversible fibrotic changes have frequently occurred. The overall mortality of sarcoidosis is approximately 5%. Mortality is associated with advanced pulmonary fibrosis (>20% fibrosis on chest CT scan and/or DL_{CO} <50%) and pulmonary hypertension. Over the past 20 years, the reported mortality from sarcoidosis has increased in the United States and England. Whether this is due to heightened awareness of the chronic nature of this disease or to other factors such as more widespread immunosuppressive therapy usage remains unclear.

For the majority of patients, initial presentation occurs during the granulomatous phase of the disease, as depicted in Fig. 367-1. It is clear that many patients resolve their disease within 2–5 years. These patients are felt to have acute, self-limiting sarcoidosis. However, there is a form of the disease that does not resolve within the first 2–5 years. These chronic patients can be identified at presentation by certain risk factors at presentation such as fibrosis on chest roentgenogram, presence of lupus pernio, bone cysts, cardiac or neurologic disease (except isolated seventh nerve paralysis), and presence of renal calculi due to hypercalciuria. In several studies, patients who required glucocorticoids for any manifestation of their disease in the first 6 months of presentation had a >50% chance of having chronic disease. In contrast, <10% of patients who required no systemic therapy in the first 6 months required chronic therapy.

TREATMENT

Sarcoidosis

The decision to treat sarcoidosis is based on two indications: to avoid danger or improve quality of life. A dangerous outcome from sarcoidosis is the possibility of organ- or life-threatening disease, including disease involving the eye, heart, or nervous system. The patient with asymptomatic elevated liver function tests or an abnormal chest roentgenogram probably does not benefit from treatment. However, these patients should be monitored for evidence of progressive, symptomatic disease. Improvement of quality of life is an important indication to treat; however, one must be careful to avoid toxicity from therapy that is more problematic than the disease itself.

One approach to therapy is summarized in **Figs. 367-9 and 367-10**. We have divided the approach into treating acute versus chronic disease. For acute disease, no therapy remains a viable option for patients with no or mild symptoms. For symptoms confined to only one organ, topical therapy is preferable. For multiorgan disease or disease too extensive for topical therapy, an approach to systemic therapy is outlined. Glucocorticoids remain the drugs of choice for this disease. However, the decision to continue to treat with glucocorticoids or to add steroid-sparing agents depends on the tolerability, duration, and dosage of glucocorticoids. **Table 367-2** summarizes the dosage and monitoring of several commonly used drugs. According to the available trials, evidence-based recommendations

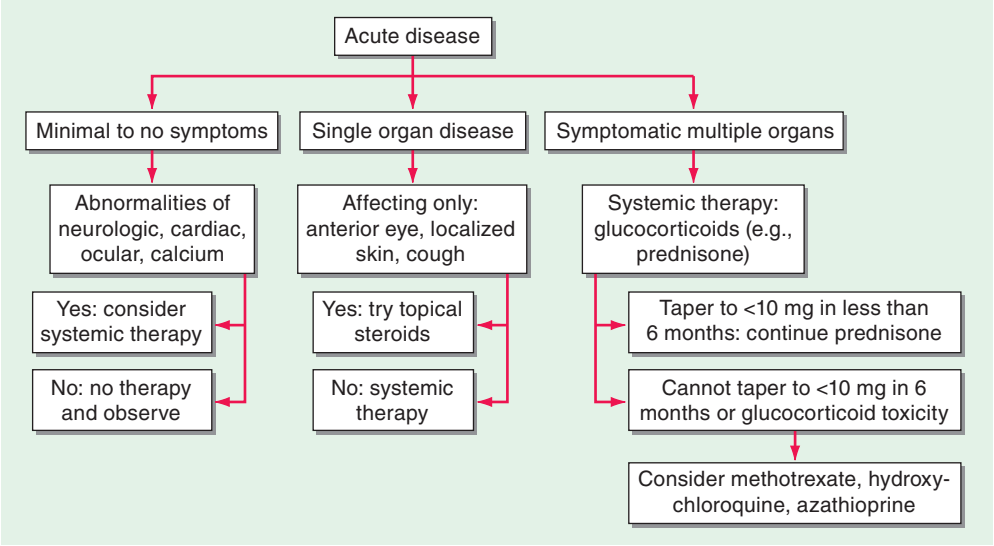

FIGURE 367-9 The management of acute sarcoidosis is based on level of symptoms and extent of organ involvement. In patients with mild symptoms, no therapy may be needed unless specified manifestations are noted.

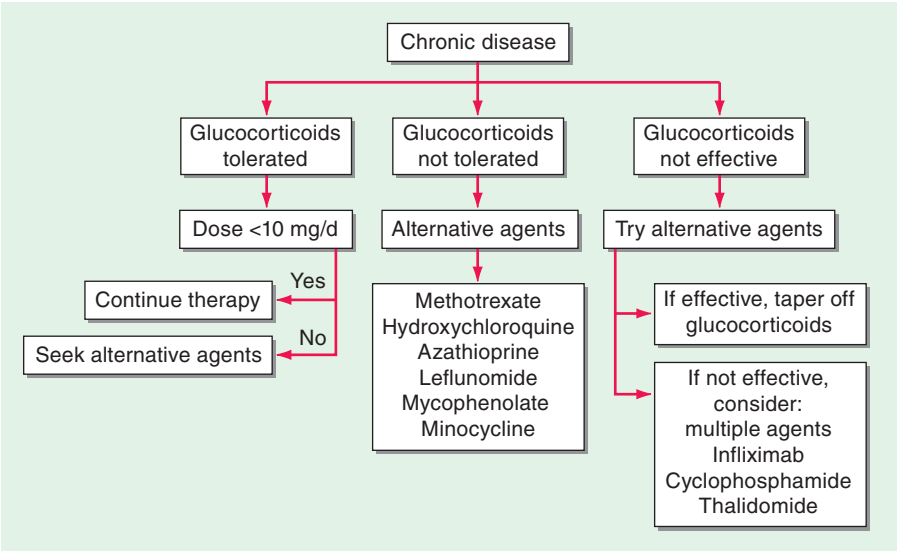

FIGURE 367-10 Approach to chronic disease is based on whether glucocorticoid therapy is tolerated or not.

are made. Most of these recommendations are for pulmonary disease because most of the trials were performed only in pulmonary disease. Treatment recommendations for extrapulmonary disease are usually similar with a few modifications. For example, the dosage of glucocorticoids is usually higher for neurosarcoidosis and lower for cutaneous disease. There was some suggestion that higher doses would be beneficial for cardiac sarcoidosis, but one study found that initial prednisone doses >40 mg/d were associated with a worse outcome because of toxicity.

Systemic therapies for sarcoidosis are usually immunosuppressive, including glucocorticoids, cytotoxics, or biologics. Although most patients receive glucocorticoids as their initial systemic therapy, toxicity associated with prolonged therapy often leads to steroid-sparing alternatives. The antimalarial drugs, such as hydroxychloroquine, are more effective for skin than pulmonary disease. Minocycline may also be useful for cutaneous sarcoidosis. For pulmonary and other extrapulmonary disease, cytotoxic agents that include methotrexate, azathioprine, leflunomide, mycophenolate, and cyclophosphamide are often used. The most widely studied cytotoxic agent has been methotrexate. This agent works in approximately two-thirds of sarcoidosis patients, regardless of the disease manifestation. In one retrospective study comparing methotrexate with azathioprine, both drugs were equally effective. However, methotrexate was associated with significantly less toxicity. As noted in Table 367-2, specific guidelines for monitoring therapy have been recommended. Cytokine modulators such as thalidomide and pentoxifylline have also been used in a limited number of cases.

The biologic anti-TNF agents have recently been studied in sarcoidosis, with prospective randomized trials completed for etanercept, golimumab, and infliximab. Etanercept has a limited role as a steroid-sparing agent. Golimumab was not significantly different than placebo in treating chronic pulmonary disease. However, this may have been due to the relatively low dose of golimumab studied. Infliximab significantly improved lung function when administered to glucocorticoid and cytotoxic pretreated patients with chronic disease. The difference in response between etanercept and infliximab is similar to that observed in Crohn's disease, where infliximab is effective and etanercept is not. However, there is a higher risk for reactivation of tuberculosis with infliximab compared with etanercept. The differential response rate could be explained by differences in mechanism of action because etanercept is a TNF receptor antagonist and infliximab is a monoclonal antibody against TNF. In contrast to etanercept, infliximab also binds to TNF on the surface

TABLE 367-2 Commonly Used Drugs to Treat Sarcoidosis

DRUG	INITIAL DOSE	MAINTENANCE DOSE	MONITORING	TOXICITY	SUPPORT THERAPY[a]	SUPPORT MONITORING[a]
Prednisone	20–40 mg qd	Taper to 5–10 mg	Glucose, blood pressure, bone density	Diabetes, osteoporosis	A: Acute pulmonary D: Extrapulmonary	
Hydroxychloroquine	200–400 mg qd	400 mg qd	Eye examination q6–12 mo	Ocular	B: Some forms of disease	D: Routine eye examination
Methotrexate	10 mg qwk	2.5–15 mg qwk	CBC, renal, hepatic q2mo	Hematologic, nausea, hepatic, pulmonary	B: Steroid sparing C: Some forms chronic disease	D: Routine hematologic, renal, and hepatic monitoring
Azathioprine	50–150 mg qd	50–200 mg qd	CBC, renal q2mo	Hematologic, nausea	C: Some forms chronic disease	D: Routine hematologic monitoring
Infliximab	3–5 mg/kg q2wk for 2 doses	3–10 mg/kg q4–8 wk	Initial PPD	Infections, allergic reaction, carcinogen	A: Chronic pulmonary disease	B: Caution in patients with latent tuberculosis or advanced congestive heart failure

[a]Grade A: supported by at least two double-blind randomized control trials; grade B: supported by prospective cohort studies; grade C: supported primarily by two or more retrospective studies; grade D: only one retrospective study or based on experience in other diseases.

Abbreviations: CBC, complete blood count; PPD, purified protein derivative test for tuberculosis.

of some cells that release TNF, which leads to cell lysis. This effect has been documented in Crohn's disease. Adalimumab is a humanized monoclonal anti-TNF antibody that also appears effective for sarcoidosis when dosed at higher strengths, as recommended for the treatment of Crohn's disease. The role of the newer therapeutic agents for sarcoidosis is still evolving. However, these targeted therapies confirm that TNF may be an important target, especially in the treatment of chronic disease. However, these agents are not a panacea because sarcoidosis-like disease has occurred in patients treated with anti-TNF agents for nonsarcoidosis indications.

368 IgG4-Related Disease

John H. Stone

IgG4-related disease (IgG4-RD) is a fibroinflammatory condition characterized by a tendency to form tumefactive lesions. The clinical manifestations of this disease, however, are protean, as IgG4-RD can affect virtually any organ system. Commonly affected organs are the pancreas, biliary tree, major salivary glands (submandibular, parotid), periorbital tissues, kidneys, lungs, lymph nodes, and retroperitoneum. In addition, IgG4-RD involvement of the meninges, aorta, prostate, thyroid, pericardium, skin, and other organs is well described. The disease affects the brain parenchyma, the joints, the bone marrow, and the bowel mucosa only rarely.

The pathologic findings are consistent across all affected organs. These findings include a lymphoplasmacytic infiltrate with a high percentage of IgG4-positive plasma cells; a characteristic pattern of fibrosis termed "storiform" (from the Latin *storea*, for "woven mat"); a tendency to target blood vessels, particularly veins, through an obliterative process ("obliterative phlebitis"); and a mild to moderate tissue eosinophilia. Although the pathology is consistent from organ to organ, it is essentially never diagnostic in and of itself. Classification criteria emphasize the importance of careful correlation among clinical, serologic, radiologic, and pathologic findings in deciding whether a patient should be classified as having IgG4-RD. Biopsy is not required in order to establish the diagnosis in classic cases, but most patients undergo a biopsy at some point in the evaluation in order to exclude malignancy.

IgG4-RD encompasses a number of conditions previously regarded as separate, organ-specific entities. A condition once known as "lymphoplasmacytic sclerosing pancreatitis" became the paradigm of IgG4-RD in 2000, when Japanese investigators recognized that these patients had elevated serum concentrations of IgG4. This form of sclerosing pancreatitis is now termed *type 1 (IgG4-related) autoimmune pancreatitis* (AIP). By 2003, extrapancreatic disease manifestations had been identified in patients with type 1 AIP, and descriptions of IgG4-RD in other organs followed. *Mikulicz's disease*, once considered to be a subset of Sjögren's syndrome that affected the lacrimal, parotid, and submandibular glands, is one of the most common presentations of IgG4-RD.

CLINICAL FEATURES

The major organ lesions are summarized in **Table 368-1**. IgG4-RD usually presents subacutely, and even in the setting of multiorgan disease, most patients do not have fevers or high elevations of C-reactive protein levels. Some patients, however, experience substantial weight loss over periods of months, largely because of exocrine pancreatic failure. Failure of the endocrine pancreas, leading to diabetes mellitus, is also common. Clinically apparent disease can evolve over months, years, or even decades before the manifestations within a given organ become sufficiently severe to bring the patient to medical attention. Some patients have disease that is marked by the appearance and then resolution or temporary improvement in symptoms within a particular organ. Other patients accumulate new organ involvement as their disease persists in previously affected organs. Many patients with IgG4-RD are misdiagnosed as having other conditions, particularly malignancies, or their findings are attributed initially to nonspecific inflammation. The disorder is often identified incidentally through radiologic findings or unexpectedly in pathology specimens.

Multiorgan disease may be evident at diagnosis but can also evolve over months to years. Some patients have disease confined to a single organ for many years. Others have either known or subclinical organ involvement at the same time as the major clinical feature. Patients with type 1 AIP may have their major disease focus in the pancreas; however, thorough evaluations by history, physical examination, blood tests, and cross-sectional imaging may demonstrate lacrimal gland enlargement, sialoadenitis, lymphadenopathy, a variety of pulmonary findings, tubulointerstitial nephritis, hepatobiliary disease, aortitis, retroperitoneal fibrosis, or other organ involvement.

Two common characteristics of IgG4-RD are allergic disease and the tendency to form tumefactive lesions that mimic malignancies **(Fig. 368-1)**. Many IgG4-RD patients have allergic features such as atopy, eczema, asthma, nasal polyps, sinusitis, and modest peripheral eosinophilia. IgG4-RD also appears to account for a significant proportion of tumorous swellings—pseudotumors—in many organ systems **(Fig. 368-2)**. Some patients undergo major surgeries (e.g., modified Whipple procedures or thyroidectomy) for the purpose of resecting malignancies before the correct diagnosis is identified.

IgG4-RD often causes major morbidity and can lead to organ failure; however, its general pattern is to cause damage in a subacute manner. Destructive bone lesions in the sinuses, head, and middle ear spaces that mimic granulomatosis with polyangiitis occur occasionally in IgG4-RD, but less aggressive lesions are the rule in most organs. In regions such as the retroperitoneum, substantial fibrosis often occurs before the diagnosis is established, leading to ureteral entrapment, hydronephrosis, postobstructive uropathy, and renal atrophy. Undiagnosed or undertreated IgG4-related sclerosing cholangitis can lead to hepatic failure within months. Similarly, IgG4-related aortitis can cause aneurysms and dissections. Substantial renal dysfunction and even renal failure can ensue from IgG4-related tubulointerstitial nephritis, and renal atrophy is a frequent sequel to this disease complication even following apparently effective immunosuppressive therapy. IgG4-related membranous glomerulonephropathy, a less common renal manifestation than tubulointerstitial nephritis, must be distinguished from idiopathic membranous glomerulonephropathy.

SEROLOGIC FINDINGS

The majority of patients with IgG4-RD have elevated serum IgG4 concentrations; however, the range of elevation varies widely. Serum concentrations of IgG4 as high as 30 or 40 times the upper limit of normal sometimes occur, usually in patients with disease that affects multiple organ systems simultaneously. Approximately 30% of patients have normal serum IgG4 concentrations despite classic histopathologic and immunohistochemical findings. Such patients tend to have disease that affects fewer organs. Patients with IgG4-related retroperitoneal fibrosis often have normal serum IgG4 concentrations, perhaps because the process has advanced to a fibrotic stage by the time the diagnosis is considered.

TABLE 368-1 Organ Manifestations of IgG4-Related Disease

ORGAN	MAJOR CLINICAL FEATURES
Orbits and periorbital tissues	Painless eyelid or periocular tissue swelling; orbital pseudotumor; dacryoadenitis; dacryocystitis; orbital myositis; and mass lesions extending into the pterygopalatine fossa and infiltrating along the trigeminal nerve
Ears, nose, and sinuses	Allergic phenomena (nasal polyps, asthma, allergic rhinitis, peripheral eosinophilia); nasal obstruction, rhinorrhea, anosmia, chronic sinusitis; occasional bone-destructive lesions
Salivary glands	Submandibular and/or parotid gland enlargement (isolated bilateral submandibular gland involvement more common); minor salivary glands sometimes involved
Meninges	Headache, radiculopathy, cranial nerve palsies, or other symptoms resulting from spinal cord compression; tendency to form mass lesions; MRI shows marked thickening and enhancement of dura
Hypothalamus and pituitary	Clinical syndromes resulting from involvement of the hypothalamus and pituitary, e.g., anterior pituitary hormone deficiency, central diabetes insipidus, or both; imaging reveals thickened pituitary stalk or mass formation on the stalk, swelling of the pituitary gland, or mass formation within the pituitary
Lymph nodes	Generalized lymphadenopathy or localized disease adjacent to a specific affected organ; the lymph nodes involved are generally 1–2 cm in diameter and nontender
Thyroid gland	Riedel's thyroiditis; fibrosing variant of Hashimoto's thyroiditis
Lungs	Asymptomatic finding on lung imaging; cough, hemoptysis, dyspnea, pleural effusion, or chest discomfort; associated with parenchymal lung involvement, pleural disease, or both; four main clinical lung syndromes: inflammatory pseudotumor, paravertebral mass often extending over several vertebrae, central airway disease, localized or diffuse interstitial pneumonia; pleural lesions have severe, nodular thickening of the visceral or parietal pleura with diffuse sclerosing inflammation, sometimes associated with pleural effusion
Aorta	Asymptomatic finding on radiologic studies; surprise finding at elective aortic surgery; aortic dissection; clinicopathologic syndromes described include lymphoplasmacytic aortitis of thoracic or abdominal aorta, aortic dissection, periaortitis and periarteritis, and inflammatory abdominal aneurysm
Retroperitoneum	Backache, lower abdominal pain, lower extremity edema, hydronephrosis from ureteral involvement, asymptomatic finding on radiologic studies. Classic radiologic appearance is periaortic inflammation extending caudally to involve the iliac vessels.
Kidneys	Tubulointerstitial nephritis; membranous glomerulonephritis in a small minority; asymptomatic tumoral lesions, typically multiple and bilateral, are sometimes detected on radiologic studies; renal involvement strongly associated with hypocomplementemia
Pancreas	Type 1 autoimmune pancreatitis, presenting as mild abdominal pain; weight loss; acute, obstructive jaundice, mimicking adenocarcinoma of the pancreas (including a pancreatic mass); between 20 and 50% of patients present with acute glucose intolerance; imaging shows diffuse (termed "sausage-shaped pancreas") or segmental pancreatic enlargement, with loss of normal lobularity; a mass often raises the suspicion of malignancy
Biliary tree and liver	Obstructive jaundice associated with autoimmunity in most cases; weight loss; steatorrhea; abdominal pain; and new-onset diabetes mellitus; mimicker of primary sclerosing cholangitis and cholangiocarcinoma
Other organs involved	Gallbladder, liver (mass), breast (pseudotumor), prostate (prostatism), pericardium (constrictive pericarditis), mesentery (sclerosing mesenteritis), mediastinum (fibrosing mediastinitis), skin (erythematous or flesh-colored papules), peripheral nerve (perineural inflammation)

Correlations between serum IgG4 concentrations, disease activity, and the need for treatment are imperfect. Serum IgG4 concentrations typically decline swiftly with the institution of therapy but often do not normalize completely. Patients can achieve clinical remissions yet have persistently elevated serum IgG4 concentrations. Following treatment and a disease response, however, steadily rising serum IgG4 concentrations are useful in identifying patients at risk for clinical flares who should be considered for re-treatment. Clinical relapses occur in some patients despite persistently normal IgG4 concentrations.

IgG4 concentrations in serum are usually measured by nephelometry assays. In the setting of extremely high serum IgG4 concentrations, these assays can generate spuriously low IgG4 values because of the

FIGURE 368-2 Thickening of extraocular muscles and meninges. ***A.*** Computed tomography scan of the orbits, showing enlargement of extraocular muscles in a patient with IgG4-related orbital disease. ***B.*** Computed tomography scan of the brain, showing thickening of the pachymeninges.

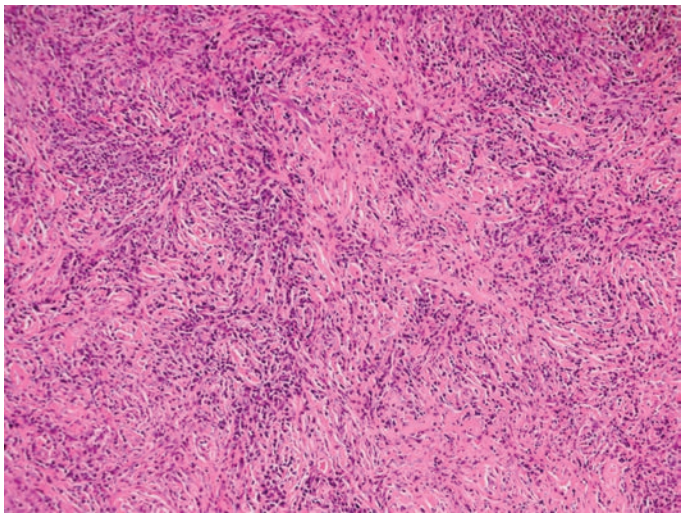

FIGURE 368-3 Hallmark histopathology characteristics of IgG4-related disease (IgG4-RD) are a dense lymphoplasmacytic infiltrate and a mild to moderate eosinophilic infiltrate. The cellular inflammation is often encased in a distinctive type of fibrosis termed "storiform," which often has a basket weave pattern. Abundant fibroblasts and strands of fibrosis accompany the lymphoplasmacytic infiltrate in this figure. This biopsy is from a patient with IgG4-related hypertrophic pachymeningitis. However, the findings are identical to the pathology found in the pancreas, kidneys, lungs, salivary glands, and other organs affected by IgG4-RD.

prozone effect. Failure to identify dramatic serum IgG4 elevations can have a substantial impact on patients because that subset of patients is at greatest risk for multiorgan disease and substantial end-organ injury. The prozone effect should be considered when the results of serologic testing for IgG4 concentrations are normal despite the presence of clinical features that strongly suggest IgG4-RD. This effect can be corrected by dilution of the serum sample in the laboratory.

EPIDEMIOLOGY

The typical patient with IgG4-RD is a middle-aged to elderly man. This epidemiology stands in stark contrast to that of many classic autoimmune conditions, which tend to affect young women. Studies of AIP patients in Japan indicate that the male-to-female ratio in that disease subset is on the order of 3:1. A striking male predominance has also been reported in IgG4-related tubulointerstitial nephritis and IgG4-related retroperitoneal fibrosis, but among IgG4-RD manifestations that involve organs of the head and neck—the orbits, lacrimal glands, and major salivary glands—the sex ratio may be closer to 1:1.

PATHOLOGY

The key histopathology characteristics of IgG4-RD are a dense lymphoplasmacytic infiltrate **(Fig. 368-3)** that is organized in a storiform pattern, obliterative phlebitis, and a mild to moderate eosinophilic infiltrate. Lymphoid follicles and germinal centers are frequently observed. The infiltrate tends to aggregate around ductal structures when it affects glands. The inflammatory lesion often aggregates into tumefactive masses that destroy the involved tissue.

Obliterative arteritis is observed in some organs, particularly the lung; however, venous involvement is more common (and is indeed a hallmark of IgG4-RD). Several histopathology features are uncommon in IgG4-RD and, when detected, mitigate against the diagnosis of IgG4-RD. These include intense neutrophilic infiltration, leukocytoclasis, granulomatous inflammation, multinucleated giant cells, and fibrinoid necrosis.

The inflammatory infiltrate is composed of an admixture of B and T lymphocytes. B cells are typically organized in germinal centers. Plasma cells staining for CD19, CD138, and IgG4 appear to radiate from the germinal centers. In contrast, the T cells, usually CD4+, are distributed more diffusely throughout the lesion and generally represent the most abundant cell type. Fibroblasts, histiocytes, and eosinophils can all be observed in moderate numbers. Some biopsy samples are particularly enriched with eosinophils. In other samples, particularly from long-standing cases, fibrosis predominates.

The histologic appearance of IgG4-RD, although highly characteristic, requires immunohistochemical confirmation of the diagnosis with IgG4 immunostaining. IgG4-positive plasma cells predominate within the lesion, but plasma cells containing immunoglobulins from each subclass can be found. The number of IgG4-positive plasma cells can be quantified by either counting the number of cells per high-power field (HPF) or by calculating the ratio of IgG4- to IgG-bearing plasma cells. Tissue fibrosis predominates in the latter phases of organ involvement, and in this relatively acellular phase of inflammation, both the IgG4:total IgG ratio and the pattern of tissue fibrosis are more important than the number of IgG4-positive cells per HPF in establishing the diagnosis.

PATHOPHYSIOLOGY

Despite the emphasis of IgG4 in the name of this disease, the IgG4 molecule is not believed to play a direct role in the pathophysiology of disease within most organs. The IgG4 molecule can undergo Fab exchange, a phenomenon in which the two halves of the molecule dissociate from each other and reassociate with hemi-molecules of different antigen specificity that have originated from other dissociated

IgG4 molecules. Partly as a result of this Fab exchange, IgG4 antibodies do not bind antigen tightly. Moreover, the molecules have low affinities for Fc receptors and C1q and are regarded generally as noninflammatory immunoglobulins. The low affinities for Fc receptors and C1q impair the ability of IgG4 antibodies to induce phagocyte activation, antibody-dependent cellular cytotoxicity, and complement-mediated damage. It is possible, therefore, that the role of IgG4 in this disease is actually as a counterregulatory mechanism rather than part of the primary inflammatory process.

Next-generation sequencing studies of CD4+ effector T cells have demonstrated a unique CD4+ cytotoxic T cell. This cell, also found in abundance at tissue sites of disease, makes interferon γ, T-cell growth factor-β, and interleukin-1, all of which may contribute to the storiform fibrosis found in this condition. The cells also elaborate perforin, granzyme A and B, and granulysin, products capable of inducing cytotoxicity. The pronounced oligoclonal expansion of this CD4+ cytotoxic T cell at tissue sites suggests that this cell is a major disease driver.

Oligoclonal expansions of plasmablasts are also present within the blood of patients with IgG4-RD. Continuous antigen presentation by B cells and plasmablasts may support this cell, which in turn produces profibrotic cytokines and other molecules, thereby directly mediating tissue injury.

TREATMENT

Vital organ involvement must be treated aggressively because IgG4-RD can lead to serious organ dysfunction and failure. Aggressive disease can lead quickly to end-stage liver disease, permanent impairment of pancreatic function, renal atrophy, aortic dissection or aneurysms, and destructive lesions in the sinuses and nasopharynx. Not every disease manifestation of IgG4-RD requires immediate treatment, however, because the disease may take an indolent form in some patients. IgG4-related lymphadenopathy, for example, can be asymptomatic for years, without evolution to other disease manifestations. Thus, watchful waiting is prudent in some cases, but monitoring is essential because serious organ involvement may evolve over time.

Glucocorticoids are the first line of therapy. Treatment regimens, extrapolated from experience with the management of type 1 AIP, generally begin with 40 mg/d of prednisone, with tapering to discontinuation or maintenance doses of 5 mg/d within 2 or 3 months. Although the clinical response to glucocorticoids is usually swift and striking, prolonged steroid-free remissions are uncommon and the risk of steroid-induced morbidity in this middle-aged to elderly patient population is high, particularly in those with baseline comorbidities and pancreatic involvement by IgG4-RD. Few data exist to support the utility of conventional steroid-sparing agents in this disease.

For patients with relapsing or glucocorticoid-resistant disease, B-cell depletion with rituximab is an excellent second-line therapy. Rituximab treatment (two doses of 1 g IV, separated by approximately 15 days) leads to a swift decline in serum IgG4 concentrations, suggesting that rituximab achieves its effects in part by preventing the repletion of short-lived plasma cells that produce IgG4. More important than its effects on IgG4 concentrations, however, may be the effect of B-cell depletion on T-cell function. Specific effects of rituximab on the CD4+ cytotoxic T cell described above have been documented in IgG4-RD. Rituximab may be an appropriate first-line therapy for some patients, particularly those at high risk for glucocorticoid toxicity and patients with immediately organ-threatening disease. The rapidly evolving understanding of the pathophysiology of IgG4-RD suggests several novel targeted approaches to treating the disease, some of which are in clinical trials. These novel strategies include inhibition of Bruton's tyrosine kinase, the depletion of CD19+ cells of the B lymphocyte lineage, and targeting of SLAM-F7, the molecule found on the surfaces of both B lymphocytes and the CD4+ cytotoxic T lymphocyte. Both of these cell types have been implicated in disease pathophysiology.

369 Familial Mediterranean Fever and Other Hereditary Autoinflammatory Diseases

Daniel L. Kastner

Familial Mediterranean fever (FMF) is the prototype of a group of inherited diseases **(Table 369-1)** that are characterized by recurrent episodes of fever with serosal, synovial, or cutaneous inflammation and, in some individuals, the eventual development of systemic AA amyloidosis **(Chap. 112)**. Because of the relative infrequency of high-titer autoantibodies or antigen-specific T cells, the term *autoinflammatory* has been proposed to describe these disorders, rather than autoimmune. The innate immune system, with its myeloid effector cells and germline receptors for pathogen-associated molecular patterns and endogenous danger signals, plays a predominant role in the pathogenesis of the autoinflammatory diseases. Although the hereditary recurrent fevers comprise a major category of the autoinflammatory diseases, other inherited disorders of inflammation in which recurrent fever plays a less prominent role are now also considered to be autoinflammatory.

BACKGROUND AND PATHOPHYSIOLOGY

FMF was first recognized among Armenians, Arabs, Turks, and non-Ashkenazi (primarily North African and Iraqi) Jews. With the advent of genetic testing, FMF has been documented with increasing frequency among Ashkenazi Jews, Italians, and other Mediterranean populations, and occasional cases have been confirmed even in the absence of known Mediterranean ancestry. FMF is generally regarded as recessively inherited, but there is an increasing awareness of clear-cut clinical cases with only a single demonstrable genetic mutation, and for certain relatively rare FMF mutations, there is strong evidence for dominant inheritance. Particularly in countries where families are small, a positive family history can only be elicited in ~50% of cases. DNA testing demonstrates carrier frequencies as high as 1:10 among affected populations, most likely due to some selective advantage.

The FMF gene encodes a 781-amino-acid, ~95-kDa protein denoted *pyrin* that is expressed in granulocytes, eosinophils, monocytes, dendritic cells, and synovial and peritoneal fibroblasts. The N-terminal 92 amino acids of pyrin define a motif, the PYRIN domain, that mediates homotypic protein-protein interactions and has been found in several other proteins, including cryopyrin (NLRP3), which is mutated in three other recurrent fever syndromes. Through the interaction of its PYRIN domain with an intermediary adaptor protein, pyrin nucleates the formation of a macromolecular *pyrin inflammasome* to activate caspase-1 (interleukin [IL] 1β–converting enzyme) and thereby IL-1β

TABLE 369-1 The Hereditary Recurrent Fever Syndromes

	FMF	TRAPS	HIDS/MKD	MWS	FCAS	NOMID
Ethnicity	Jewish, Arab, Turkish, Armenian, Italian	Any ethnic group	Predominantly Dutch, northern European	Any ethnic group	Any ethnic group	Any ethnic group
Inheritance	Recessive or dominant[a]	Dominant	Recessive	Dominant	Dominant	Most commonly de novo mutations; somatic mosaicism in a significant minority
Gene/chromosome	*MEFV*/16p13.3	*TNFRSF1A*/12p13	*MVK*/12q24	*NLRP3*/1q44	*NLRP3*/1q44	*NLRP3*/1q44
Protein	Pyrin	p55 TNF receptor	Mevalonate kinase	NLRP3 (cryopyrin)	NLRP3 (cryopyrin)	NLRP3 (cryopyrin)
Attack length	1–3 days	Often >7 days	3–7 days	1–2 days	Minutes–3 days	Continuous, with flares
Serosa	Pleurisy, peritonitis; asymptomatic pericardial effusions	Pleurisy, peritonitis, pericarditis	Abdominal pain, but seldom peritonitis; pleurisy, pericarditis uncommon	Abdominal pain; pleurisy, pericarditis rare	Rare	Rare

Joints	Acute monoarthritis; chronic hip arthritis (rare)	Acute monoarthritis, arthralgia	Arthralgia, oligoarthritis	Arthralgia, large joint oligoarthritis	Polyarthralgia	Epiphyseal, patellar overgrowth, clubbing
Muscle	Exercise-induced myalgia common; protracted febrile myalgia rare	Migratory myalgia	Uncommon	Myalgia common	Sometimes myalgia	Sometimes myalgia
Eyes, ears	Uncommon	Periorbital edema, conjunctivitis, rarely uveitis	Uncommon	Conjunctivitis, episcleritis, optic disc edema; sensorineural hearing loss	Conjunctivitis	Conjunctivitis, uveitis, optic disc edema, blindness, sensorineural hearing loss
CNS	Aseptic meningitis rare	Headache	Headache	Headache	Headache	Aseptic meningitis, seizures
Amyloidosis	Most common in M694V homozygotes	~15% of cases, most often cysteine mutations, T50M	Sometimes associated with V377I/I268T *MVK* genotype	~25% of cases	Uncommon	Late complication
Treatment	Oral colchicine prophylaxis, IL-1 inhibitors for refractory cases	Glucocorticoids, IL-1 inhibitors, etanercept	NSAIDs for fever; IL-1 inhibitors	Canakinumab, rilonacept, anakinra	Canakinumab, rilonacept, anakinra	Anakinra

[a]A substantial percentage of patients with clinical FMF have only a single demonstrable *MEFV* mutation on DNA sequencing.

Abbreviations: CNS, central nervous system; FCAS, familial cold autoinflammatory syndrome; FMF, familial Mediterranean fever; HIDS/MKD, hyperimmunoglobulinemia D with periodic fever syndrome, also known as mevalonate kinase deficiency; IL, interleukin; MWS, Muckle-Wells syndrome; NOMID, neonatal-onset multisystem inflammatory disease; NSAIDs, nonsteroidal anti-inflammatory drugs; TNF, tumor necrosis factor; TRAPS, TNF receptor-associated periodic syndrome.

and IL-18 secretion and gasdermin D-mediated cell death (pyroptosis). Certain bacterial toxins that block leukocyte cytoskeletal assembly by inactivating RhoA GTPase trigger pyrin inflammasome activation as a part of the normal host defense; in FMF patients, the threshold for pyrin inflammasome activation is reduced. Population genetic and immune functional studies support a role for bubonic plague pandemics in selecting for FMF founder mutations that had arisen in Biblical times in the Middle East.

ACUTE ATTACKS

Febrile episodes in FMF may begin even in early infancy; 90% of patients have had their first attack by age 20. Typical FMF episodes generally last 24–72 h, with arthritic attacks tending to last somewhat longer. In some patients, the episodes occur with great regularity, but more often, the frequency of attacks varies over time, ranging from as often as once every few days to remissions lasting several years. Attacks are often unpredictable, although some patients relate them to physical exertion, emotional stress, or menses; pregnancy may be associated with remission.

If measured, fever is nearly always present throughout FMF attacks. Severe hyperpyrexia and even febrile seizures may be seen in infants, and fever is sometimes the only manifestation of FMF in young children.

Over 90% of FMF patients experience abdominal attacks at some time. Episodes range in severity from dull, aching pain and distention with mild tenderness on direct palpation to severe generalized pain with absent bowel sounds, rigidity, rebound tenderness, and air-fluid levels on upright radiographs. Computed tomography (CT) scanning may demonstrate a small amount of fluid in the abdominal cavity. If such patients undergo exploratory laparotomy, a sterile, neutrophil-rich peritoneal exudate is present, sometimes with adhesions from previous episodes. Ascites is rare.

Pleural attacks are usually manifested by unilateral, sharp, stabbing chest pain. Radiographs may show atelectasis and sometimes an effusion. If performed, thoracentesis demonstrates an exudative fluid rich in neutrophils. After repeated attacks, pleural thickening may develop.

FMF arthritis is most frequent among individuals homozygous for the M694V mutation, which is especially common in the non-Ashkenazi Jewish population. Acute arthritis in FMF is usually monoarticular, affecting the knee, ankle, or hip, although other patterns can be seen. Large sterile effusions rich in neutrophils are frequent, without commensurate erythema or warmth. Even after repeated arthritic attacks, radiographic changes are rare. Before the advent of colchicine prophylaxis, chronic arthritis of the knee or hip was seen in ~5% of FMF patients with arthritis. Chronic sacroiliitis can occur in FMF irrespective of the HLA-B27 antigen, even in the face of colchicine therapy. In the United States, FMF patients are much more likely to have arthralgia than arthritis.

The most characteristic cutaneous manifestation of FMF is erysipelas-like erythema, a raised erythematous rash that most commonly occurs on the dorsum of the foot, ankle, or lower leg alone or in combination with abdominal pain, pleurisy, or arthritis. Biopsy demonstrates perivascular

infiltrates of granulocytes and monocytes. This rash is seen most often in M694V homozygotes and is relatively rare in the United States.

Exercise-induced (nonfebrile) myalgia is common in FMF, and a small percentage of patients develop a protracted febrile myalgia that can last several weeks. Symptomatic pericardial disease is rare, although small pericardial effusions may be noted on echocardiography. Unilateral acute scrotal inflammation may occur in prepubertal boys. Aseptic meningitis has been reported in FMF, but the causal connection is controversial. Vasculitis, including Henoch-Schönlein purpura and polyarteritis nodosa **(Chap. 363)**, may be seen at increased frequency in FMF. The M694V FMF mutation has been shown to be a risk factor for Behçet's disease and ankylosing spondylitis.

Laboratory features of FMF attacks are consistent with acute inflammation and include an elevated erythrocyte sedimentation rate, leukocytosis, thrombocytosis (in children), and elevations in C-reactive protein, fibrinogen, haptoglobin, and serum immunoglobulins. Transient albuminuria and hematuria may also be seen.

AMYLOIDOSIS

Before the advent of colchicine prophylaxis, systemic amyloidosis was a common complication of FMF. It is caused by deposition of a fragment of serum amyloid A, an acute-phase reactant, in the kidneys, adrenals, intestine, spleen, lung, and testes **(Chap. 112)**. Amyloidosis should be suspected in patients who have proteinuria between attacks; renal or rectal biopsy is used most often to establish the diagnosis. Risk factors include the M694V homozygous genotype, positive family history (independent of FMF mutational status), the *SAA1* genotype, male gender, noncompliance with colchicine or IL-1 inhibitory therapy, and having grown up in the Middle East.

DIAGNOSIS

For typical cases, physicians experienced with FMF can often make the diagnosis on clinical grounds alone. Clinical criteria sets for FMF have been shown to have high sensitivity and specificity in parts of the world where the pretest probability of FMF is high. Genetic testing can provide a useful adjunct in ambiguous cases or for physicians not experienced in FMF. Most of the more severe disease-associated FMF mutations are in exon 10 of the gene. An updated list of mutations for FMF and other hereditary recurrent fevers can be found online at *http://fmf.igh.cnrs.fr/infevers/*.

Genetic testing has permitted a broadening of the clinical spectrum and geographic distribution of FMF and may be of prognostic value. Most studies indicate that M694V homozygotes have an earlier age of onset and a higher frequency of arthritis, rash, and amyloidosis. In contrast, the E148Q variant in exon 2 is quite common in certain Asian populations and is more likely to affect overall levels of inflammation than to cause clinical FMF. E148Q is sometimes found in *cis* with exon 10 mutations, which may complicate the interpretation of genetic test results. Only ~70% of patients with clinically typical FMF have two identifiable mutations in *trans*, consistent with the concept that FMF mutations are gain-of-function with regard to inflammasome activation, with a dosage effect. In those cases in which only a single mutation is identified, clinical judgment is very important, and sometimes a therapeutic trial of colchicine or an IL-1 inhibitor may help to confirm the diagnosis.

If a patient is seen during his or her first attack, the differential diagnosis may be broad, although delimited by the specific organ involvement. After several attacks, the differential diagnosis may include the other hereditary recurrent fever syndromes (Table 362-1); the syndrome of periodic fever with aphthous ulcers, pharyngitis, and cervical adenopathy (PFAPA); systemic-onset juvenile rheumatoid arthritis or adult Still's disease; porphyria; hereditary angioedema; inflammatory bowel disease; and, in women, gynecologic disorders.

TREATMENT

Familial Mediterranean Fever

The initial treatment of choice for FMF is daily oral colchicine, which decreases the frequency and intensity of attacks and prevents the development of amyloidosis in compliant patients. Intermittent dosing at the onset of attacks is not as effective as daily prophylaxis and is of unproven value in preventing amyloidosis. The usual adult dose of colchicine is 1.2–1.8 mg/d, which causes substantial reduction in symptoms in two-thirds of patients and some improvement in >90%. Children may require lower doses, although not proportionately to body weight.

Common side effects of colchicine include bloating, abdominal cramps, lactose intolerance, and diarrhea. They can be minimized by starting at a low dose and gradually advancing as tolerated, splitting the dose, use of simethicone for flatulence, and avoidance of dairy products. If taken by either parent at the time of conception, colchicine may cause a small increase in the risk of trisomy 21 (Down's syndrome). Colchicine is usually continued during pregnancy, because the risk of miscarriage due to FMF attacks is thought to outweigh any effect of colchicine on fetal development. In elderly patients with renal insufficiency, colchicine can cause a myoneuropathy characterized by proximal muscle weakness and elevation of the creatine kinase. Cyclosporine inhibits hepatic excretion of colchicine by its effects on the multidrug resistance 1 (MDR1) transport system, sometimes leading to colchicine toxicity in patients who have undergone renal transplantation for amyloidosis. Intravenous colchicine should generally not be administered to patients already taking oral colchicine, because severe, sometimes fatal, toxicity has been observed in this setting.

For FMF patients who do not respond to colchicine or cannot tolerate therapeutic doses, injectable IL-1 inhibitors may be used. Based on a randomized placebo-controlled phase 3 trial, the monoclonal anti-IL-1β antibody canakinumab received U.S. Food and Drug Administration (FDA) approval for this indication. In a small randomized placebo-controlled trial, weekly subcutaneous rilonacept, a recombinant IL-1 receptor fusion protein, significantly reduced the frequency of attacks. There is also substantial anecdotal experience with daily subcutaneous anakinra, a recombinant IL-1 receptor antagonist, in preventing the acute attacks of FMF and, in some cases, reducing established amyloid deposits. Bone marrow transplantation has been suggested for refractory FMF, but the risk-benefit ratio is currently regarded as unacceptable.

OTHER HEREDITARY RECURRENT FEVERS

TNF RECEPTOR–ASSOCIATED PERIODIC SYNDROME

Tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS) is caused by dominantly inherited mutations in the extracellular domains of the 55-kDa TNF receptor (TNFR1, p55). Although originally described in a large Irish family (and hence the name *familial Hibernian fever*), TRAPS has a broad ethnic distribution. TRAPS episodes often begin in childhood. The duration of attacks ranges from 1 to 2 days to as long as several weeks, and in severe cases, symptoms may be nearly continuous. In addition to peritoneal, pleural, and synovial attacks similar to FMF, TRAPS patients frequently have ocular inflammation (most often conjunctivitis and/or periorbital edema), and a distinctive migratory myalgia with overlying painful erythema may be present. TRAPS patients generally respond better to glucocorticoids than to prophylactic colchicine. Untreated, ~15% develop amyloidosis. The diagnosis of TRAPS is based on the demonstration of a *TNFRSF1A* mutation in the presence of characteristic symptoms. Two particular variants, R92Q and P46L, are common in certain populations and may act more as functional polymorphisms than as disease-causing mutations. In contrast, pathogenic *TNFRSF1A* mutations, including a number of substitutions at highly conserved cysteine residues, are associated with intracellular TNFR1 misfolding, aggregation, and retention, with consequent ligand-independent kinase activation, mitochondrial reactive oxygen species production, and proinflammatory cytokine release. Etanercept, a TNF inhibitor, ameliorates TRAPS attacks, but the long-term experience with this agent has been less favorable. IL-1 inhibition has been beneficial in a large percentage of the patients in whom it has been used, and canakinumab recently

received FDA approval for the treatment of TRAPS. Monoclonal anti-TNF antibodies should be avoided, because they may exacerbate TRAPS attacks.

HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME (ALSO KNOWN AS MEVALONATE KINASE DEFICIENCY)

Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) is a recessively inherited recurrent fever syndrome found primarily in individuals of northern European ancestry. It is caused by mutations in mevalonate kinase (*MVK*), encoding an enzyme involved in the synthesis of cholesterol and nonsterol isoprenoids, including geranylgeranyl pyrophosphate. The latter compound is essential for proper localization of RhoA GTPase to the cell membrane, and the mislocalization of RhoA leads to its inactivation and the consequent activation of the pyrin inflammasome. HIDS attacks usually begin in infancy and last 3–5 days. Clinically distinctive features include painful cervical adenopathy, a diffuse maculopapular rash sometimes affecting the palms and soles, and aphthous ulcers; pleurisy is rare. Amyloidosis has been observed associated with the V377I/I268T *MVK* genotype. Although originally defined by the persistent elevation of serum IgD, disease activity is not related to IgD levels, and some patients with FMF or TRAPS may have modestly increased serum IgD. Moreover, occasional patients with *MVK* mutations and recurrent fever have normal IgD levels, while all patients with mutations have markedly elevated urinary mevalonate levels during their attacks. For these reasons, some have proposed renaming this disorder *mevalonate kinase deficiency* (MKD). Canakinumab was recently approved by the FDA for the treatment of HIDS/MKD.

NLRP3-ASSOCIATED AUTOINFLAMMATORY DISEASE (ALSO KNOWN AS THE CRYOPYRINOPATHIES OR CRYOPYRIN-ASSOCIATED PERIODIC SYNDROMES)

Three hereditary febrile syndromes, familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (NOMID), are all caused by mutations in *NLRP3* (formerly known as *CIAS1*), the gene encoding cryopyrin (or NLRP3), and represent a clinical spectrum of disease. FCAS patients develop chills, fever, headache, arthralgia, conjunctivitis, and an urticaria-like rash in response to generalized cold exposure. In MWS, an urticarial rash is noted, but it is not usually induced by cold; MWS patients also develop fevers, abdominal pain, limb pain, arthritis, conjunctivitis, and, over time, sensorineural hearing loss. NOMID is the most severe of the three disorders, with chronic aseptic meningitis, a characteristic arthropathy, and rash. Like the FMF protein pyrin, cryopyrin has an N-terminal PYRIN domain, allowing the formation of an *NLRP3 inflammasome* that mediates caspase-1 activation, IL-1β and IL-18 release, and pyroptosis. Peripheral blood leukocytes from patients with FCAS, MWS, and NOMID release increased amounts of IL-1β upon in vitro stimulation, relative to healthy controls. Macrophages from cryopyrin-deficient mice exhibit decreased IL-1β production in response to certain gram-positive bacteria, bacterial RNA, and monosodium urate crystals. Patients with all three cryopyrinopathies or cryopyrin-associated periodic syndromes (CAPS) show a dramatic response to injections of IL-1 inhibitors. Canakinumab and rilonacept are approved by the FDA for the treatment of FCAS and MWS, whereas anakinra is approved for the treatment of NOMID.

Approximately one-third of patients with clinical manifestations of NOMID do not have germline mutations in *NLRP3*, but they have been found to be mosaic for somatic *NLRP3* mutations. Such patients also respond dramatically to IL-1 inhibition. Somatic mosaicism in *NLRP3* has been reported rarely in Schnitzler's syndrome, which presents in middle age with recurrent fever, urticarial rash, elevated acute-phase reactants, monoclonal IgM gammopathy, and abnormal bone remodeling. IL-1 inhibition is the treatment of choice for Schnitzler's syndrome.

PERIODIC FEVER WITH APHTHOUS STOMATITIS, PHARYNGITIS, AND CERVICAL ADENITIS

Periodic fever with aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA) is the most common periodic fever syndrome in children, notable for the almost clock-like regularity of episodes and the tendency for resolution of attacks by early adulthood. PFAPA tends to run in families, but not in a Mendelian fashion. Recent studies indicate that common shared variants in the *IL12A*, *IL10*, *STAT4,* and *CCR1-CCR3* loci confer susceptibility for a spectrum of phenotypes ranging from common aphthous ulcers to PFAPA to Behçet's disease. Therapeutic options for PFAPA include intermittent glucocorticoids; daily oral colchicine, cimetidine, or apremilast; or tonsillectomy/adenoidectomy.

OTHER INHERITED AUTOINFLAMMATORY DISEASES

There are a number of other Mendelian autoinflammatory diseases in which recurrent fevers are not a prominent clinical sign but that involve abnormalities of innate immunity. The syndrome of pyogenic arthritis with pyoderma gangrenosum and acne (PAPA) is a dominantly inherited disorder that presents with episodes of sterile pyogenic monoarthritis often induced by trauma, severe pyoderma gangrenosum, and severe cystic acne usually beginning in puberty. It is caused by mutations in *PSTPIP1*, which encodes a pyrin-binding protein, and the arthritic manifestations often respond to IL-1 inhibition. Dominantly inherited gain-of-function mutations in *NLRC4* lead to increased IL-1 and IL-18 production and potentially life-threatening recurrent macrophage activation syndrome.

Whereas the aforementioned disorders all involve mutations in IL-1-related molecules, other autoinflammatory diseases are caused by mutations in other components of innate immunity. *Blau's syndrome* is caused by mutations in *CARD15* (also known as *NOD2*), which regulates nuclear factor κB activation. Blau's syndrome is characterized by granulomatous dermatitis, uveitis, and arthritis; distinct *CARD15* variants predispose to Crohn's disease. Recessive mutations in one or more components of the proteasome lead to excessive interferon signaling and a severe form of generalized panniculitis. De novo gain-of-function mutations in *TMEM173*, encoding the stimulator of interferon genes (STING), cause severe vasculopathy and pulmonary fibrosis. Recessive loss-of-function mutations in the gene encoding adenosine deaminase 2 (ADA2) cause a vasculopathy that can manifest as livedoid rash, early-onset lacunar strokes, or polyarteritis nodosa, often responsive to TNF inhibition. Mutations in the gene encoding the A20 ubiquitin-modifying enzyme cause a Behçet's-like monogenic illness ("HA20"), whereas mutations in a different deubiquitinase (OTULIN) cause a form of panniculitis ("otulipenia"). Mutations at the site where RIPK1 is inactivated by caspase-8 cause a condition manifesting recurrent fevers, painful lymphadenopathy, and organomegaly, denoted CRIA (cleavage-resistant RIPK1-induced autoinflammatory) syndrome, that may respond to IL-6 inhibition.

Finally, it should be noted that a number of common, genetically complex disorders are now sometimes considered autoinflammatory, because of evidence that components of the innate immune system, such as the inflammasome, may play a role in the pathogenesis. Two prominent examples are gout and atherosclerosis. Myeloid-restricted somatic mutations in an essential ubiquitylation enzyme have recently been implicated in a severe adult-onset autoinflammatory disease termed VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) syndrome, which can present as relapsing polychondritis, vasculitis, or myelodysplastic syndrome.

GLOBAL CONSIDERATIONS

All the disorders discussed in this chapter have been observed in multiple populations. However, as noted herein, FMF is most frequently observed in Mediterranean and Middle Eastern populations and HIDS in northern European populations, particularly the Dutch. A recessive founder mutation in *ADA2* is particularly common in the Georgian Jewish population and is associated with polyarteritis nodosa.

Section 3 Disorders of the Joints and Adjacent Tissues

370 Approach to Articular and Musculoskeletal Disorders

John J. Cush

Musculoskeletal complaints account for >315 million outpatient visits per year and >20% of all outpatient visits in the United States. The Centers for Disease Control and Prevention estimate that 58.5 million (or 1 in 4 adults) of the U.S. population has physician-diagnosed arthritis. While many patients will have self-limited conditions requiring minimal evaluation, reassurance, and symptomatic therapy, specific musculoskeletal presentations or their persistence may herald a more serious condition that requires further evaluation or laboratory testing to establish a diagnosis. The goal of the musculoskeletal evaluation is to formulate a differential diagnosis that leads to an accurate diagnosis and timely therapy, while avoiding excessive diagnostic testing and unnecessary treatment **(Table 370-1)**. There are several urgent conditions that must be diagnosed promptly to avoid damage and morbidity. These "red flag" diagnoses include septic arthritis, acute crystal-induced arthritis (e.g., gout), and fracture. Each may be suspected by an acute onset and monarticular or focal musculoskeletal pain.

TABLE 370-1 Evaluation of Patients with Musculoskeletal Complaints

Goals
Accurate diagnosis
Timely provision of therapy
Avoidance of unnecessary diagnostic testing
Identification of acute, focal/monarticular "red flag" conditions
Approach
Determine the chronology (acute vs chronic)
Determine the nature of the pathologic process (inflammatory vs noninflammatory)
Determine the extent of involvement (monarticular, polyarticular, focal, widespread)
Anatomic localization of complaint (articular vs nonarticular)
Consider the most common disorders first
Consider the need for diagnostic testing
Formulate a differential diagnosis

The majority of individuals with musculoskeletal complaints can be diagnosed with a thorough history and a comprehensive physical and musculoskeletal examination. The initial encounter should determine whether the musculoskeletal complaint signals a red flag condition (septic arthritis, gout, or fracture) or not. The evaluation should ascertain if the complaint is (1) *articular* or *nonarticular*, (2) *inflammatory* or *noninflammatory*, (3) *acute* or *chronic*, and (4) *localized (monarticular)* or *widespread* (*polyarticular*).

With this approach, the musculoskeletal presentation can be characterized (e.g., acute inflammatory monarthritis or a chronic noninflammatory, nonarticular widespread pain) to narrow the diagnostic possibilities. However, some patients will not fit immediately into an established diagnostic category. Many musculoskeletal disorders resemble each other at the outset, and some may take weeks or months (but not years) to evolve into a recognizable diagnostic entity. This consideration should temper the desire to establish a definitive diagnosis at the first encounter.

ARTICULAR VERSUS NONARTICULAR

The musculoskeletal evaluation must discriminate the anatomic origin(s) of the patient's complaint. For example, ankle pain can result from a variety of pathologic conditions involving disparate anatomic structures, including gouty arthritis, calcaneal fracture, Achilles tendinitis, plantar fasciitis, cellulitis, and peripheral or entrapment neuropathy. Distinguishing between articular and nonarticular conditions requires a careful and detailed examination. Articular structures include the synovium, synovial fluid, articular cartilage, intraarticular ligaments, joint capsule, and juxtaarticular bone. Nonarticular (or periarticular) structures, such as supportive extraarticular ligaments, tendons, bursae, muscle, fascia, bone, nerve, and overlying skin, may be involved in the pathologic process. Although musculoskeletal complaints are often ascribed to the joints, nonarticular disorders are more frequent and are often confused with arthritis. Distinguishing between articular and nonarticular (also called periarticular) pain may be challenging to the unskilled examiner. Articular disorders may be characterized by deep or diffuse pain, limited range of motion on active and passive movement, and swelling (caused by synovial proliferation, effusion, or bony enlargement), crepitation, instability, "locking," or deformity. By contrast, nonarticular disorders tend to be painful on active, but not passive (or assisted), range of motion. Periarticular conditions often demonstrate point or focal tenderness in regions adjacent to articular structures, may radiate or be elicited with a specific movement or position, and have physical findings remote from the joint capsule. Moreover, nonarticular disorders seldom demonstrate swelling, crepitus, instability, or deformity.

INFLAMMATORY VERSUS NONINFLAMMATORY DISORDERS

In the course of a musculoskeletal evaluation, the examiner should determine the nature of the underlying pathologic process and whether inflammatory or noninflammatory findings exist. Inflammatory disorders may be infectious (*Neisseria gonorrhoeae* or *Mycobacterium tuberculosis*), crystal-induced (gout, pseudogout), immune-related (rheumatoid arthritis [RA], systemic lupus erythematosus [SLE]), reactive (rheumatic fever, reactive arthritis), or idiopathic. Inflammatory disorders may be suggested by any of the four cardinal signs of inflammation (erythema, warmth, pain, or swelling), systemic symptoms (fatigue, fever, rash, weight loss), or laboratory evidence of inflammation (elevated erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP], thrombocytosis, anemia of chronic disease, or hypoalbuminemia). Articular stiffness commonly accompanies chronic musculoskeletal disorders. The duration of stiffness may be prolonged (hours) with inflammatory disorders (such as RA or polymyalgia rheumatica [PMR]) and improves with activity. By contrast, intermittent stiffness (also known as gel phenomenon), typical of noninflammatory conditions (such as osteoarthritis [OA]), is shorter in duration (<60 min) and is exacerbated by activity. Fatigue may be

profound with inflammation (as seen in RA and PMR) but may also be a consequence of fibromyalgia (a noninflammatory disorder), chronic pain, poor sleep, depression, anemia, cardiac failure, endocrinopathy, or malnutrition.

Noninflammatory disorders may be related to trauma (rotator cuff tear), repetitive use (bursitis, tendinitis), degeneration or ineffective repair (OA), neoplasm (pigmented villonodular synovitis), or pain amplification (fibromyalgia). Noninflammatory disorders are often characterized by pain without synovial swelling or warmth, absence of inflammatory or systemic features, intermittent gel phenomena rather than prolonged morning stiffness, and normal (for age) or negative laboratory investigations.

With identification of the nature of the underlying process and the site of the complaint, the examiner can further categorize the musculoskeletal presentation (e.g., acute inflammatory monoarthritis, chronic noninflammatory, nonarticular widespread pain). By narrowing the diagnostic considerations, the examiner can assess the need for immediate diagnostic or therapeutic intervention or for continued observation. **Figure 370-1** presents an algorithmic approach to the evaluation of patients with musculoskeletal complaints. This approach relies on clinical and historic features, rather than laboratory testing, to diagnose many common rheumatic disorders.

A simpler, alternative approach would consider the most commonly encountered complaints first, based on frequency in younger versus

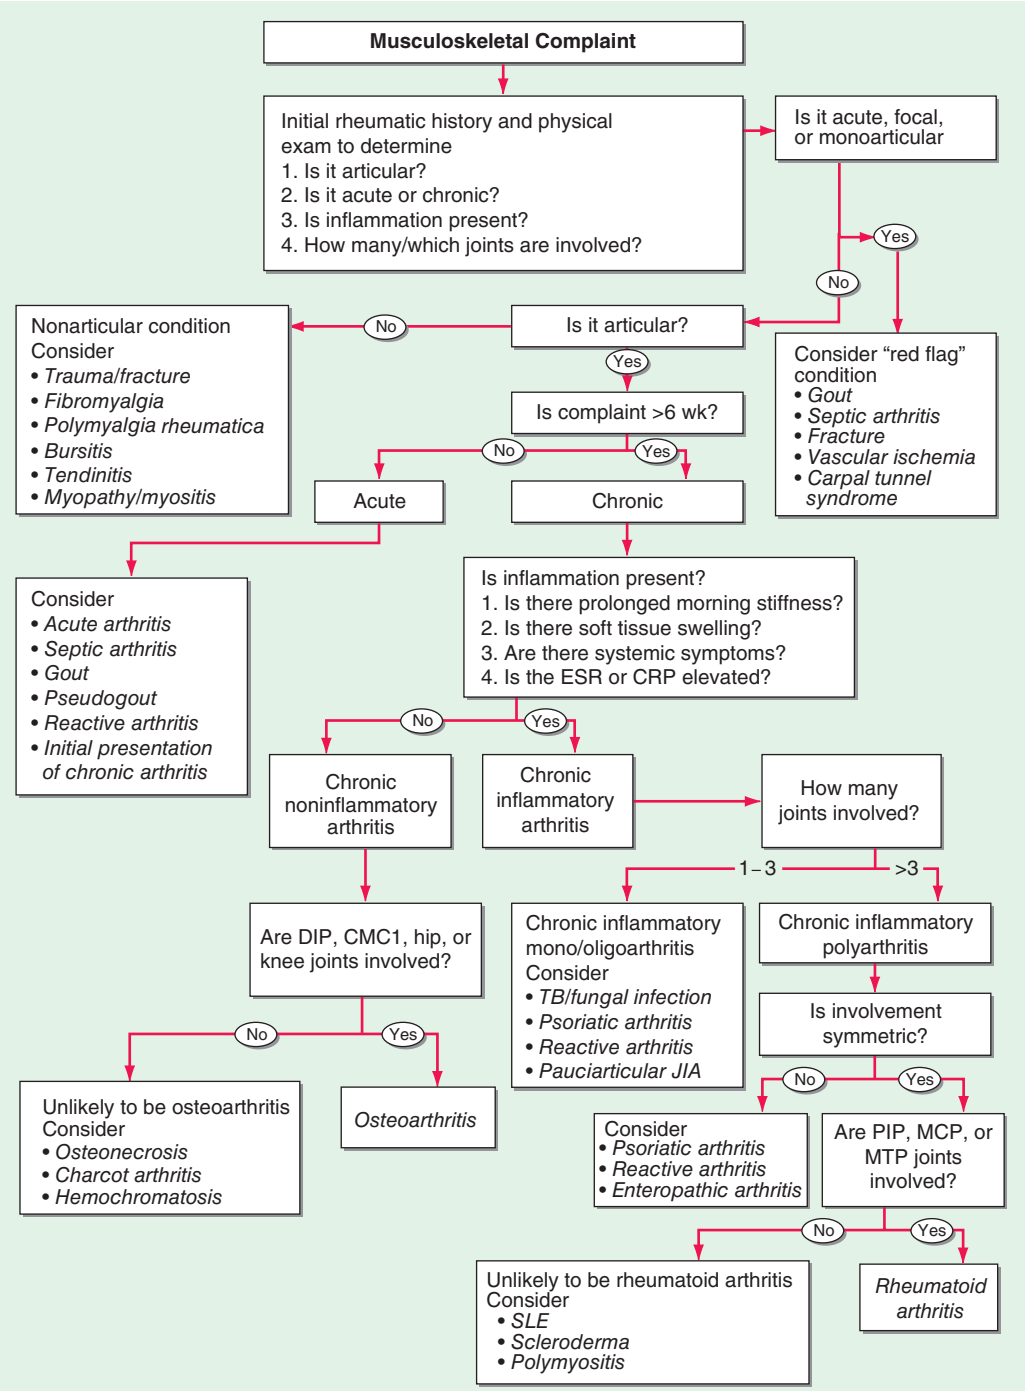

FIGURE 370-1 Algorithm for the diagnosis of musculoskeletal complaints. An approach to formulating a differential diagnosis (shown in italics). CMC, carpometacarpal; CRP, C-reactive protein; DIP, distal interphalangeal; ESR, erythrocyte sedimentation rate; JIA, juvenile idiopathic arthritis; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal; PMR, polymyalgia rheumatica; SLE, systemic lupus erythematosus; TB, tuberculosis.

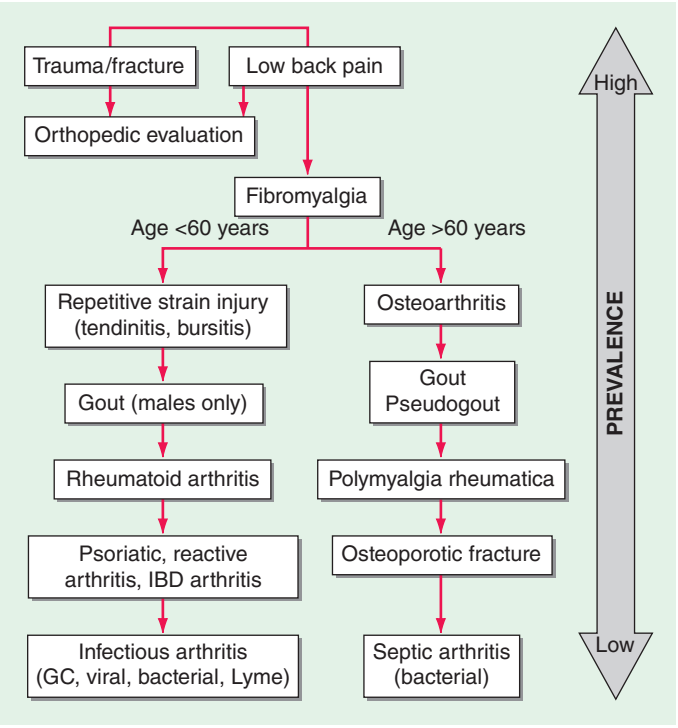

FIGURE 370-2 Algorithm for consideration of the most common musculoskeletal conditions. GC, gonococcal; IBD, inflammatory bowel disease.

older populations. The most prevalent causes of musculoskeletal complaints are shown in **Fig. 370-2**. Because trauma, fracture, overuse syndromes, and fibromyalgia are among the most common causes of musculoskeletal pain, these should be considered with each new encounter. If excluded, other frequently occurring disorders should be considered according to the patient's age. Hence, those aged <60 years are commonly affected by repetitive use/strain disorders, gout (men only), RA, spondyloarthritis, and uncommonly, infectious arthritis. Patients aged >60 years are frequently affected by OA, crystal (gout and pseudogout) arthritis, PMR, osteoporotic fracture, and uncommonly, septic arthritis. These conditions are between 10 and 100 times more prevalent than other serious autoimmune conditions, such as SLE, scleroderma, polymyositis, and vasculitis.

CLINICAL HISTORY

Historic features may reveal important clues to the diagnosis. Aspects of the patient profile, complaint chronology, extent of joint involvement, and precipitating factors can provide important information. Certain diagnoses are more frequent in different *age* groups. SLE and reactive arthritis occur more frequently in the young, whereas fibromyalgia and RA are frequent in middle age, and OA and PMR are more prevalent among the elderly. Diagnostic clustering is also evident when *sex* and *race* are considered. Gout, spondyloarthritis, and ankylosing spondylitis are more common in men, whereas RA, fibromyalgia, osteoporosis, and lupus are more frequent in women. *Racial predilections* may be evident. Thus, PMR, giant cell arteritis, and granulomatosis with polyangiitis (GPA; formerly called Wegener's granulomatosis) commonly affect whites, whereas sarcoidosis and SLE more commonly affect African Americans. *Familial aggregation* is unlikely for most arthropathies but may be seen with ankylosing spondylitis, gout, and Heberden's nodes of OA.

The chronology of the complaint is an important diagnostic feature and can be divided into the *onset, evolution*, and *duration*. The onset of disorders such as septic arthritis or gout tends to be abrupt, whereas OA, RA, and fibromyalgia may have more indolent presentations. The patients' complaints may evolve differently and be classified as chronic (OA), intermittent (crystal or Lyme arthritis), migratory (rheumatic fever, gonococcal or viral arthritis), or additive (RA, psoriatic arthritis). Musculoskeletal disorders are typically classified as acute or chronic based on a symptom duration that is either <6 weeks or >6 weeks, respectively. Acute arthropathies tend to be infectious, crystal-induced, or reactive. Chronic conditions include noninflammatory or immunologic arthritides (e.g., OA, RA) and nonarticular disorders (e.g., fibromyalgia).

The *extent* or *distribution* of articular involvement is often informative. Articular disorders are classified based on the number of joints involved, as either *monarticular* (one joint), *oligoarticular* or *pauciarticular* (two or three joints), or *polyarticular* (four or more joints). Although crystal and infectious arthritis are often mono- or oligoarticular, OA and RA are usually polyarticular. Nonarticular disorders may be classified as either focal or widespread. Complaints secondary to tendinitis or carpal tunnel syndrome are typically focal, whereas weakness and myalgia, caused by polymyositis or fibromyalgia, are more widespread in their presentation. Joint involvement in RA tends to be symmetric and polyarticular. By contrast, spondyloarthritis, reactive arthritis, gout, and sarcoid are often asymmetric and oligoarticular. OA and psoriatic arthritis may be either symmetric or asymmetric and oligo- or polyarticular. The upper extremities are frequently involved in RA and OA, whereas lower extremity arthritis is characteristic of reactive arthritis and gout at their onset. Involvement of the axial skeleton is common in OA and ankylosing spondylitis but is infrequent in RA, with the notable exception of the cervical spine.

The clinical history should also identify *precipitating events*, such as trauma (osteonecrosis, meniscal tear), drug administration **(Table 370-2)**, antecedent or intercurrent infection (reactive arthritis, hepatitis, chikungunya), or illnesses that may have contributed to the patient's complaint. Certain comorbidities may have musculoskeletal consequences. This is especially so for diabetes mellitus (carpal tunnel syndrome), renal insufficiency (gout), depression or insomnia (fibromyalgia), myeloma (spinal pain), cancer (myositis), and osteoporosis (fracture) or when using certain drugs such as glucocorticoids (osteonecrosis, septic arthritis), diuretics, or chemotherapy (gout) (Table 370-2).

Lastly, a thorough *rheumatic review of systems* may disclose useful diagnostic information. A variety of musculoskeletal disorders may be associated with systemic features such as fever (Still's disease, infection), rash (SLE, psoriatic arthritis), nail abnormalities (psoriatic or reactive arthritis), myalgias (fibromyalgia, statin- or drug-induced myopathy), or weakness (polymyositis, neuropathy). In addition, some conditions are associated with involvement of other organ systems including the eyes (Behçet's disease, sarcoidosis, spondyloarthritis), gastrointestinal tract (scleroderma, inflammatory bowel disease), genitourinary tract (reactive arthritis, gonococcemia), or nervous system (Lyme disease, vasculitis).

FIBROMYALGIA

Syphilis and tuberculosis have been called the "great masqueraders" as their protean symptoms and potential for multiorgan involvement may result in delays in diagnosis and treatment. In the modern era, other serious diagnoses (including lupus, sarcoidosis, vasculitis, and lymphoma) have also been labeled as great masqueraders. All of these are either uncommon or rare, compared to the more common masquerader of musculoskeletal complaints—fibromyalgia. Fibromyalgia **(see Chap. 373)** is a pain amplification disorder unified by sleep disturbance, exaggerated pain and sensitivity (owing to lowered pain thresholds), and a multiplicity of symptoms with a paucity of abnormalities on clinical examination or laboratory testing. Tender "trigger points" may be elicited over the epicondyles, trochanteric bursae, anserine bursae, and specific muscles (gluteal, trapezius, supraspinatus). Fibromyalgia is characterized by widespread aches and pains, even though presenting symptoms tend to be fewer or focal. Fibromyalgia coexists with numerous comorbidities including irritable bowel syndrome, dysmenorrhea, migraine, depression, anxiety, memory loss, nonanatomic paresthesia or dysesthesia, fatigue, myalgias, temporomandibular joint pain, hypermobility, and multiple chemical sensitivities. Fibromyalgia

TABLE 370-2 Drug-Induced Musculoskeletal Conditions

Arthralgias	Quinidine, cimetidine, beta blockers, quinolones, chronic acyclovir, interferons, IL-2, nicardipine, vaccines, rifabutin, aromatase inhibitors, HIV protease inhibitors, DPP-4 inhibitors (sitagliptin, linagliptin, alogliptin), paclitaxel, checkpoint inhibitors (ipilimumab, pembrolizumab, nivolumab, atezolizumab, durvalumab, cemiplimab)
Myalgias/myopathy	Glucocorticoids, penicillamine, hydroxychloroquine, AZT, lovastatin, simvastatin, atorvastatin, pravastatin, clofibrate, amiodarone, interferon, IL-2, alcohol, cocaine, paclitaxel, docetaxel, imatinib mesylate, colchicine, quinolones, cyclosporine, tacrolimus, protease inhibitors, checkpoint inhibitors
Tendon rupture/tendinitis	Quinolones, glucocorticoids, isotretinoin, statins, aromatase inhibitors, collagenase injections
Gout	Diuretics, aspirin, cytotoxics, cyclosporine, tacrolimus, alcohol, moonshine, ethambutol, fructose-containing soft drinks
Drug-induced lupus	Hydralazine, procainamide, quinidine, phenytoin, carbamazepine, methyldopa, isoniazid, chlorpromazine, lithium, penicillamine, tetracyclines, TNF inhibitors, ACE inhibitors, ticlopidine, terbinafine, aromatase inhibitors
Drug-induced subacute lupus	Proton pump inhibitors, calcium channel blockers (diltiazem), ACE inhibitors, TNF inhibitors, terbinafine, interferons (α and β-1a), paclitaxel, docetaxel, gemcitabine, capecitabine, aromatase inhibitors, HCTZ
Osteonecrosis/atypical fractures	Glucocorticoids, alcohol, radiation, bisphosphonates
Osteopenia	Glucocorticoids, chronic heparin, phenytoin, aromatase inhibitors, antiandrogen therapy, thiazolidinediones
Psoriasis	TNF inhibitors, beta blockers, lithium, hydroxychloroquine, chloroquine, minocycline, ACE inhibitors, terbinafine, checkpoint inhibitors.
Scleroderma	Vinyl chloride, bleomycin, baricitinib, pentazocine, organic solvents, carbidopa, tryptophan, rapeseed oil
Raynaud's phenomenon	Cisplatin, bleomycin, beta blockers, clonidine, bromocriptine, ergot alkaloids, cocaine, methylphenidate, dextroamphetamine, phentermine, interferon therapy
Vasculitis	Allopurinol, amphetamines, cocaine (often levamisole adulterated), cannabis, thiazides, penicillamine, propylthiouracil, montelukast, TNF inhibitors, hepatitis B vaccine, trimethoprim/sulfamethoxazole, minocycline, hydralazine

Abbreviations: ACE, angiotensin-converting enzyme; AZT, zidovudine; HCTZ, hydrochlorothiazide; IL-2, interleukin 2; TNF, tumor necrosis factor.

affects nearly 5 million Americans but is underrecognized or misdiagnosed as arthritis, lupus, multiple sclerosis, autoimmune disease, or other conditions. Early consideration of this very common disorder can avert needless investigation, therapy, and concern for those afflicted (Fig. 370-2).

RHEUMATOLOGIC EVALUATION OF THE ELDERLY

The incidence of rheumatic diseases rises with age, such that 58% of those >65 years will have joint complaints. Musculoskeletal disorders in elderly patients are often not diagnosed because the signs and symptoms may be insidious, overlooked, or overshadowed by comorbidities. These difficulties are compounded by the diminished reliability of laboratory testing in the elderly, who often manifest nonpathologic abnormal results. For example, the ESR may be misleadingly elevated, and low-titer positive tests for rheumatoid factor (RF) and antinuclear antibodies (ANAs) may be seen in up to 15% of elderly patients. Although nearly all rheumatic disorders afflict the elderly, geriatric patients are particularly prone to OA, osteoporosis, osteoporotic fractures, gout, pseudogout, PMR, vasculitis, and drug-induced disorders (Table 370-2). The elderly should be approached in the same manner as other patients with musculoskeletal complaints, but with an emphasis on identifying the potential rheumatic consequences of medical comorbidities and therapies used in the elderly. The physical examination should identify the nature of the musculoskeletal complaint as well as coexisting diseases that may influence diagnosis and choice of treatment.

RHEUMATOLOGIC EVALUATION OF THE HOSPITALIZED PATIENT

Evaluation of a hospitalized patient with rheumatic complaints is often more complex owing to symptom severity, acute presentations, and greater interplay of comorbidities. Patients with rheumatic disorders tend to be admitted for one of several reasons: (1) acute onset of inflammatory arthritis (possibly gout or septic arthritis); (2) undiagnosed systemic or febrile illness; (3) musculoskeletal trauma; (4) exacerbation or deterioration of an existing musculoskeletal disorder (e.g., SLE); or (5) new medical comorbidities (e.g., thrombotic event, lymphoma, infection) arising in patients with an established rheumatic disorder. Notably, rheumatic patients are seldom if ever admitted because of widespread pain or serologic abnormalities or for the initiation of new therapies.

Acute monoarticular inflammatory arthritis is a "red flag" presentation (e.g., septic arthritis, gout, pseudogout) that may require arthrocentesis or hospitalization if infection is suspected. New-onset inflammatory polyarthritis has a wide differential diagnosis (e.g., RA, hepatitis-related arthritis, chikungunya arthritis, serum sickness, drug-induced lupus, SLE, polyarticular septic arthritis) and may require targeted laboratory investigations more so than synovial fluid analyses. Patients with febrile, multisystem disorders require exclusion of crystal, infectious, or neoplastic etiologies and an evaluation driven by the dominant symptom/finding with the greatest specificity. Conditions worthy of consideration may include gout or pseudogout, vasculitis (giant cell arteritis in the elderly or polyarteritis nodosa in younger patients), adult-onset Still's disease, SLE, antiphospholipid antibody syndrome, IgG4-related disease, and sarcoidosis. A preexisting rheumatic diagnosis (e.g., SLE, RA, ankylosing spondylitis) should be confirmed by careful history and examination and review of medical records, as this will influence the ensuing in-patient evaluation. Notably, when established rheumatic disease patients are admitted to the hospital, it is usually not for their autoimmune disease, but rather a comorbid medical problem or complication of drug therapy. Patients with chronic inflammatory disorders (e.g., RA, SLE, psoriasis) have an augmented risk of infection, cardiovascular events, pulmonary disorders, and neoplasia.

Certain conditions, such as acute gout, can be precipitated in hospitalized patients by surgery, dehydration, or medications and should be considered when hospitalized patients are evaluated for the acute onset of a musculoskeletal condition. Lastly, overly aggressive and unfocused laboratory testing will often yield abnormal findings that are better explained by the patient's preexisting condition (chronic lung, renal, or liver disease) rather than a new inflammatory or autoimmune disorder (lupus, vasculitis).

PHYSICAL EXAMINATION

The goal of the physical examination is to ascertain the structures involved, the nature of the underlying pathology, the functional consequences of the process, and the presence of systemic or extraarticular manifestations. A knowledge of topographic anatomy is necessary to identify the primary site(s) of involvement and differentiate articular from nonarticular disorders. The musculoskeletal examination depends largely on careful inspection, palpation, contralateral comparison, and a variety of specific physical maneuvers to elicit diagnostic signs **(Table 370-3)**. Although most articulations of the appendicular skeleton can be examined in this manner, adequate inspection and

TABLE 370-3 Glossary of Musculoskeletal Terms

Crepitus	A palpable (less commonly audible) vibratory or crackling sensation elicited with joint motion; fine joint crepitus is common and often insignificant in large joints; coarse joint crepitus indicates advanced cartilaginous and degenerative changes (as in osteoarthritis)
Subluxation	Alteration of joint alignment such that articulating surfaces incompletely approximate each other
Dislocation	Abnormal displacement of articulating surfaces such that the surfaces are not in contact
Range of motion	For diarthrodial joints, the arc of measurable movement through which the joint moves in a single plane
Contracture	Loss of full movement resulting from a fixed resistance caused either by tonic spasm of muscle (reversible) or by fibrosis of periarticular structures (permanent)
Deformity	Abnormal shape or size resulting from bony hypertrophy, malalignment of articulating structures, or damage to periarticular supportive structures
Enthesitis	Inflammation of the entheses (tendinous or ligamentous insertions on bone)
Epicondylitis	Infection or inflammation involving an epicondyle

palpation are not possible for many axial (e.g., zygapophyseal) and inaccessible (e.g., sacroiliac or hip) joints. For such joints, there is a greater reliance on specific maneuvers and imaging for assessment.

Examination of involved and uninvolved joints will determine whether *pain, warmth, erythema*, or *swelling* is present. The locale and level of pain elicited by palpation or movement should be quantified. Examination of 28 easily palpated joints (proximal interphalangeals [PIPs], metacarpophalangeals [MCPs], wrists, elbows, shoulders, and knees) can quantify the number of tender or swollen joints (0–28) involved. Careful examination should distinguish between true articular swelling (caused by bony hypertrophy, synovial effusion or proliferation) and nonarticular (or periarticular) involvement, which usually extends beyond the normal joint margins. Cautious palpation can distinguish synovial effusion (fluctuant swelling) from synovial hypertrophy (grape-like compressibility) and bony hypertrophy (firm as a nut). Small to moderate knee effusions may be identified by the "bulge sign" or "ballottement of the patellae." Bursal effusions (e.g., effusions of the olecranon or prepatellar bursa) are often focal and periarticular, overlie bony prominences, and are fluctuant with defined borders. Joint *stability* can be assessed by stabilizing the proximal joint and applying manual stress to the distal appendage in different planes. *Subluxation* or *dislocation*, which may be secondary to traumatic, mechanical, or inflammatory causes, can be assessed by inspection and palpation. Joint *swelling* or *volume* can be assessed by palpation. Distention of the articular capsule usually causes pain and evident enlargement or fluctuance. The patient will attempt to minimize the pain by maintaining the joint in the position of least intraarticular pressure and greatest volume (usually partial flexion), possibly leading to flexion contracture over time. Active and passive *range of motion* should be assessed in all planes, with contralateral comparison. A goniometer may be used to quantify the arc of movement. Each joint should be passively manipulated through its full range of motion (including, as appropriate, flexion, extension, rotation, abduction, adduction, lateral bending, inversion, eversion, supination, pronation, medial/lateral deviation, and plantar- or dorsiflexion). Extreme range of motion and connective tissue laxity may be seen with hypermobility syndrome, Ehlers-Danlos syndrome, or Marfan's syndrome. Limitation of motion or contractures are frequently caused by inflammation, effusion, pain, deformity, or neuromyopathic causes. If passive motion exceeds active motion, a periarticular process (e.g., tendinitis, tendon rupture, or myopathy) should be considered. *Contractures* may reflect antecedent synovial inflammation or trauma. Minor joint *crepitus* is common during joint palpation and maneuvers but may indicate significant cartilage degeneration as it becomes coarser (e.g., OA). Joint *deformity* usually indicates a long-standing or aggressive pathologic process. Deformities may result from ligamentous destruction, soft tissue contracture, bony enlargement, ankylosis, erosive disease, subluxation, trauma, or loss of proprioception. Examination of the musculature will document strength, atrophy, pain, or spasm. Appendicular muscle weakness should be characterized as proximal or distal. Muscle strength should be assessed by observing the patient's performance (e.g., walking, rising from a chair, grasping, writing). Strength may also be graded on a 5-point scale: 0 for no movement; 1 for trace movement or twitch; 2 for movement with gravity eliminated; 3 for movement against gravity only; 4 for movement against gravity and resistance; and 5 for normal strength. The examiner should assess for often overlooked nonarticular or periarticular involvement, especially when articular complaints are not supported by objective findings referable to the joint capsule. The identification of soft tissue or nonarticular pain will prevent unwarranted and often expensive additional evaluations. Specific maneuvers may reveal common nonarticular abnormalities, such as a carpal tunnel syndrome (which can be identified by Tinel's sign of Durkan's test). Other examples of soft tissue abnormalities include olecranon bursitis, epicondylitis (e.g., tennis elbow), enthesitis (e.g., Achilles tendinitis), and tender trigger points associated with fibromyalgia.

APPROACH TO REGIONAL RHEUMATIC COMPLAINTS

Although all patients should be evaluated in a logical and thorough manner, many focal musculoskeletal complaints are commonly caused by disorders that exhibit a predictable pattern of onset, evolution, and localization; they can often be easily diagnosed with limited historic information and selected maneuvers or tests. Although nearly every musculoskeletal complaint could be approached in this manner, the evaluation of four commonly involved anatomic regions—the hand, shoulder, hip, and knee—are reviewed here.

HAND PAIN

Focal or unilateral hand pain may result from trauma, overuse, infection, or a reactive or crystal-induced arthritis. By contrast, bilateral hand complaints commonly suggest a degenerative (e.g., OA), systemic, or inflammatory/immune (e.g., RA) etiology. The distribution or pattern of joint involvement is highly suggestive of certain disorders **(Fig. 370-3)**. Thus, OA (or degenerative arthritis) may manifest as distal interphalangeal (DIP) and PIP joint pain and bony hypertrophy leading to Heberden's and Bouchard's nodes, respectively. Pain, with or without bony swelling, involving the base of the thumb (first carpometacarpal joint) is also highly suggestive of OA. By contrast, RA manifests as an additive, symmetric, polyarticular arthritis involving the PIP, MCP, intercarpal, and carpometacarpal joints (wrist) with pain and palpable synovial tissue hypertrophy. Psoriatic arthritis may mimic the pattern of joint involvement seen in OA (DIP and PIP joints) but can be distinguished by the presence of inflammatory signs (erythema, warmth, synovial swelling), with or without carpal involvement, nail pitting, or onycholysis. Whereas lateral or medial subluxations at the PIP or DIP joints are most likely due to inflammatory OA or psoriatic arthritis, dorsal or ventral deformities (swan neck or boutonnière deformities) are typical of RA. Hemochromatosis should be considered when degenerative changes (bony hypertrophy) are seen at the second and third MCP joints with associated radiographic chondrocalcinosis or episodic, inflammatory wrist arthritis.

Dactylitis manifests as soft tissue swelling of the whole digit and may have a sausage-like appearance. Common causes of dactylitis include psoriatic arthritis, spondyloarthritis, juvenile spondylitis, mixed connective tissue disease, scleroderma, sarcoidosis, and sickle cell disease. Soft tissue swelling over the dorsum of the hand and wrist may suggest an inflammatory extensor tendon tenosynovitis possibly caused by gonococcal infection, gout, or inflammatory arthritis (e.g.,

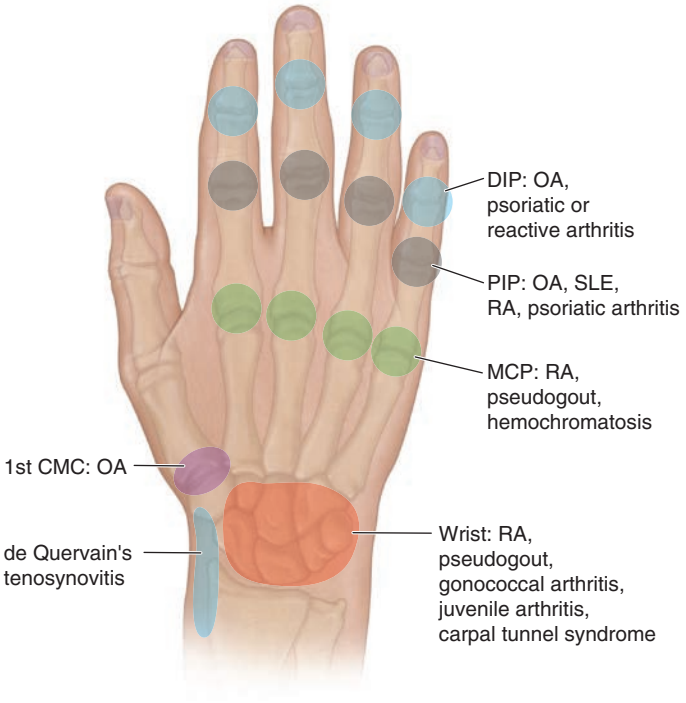

FIGURE 370-3 Sites of hand or wrist involvement and their potential disease associations. CMC, carpometacarpal; DIP, distal interphalangeal; MCP, metacarpophalangeal; OA, osteoarthritis; PIP, proximal interphalangeal; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus. *(Reproduced with permission from JJ Cush et al [eds], Evaluation of musculoskeletal complaints, in Rheumatology: Diagnosis and Therapeutics, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2005.)*

RA). Tenosynovitis is suggested by localized warmth, swelling, or pitting edema and may be confirmed when the soft tissue swelling tracks with tendon movement during flexion and extension of fingers, or when pain is induced while stretching the extensor tendon sheaths (flexing the digits distal to the MCP joints and maintaining the wrist in a fixed, neutral position). Volar (palmar) tendon swellings may be from tenosynovitis, Dupuytren's contractures, tendon nodules, or synovial cysts.

Focal wrist pain localized to the radial aspect may be caused by de Quervain's tenosynovitis resulting from inflammation of the tendon sheath(s) involving the abductor pollicis longus or extensor pollicis brevis (Fig. 370-3). This commonly results from overuse or follows pregnancy and may be diagnosed with Finkelstein's test. A positive result is present when radial wrist pain is induced after the thumb is flexed and placed inside a clenched fist and the patient actively deviates the hand downward with ulnar deviation at the wrist. Carpal tunnel syndrome is another common disorder of the upper extremity and results from compression of the median nerve within the carpal tunnel. Manifestations include pain in the wrist that may radiate with paresthesia to the thumb, second and third fingers, and radial half of the fourth finger and, at times, atrophy of thenar musculature. Carpal tunnel syndrome is commonly associated with pregnancy, edema, trauma, OA, inflammatory arthritis, and infiltrative disorders (e.g., amyloidosis). The diagnosis may be suggested by a positive Durkan's test or Tinel's sign. With each test, paresthesia in a median nerve distribution is induced or increased by 30 s of compression over the carpal tunnel (Durkan's test) or "thumping" the volar aspect of the wrist (Tinel's sign). The low sensitivity and moderate specificity of these tests may require nerve conduction velocity testing to confirm a suspected diagnosis.

SHOULDER PAIN

During the evaluation of shoulder disorders, the examiner should carefully note any history of trauma, fibromyalgia, infection, inflammatory disease, occupational hazards, or previous cervical disease. In addition, the patient should be questioned as to the activities or movement(s) that elicit shoulder pain. While arthritis is suggested by pain on movement in all planes, pain with specific active motion suggests a periarticular (nonarticular) process. Shoulder pain may originate in the glenohumeral or acromioclavicular joints, subacromial (subdeltoid) bursa, periarticular soft tissues (e.g., fibromyalgia, rotator cuff tear/tendinitis), or cervical spine **(Fig. 370-4)**. Shoulder pain is referred frequently from the cervical spine but may also be referred from intrathoracic lesions (e.g., a Pancoast tumor) or from gallbladder, hepatic, or diaphragmatic disease. These same visceral causes may also manifest as focal scapular pain. Fibromyalgia should be suspected when glenohumeral pain is accompanied by diffuse periarticular (i.e., subacromial, bicipital) pain, tender points (i.e., trapezius or supraspinatus), and a sleep disturbance. The shoulder should be put through its full range of motion both actively and passively (with examiner assistance): forward flexion, extension, abduction, adduction, and internal and external rotation. Manual inspection of the periarticular structures will often provide important diagnostic information. Glenohumeral involvement is best detected by placing the thumb over the glenohumeral joint just medial and inferior to the coracoid process and applying pressure anteriorly while internally and externally rotating the humeral head. Pain localized to this region is indicative of glenohumeral pathology. Synovial effusion or tissue is seldom palpable but, if present, may suggest infection, RA, amyloidosis, or an acute tear of the rotator cuff. The examiner should apply direct manual pressure over the subacromial bursa that lies lateral to and immediately beneath the acromion (Fig. 370-4). Subacromial bursitis is a frequent cause of shoulder pain. Anterior to the subacromial bursa, the bicipital tendon traverses the bicipital groove. This tendon is best identified by palpating it in its groove as the patient rotates the humerus internally and externally. Direct pressure over the tendon may reveal pain indicative of bicipital tendinitis. Palpation of the acromioclavicular joint may disclose local

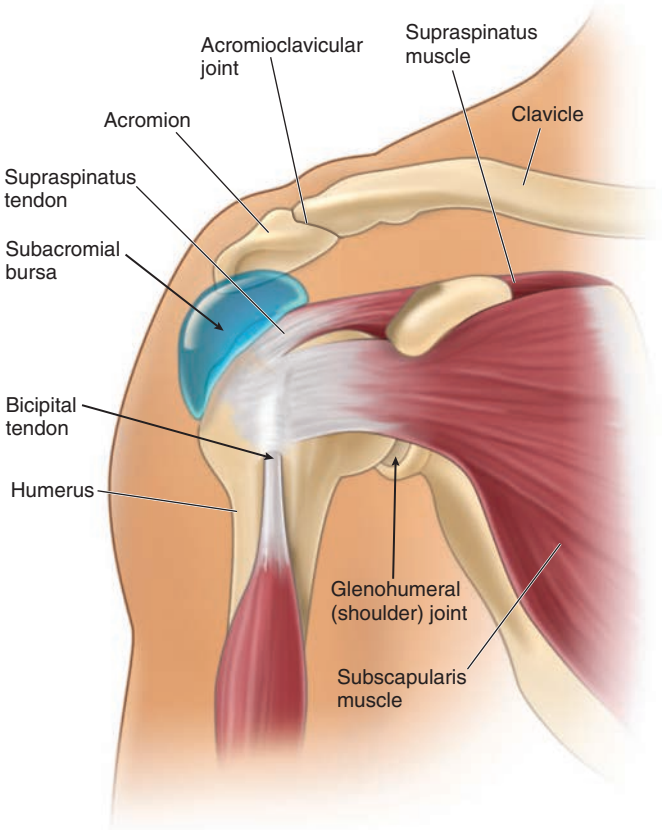

FIGURE 370-4 Origins of shoulder pain. The schematic diagram of the shoulder indicates, with *arrows*, the anatomic origins of shoulder pain.

pain, bony hypertrophy, or, uncommonly, synovial swelling. Whereas OA and RA commonly affect the acromioclavicular joint, OA seldom involves the glenohumeral joint, unless there is avascular necrosis or a traumatic or occupational cause.

Rotator cuff tendinitis or tear is a very common cause of shoulder pain. Nearly 30% of the elderly will have shoulder pain, with rotator cuff tendinitis or tear as a primary cause. The rotator cuff is formed by four tendons that attach the scapula to the proximal humerus (supraspinatus, infraspinatus, teres minor, and subscapularis tendons). Of these, the supraspinatus muscle is the most commonly damaged. Rotator cuff tendinitis is suggested by pain on active abduction (but not passive abduction), pain over the lateral deltoid muscle, night pain, and evidence of the impingement signs (pain with overhead arm activities). The Neer test for impingement is performed by the examiner raising the patient's arm into forced flexion while stabilizing and preventing rotation of the scapula. A positive sign is present if pain develops before 180° of forward flexion. Tear of the rotator cuff is common in the elderly and often results from trauma; it may manifest in the same manner as tendinitis. The drop arm test is abnormal with supraspinatus pathology and is demonstrated by passive abduction of the arm to 90° by the examiner. If the patient is unable to hold the arm up actively or unable to lower the arm slowly without dropping, the test is positive. Tendinitis or tear of the rotator cuff is best confirmed by magnetic resonance imaging (MRI) or ultrasound.

KNEE PAIN

Knee pain may result from intraarticular (OA, RA) or periarticular (anserine bursitis, collateral ligament strain) processes or be referred from hip pathology. A careful history should delineate the chronology of the knee complaint and whether there are predisposing conditions, trauma, or medications that might underlie the complaint. For example, patellofemoral disease (e.g., OA) may cause anterior knee pain that worsens with climbing stairs. Observation of the patient's gait is also important. The knee should be carefully inspected in the upright (weight-bearing) and supine positions for swelling, erythema, malalignment, visible trauma, muscle wasting, and leg length discrepancy. The most common malalignment in the knee is *genu varum* (bowlegs) or *genu valgum* (knock-knees) resulting from asymmetric cartilage loss medially or laterally, respectively. Bony swelling of the knee joint commonly results from hypertrophic osseous changes seen with disorders such as OA and neuropathic arthropathy. Swelling caused by hypertrophy of the synovium or synovial effusion may manifest as a fluctuant, ballotable, or soft tissue enlargement in the suprapatellar pouch (suprapatellar reflection of the synovial cavity) or regions lateral and medial to the patella. Synovial effusions may also be detected by balloting the patella downward toward the femoral groove or by eliciting a "bulge sign." With the knee extended, the examiner should manually compress, or "milk," synovial fluid down from the suprapatellar pouch and lateral to the patellae. The application of manual pressure lateral to the patella may cause an observable shift in synovial fluid (bulge) to the medial aspect. The examiner should note that this maneuver is only effective in detecting small to moderate effusions (<100 mL). Inflammatory disorders such as RA, gout, pseudogout, and psoriatic arthritis may involve the knee joint and produce significant pain, stiffness, swelling, or warmth. A popliteal or *Baker's cyst* may be palpated with the knee partially flexed and is best viewed posteriorly with the patient standing and knees fully extended to visualize isolated or unilateral popliteal swelling or fullness.

Anserine bursitis is an often-missed periarticular cause of knee pain in adults. The pes anserine bursa underlies the insertion of the conjoined tendons (sartorius, gracilis, semitendinosus) on the anteromedial proximal tibia and may be painful following trauma, overuse, or inflammation (bursitis). It is often tender in patients with fibromyalgia, obesity, and knee OA. Other forms of bursitis may also present as knee pain. The prepatellar bursa is superficial and is located over the inferior portion of the patella. The infrapatellar bursa is deeper and lies beneath the patellar ligament before its insertion on the tibial tubercle.

Internal derangement of the knee may result from trauma or degenerative processes. Damage to the meniscal cartilage (medial or lateral) frequently presents as chronic or intermittent knee pain. Such an injury should be suspected when there is a history of trauma, athletic activity, or chronic knee arthritis, and when the patient relates symptoms of "locking" or "giving way" of the knee. With the knee flexed 90° and the patient's foot on the table, pain elicited during palpation over the joint line or when the knee is stressed laterally or medially may suggest a meniscal tear. A positive McMurray test may also indicate a meniscal tear. To perform this test, the knee is first flexed at 90°, and the leg is then extended while the lower extremity is simultaneously torqued medially or laterally. A painful click during inward rotation may indicate a lateral meniscus tear, and pain during outward rotation may indicate a tear in the medial meniscus. Lastly, damage to the cruciate ligaments should be suspected with acute onset of pain, possibly with swelling, a history of trauma, or a synovial fluid aspirate that is grossly bloody. Examination of the cruciate ligaments is best accomplished by eliciting a drawer sign. With the patient recumbent, the knee should be partially flexed and the foot stabilized on the examining surface. The examiner should manually attempt to displace the tibia anteriorly or posteriorly with respect to the femur. If anterior movement is detected, then anterior cruciate ligament damage is likely. Conversely, significant posterior movement may indicate posterior cruciate damage. Contralateral comparison will assist the examiner in detecting significant anterior or posterior movement.

HIP PAIN

The hip is best evaluated by observing the patient's gait and assessing range of motion. The vast majority of patients reporting "hip pain" localize their pain unilaterally to the posterior gluteal musculature **(Fig. 370-5)** with radiation down the posterolateral aspect of the thigh, and the pain may be associated with complaints of low back pain. This presentation frequently results from degenerative arthritis of the lumbosacral spine or disks and commonly follows a dermatomal distribution with involvement of nerve roots between L4 and S1. Sciatica is caused by impingement of the L4, L5, or S1 nerve (i.e., from a herniated disk) and manifests as unilateral neuropathic pain extending from the gluteal region down the posterolateral leg to the foot. Some individuals instead localize their "hip pain" laterally to the area overlying the trochanteric bursa. Because of the depth of this bursa, swelling and warmth are usually absent. Diagnosis of trochanteric bursitis or enthesitis can be confirmed by inducing point tenderness over the trochanteric bursa. Gluteal and trochanteric pain are common findings in fibromyalgia. Range of movement may be limited by pain. Pain in the hip joint is less common and tends to be located anteriorly, over the inguinal ligament; it may radiate medially to the groin. Uncommonly, iliopsoas bursitis may mimic true hip joint pain. Diagnosis of iliopsoas bursitis may be suggested by a history of trauma or inflammatory arthritis. Pain associated with iliopsoas bursitis is localized to the groin or anterior thigh and tends to worsen with hyperextension of the hip; many patients prefer to flex and externally rotate the hip to reduce the pain from a distended bursa.

TELEHEALTH MUSCULOSKELETAL EVALUATION

Telemedicine has grown significantly in recent years as a means of remote patient assessment and providing remote clinical care. Engagement of patients via electronic telecommunication allows for virtual patient evaluations with a time, cost, and convenience advantage, but can be a technological disadvantage for the elderly or disadvantaged populations. Telemedicine is most efficient with quality audio and video connections and can be used for patient education, monitoring, and routine disease assessments. Patients evaluated by telemedicine should undergo the same medical history and inquiry as a routine clinic evaluation, but evaluation will differ in the scope of examination and maneuvers. The musculoskeletal televideo examination may be appropriate and effective in many, primarily by supplanting physical

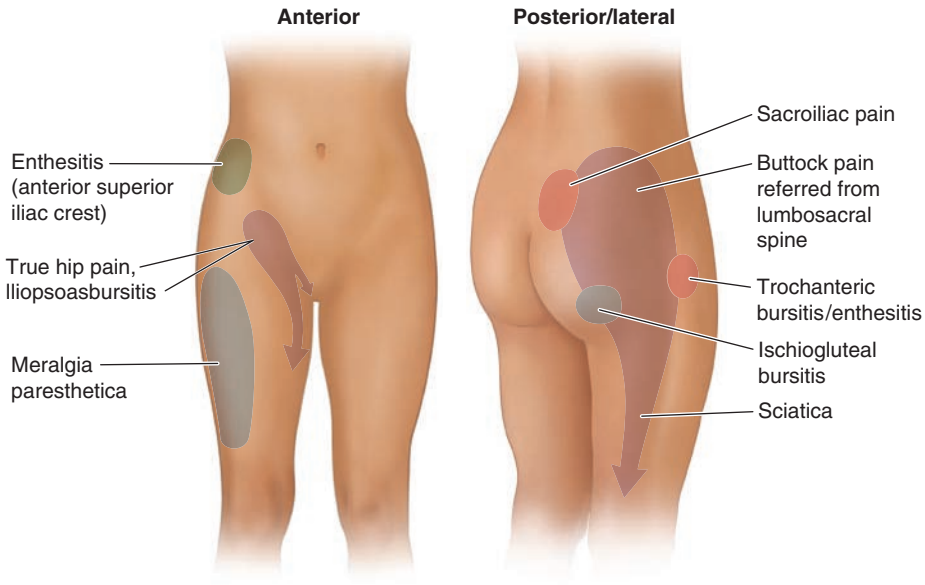

FIGURE 370-5 Origins of hip pain and dysesthesias. *(Reproduced with permission from JJ Cush et al [eds], Evaluation of musculoskeletal complaints, in Rheumatology: Diagnosis and Therapeutics, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2005.)*

palpation with observation, range of motion, patient self-assessments, and contralateral comparison. Specifically, the televideo exam should assess the following: (1) patient gait (to assess lower extremity abnormalities); (2) rising from a seated position (to assess for weakness); (3) cervical range of motion (flexion, extension, lateral bending); (4) assessment by contralateral comparison (e.g., "praying hands," "make a fist," "flex wrists," and "hands on ears, elbows out" to assess shoulder range of motion); and (5) side-by-side inspection of knees, ankles, and feet. Effective telehealth is contingent on clinical experience, knowledge of and familiarity with the patient, and training the patient on the use of technology and goals and limits of a televideo visit.

LABORATORY INVESTIGATIONS

The vast majority of musculoskeletal disorders can be logically diagnosed by a complete history and physical examination. An additional objective of the initial encounter is to determine whether additional investigations or immediate therapy is required. Laboratory evaluation is indicated with (1) monarticular conditions; (2) traumatic or inflammatory conditions; (3) the presence of neurologic findings; (4) systemic manifestations; or (5) chronic symptoms (>6 weeks) and a lack of response to symptomatic measures. The extent and nature of the additional investigation should be dictated by the clinical features and suspected pathologic process. Laboratory tests should be used to confirm a specific clinical diagnosis and not be used to screen or evaluate patients with vague rheumatic complaints. Indiscriminate use of broad batteries of diagnostic tests and radiographic procedures is rarely a useful or cost-effective means to establish a diagnosis.

Besides a complete blood count, including a white blood cell (WBC) and differential count, the routine evaluation should include a determination of an acute-phase reactant such as the ESR or CRP, which can be useful in discriminating inflammatory from noninflammatory disorders. Both are inexpensive, easily obtained, and may be elevated with infection, inflammation, autoimmune disorders, neoplasia, pregnancy, renal insufficiency, advanced age, or hyperlipidemia. Extreme elevation of the acute-phase reactants (CRP, ESR) is seldom seen without evidence of serious illness (e.g., sepsis, pleuropericarditis, PMR, giant cell arteritis, adult Still's disease).

Serum uric acid determinations are useful in the diagnosis of gout and in monitoring the response to urate-lowering therapy. Uric acid, the end product of purine metabolism, is primarily excreted in the urine. Serum values range from 238 to 516 μmol/L (4.0–8.6 mg/dL) in men; the lower values (178–351 μmol/L [3.0–5.9 mg/dL]) seen in women are caused by the uricosuric effects of estrogen. Urinary uric acid levels are normally <750 mg per 24 h. Although hyperuricemia is associated with an increased incidence of gout and nephrolithiasis, levels may not correlate with the severity of articular disease. Uric acid levels (and the risk of gout) may be increased by inborn errors of metabolism (Lesch-Nyhan syndrome), disease states (renal insufficiency, myeloproliferative disease, psoriasis), or drugs (alcohol, cytotoxic therapy, thiazides). Although nearly all patients with gout will demonstrate hyperuricemia at some time during their illness, up to 50% of patients with an acute gouty attack will have normal serum uric acid levels. Monitoring serum uric acid is useful in assessing the response to urate-lowering therapy or chemotherapy, with the target goal being a serum urate <6 mg/dL.

Serologic tests for RF, cyclic anticitrullinated peptide (CCP or ACPA) antibodies, ANAs, complement levels, Lyme and antineutrophil cytoplasmic antibodies (ANCAs), or antistreptolysin O (ASO) titer should be carried out only when there is clinical evidence to specifically suggest a specific diagnosis because these have poor predictive value when used for screening, especially when the pretest probability is low. For most of these, there is no value to repeated or serial serologic testing. Although 4–5% of a healthy population will have positive tests for RF and ANAs, only 1% and <0.4% of the population will have RA or SLE, respectively. IgM RF (autoantibodies against the Fc portion of IgG) is found in 80% of patients with RA but is poorly specific as it may also be seen in low titers in patients with chronic infections (tuberculosis, leprosy, hepatitis); other autoimmune diseases (SLE, Sjögren's syndrome); and chronic pulmonary, hepatic, or renal disease. When considering RA, both serum RF and anti-CCP antibodies should be obtained as these are complementary. Both are comparably sensitive, but CCP antibodies are more specific than RF. In RA, the presence of high titers of anti-CCP or RF antibodies, or double positivity, may indicate a greater risk for more severe, erosive polyarthritis. ANAs are found in nearly all patients with SLE and may also be seen in patients with other autoimmune diseases (polymyositis, scleroderma, antiphospholipid syndrome, Sjögren's syndrome), drug-induced lupus (Table 370-2), chronic thyroid, liver or renal disorders, and advanced age. Positive ANAs are found in 5% of adults and in up to 14% of elderly or chronically ill individuals. The ANA test is very sensitive but poorly specific for lupus, as only 1–2% of all positive results will be caused by lupus alone up to 80% of patients with thyroid disease will be ANA positive. The interpretation of a positive ANA test may depend on the magnitude of the titer and the pattern observed by

TABLE 370-4 Antinuclear Antibody (ANA) Patterns and Clinical Associations

ANA PATTERN	ANTIGEN IDENTIFIED	CLINICAL CORRELATE
Diffuse	Deoxyribonucleoprotein	Nonspecific
	Histones	Drug-induced lupus, lupus
Peripheral (rim)	ds-DNA	50% of SLE (specific)
Speckled	U1-RNP	>90% of MCTD
	Sm	30% of SLE (specific)
	Ro (SS-A)	Sjögren's 60%, SCLE, neonatal lupus, ANA(–) lupus
	La (SS-B)	50% of Sjögren's, 15% lupus
	Scl-70 (topoisomerase I)	40% of diffuse scleroderma
	Jo-1 (histidyl t-RNA synthetase)	PM with pneumonitis + arthritis
Nucleolar	RNA polymerase I, others	40% of PSS
Centromere	Kinetochore	75% CREST (limited scleroderma), PBC, Sjogren's, thyroiditis

Abbreviations: CREST, *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal involvement, *s*clerodactyly, and *t*elangiectasia; MCTD, mixed connective tissue disease; PBC, primary biliary cirrhosis; PSS, progressive systemic sclerosis; SCLE, subacute cutaneous lupus erythematosus; SLE, systemic lupus erythematosus.

immunofluorescence microscopy (Table 370-4). Diffuse and speckled patterns are least specific, whereas a peripheral, or rim, pattern (related to autoantibodies against double-strand [native] DNA) is highly specific and suggestive of lupus. Centromeric patterns are seen in patients with limited scleroderma (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal involvement, *s*clerodactyly, *t*elangiectasia [CREST] syndrome), primary biliary sclerosis, Sjögren's syndrome, or thyroiditis, and nucleolar patterns may be seen in patients with diffuse systemic sclerosis or inflammatory myositis.

Aspiration and analysis of synovial fluid are always indicated in acute monoarthritis or when an infectious or crystal-induced arthropathy is suspected. Synovial fluid may distinguish between noninflammatory and inflammatory processes by analysis of the appearance, viscosity, and cell count. Tests for synovial fluid glucose, protein, lactate dehydrogenase, lactic acid, or autoantibodies are not recommended as they have no diagnostic value. Normal synovial fluid is clear or a pale straw color and is viscous, primarily because of the high levels of hyaluronate. Noninflammatory synovial fluid is clear, viscous, and amber-colored, with a WBC count of <2000/μL and a predominance of mononuclear cells. The viscosity of synovial fluid is assessed by expressing fluid from the syringe one drop at a time. Normally, there is a stringing effect, with a long tail behind each synovial drop. Effusions caused by OA or trauma will have normal viscosity. Inflammatory fluid is turbid and yellow, with an increased WBC count (2000–50,000/μL) and a polymorphonuclear leukocyte predominance. Inflammatory fluid has reduced viscosity (no stringing), diminished hyaluronate, and little or no tail following each drop of synovial fluid. Such effusions are found in RA, gout, and other inflammatory arthritides. Septic fluid is opaque and purulent, with a WBC count usually >50,000/μL, a predominance of polymorphonuclear leukocytes (>75%), and low viscosity. Such effusions are typical of septic arthritis but may also occur with RA or gout. Lastly, hemorrhagic synovial fluid (hemarthrosis) may be seen with trauma (ligament or cartilage tears), osteochondral fracture, neuropathic arthritis, or coagulopathy. An algorithm for synovial fluid aspiration and analysis is shown in Fig. 370-6. Synovial fluid should be analyzed immediately for appearance, viscosity, and cell count. Monosodium urate crystals (observed in gout) are seen by polarized microscopy and are long, needle-shaped, negatively birefringent, and usually intracellular. In chondrocalcinosis and pseudogout, calcium pyrophosphate dihydrate crystals are usually short, rhomboid-shaped, and positively birefringent. Whenever infection is suspected, synovial fluid should be Gram stained and cultured appropriately. If gonococcal arthritis is suspected, nucleic acid amplification tests should be used

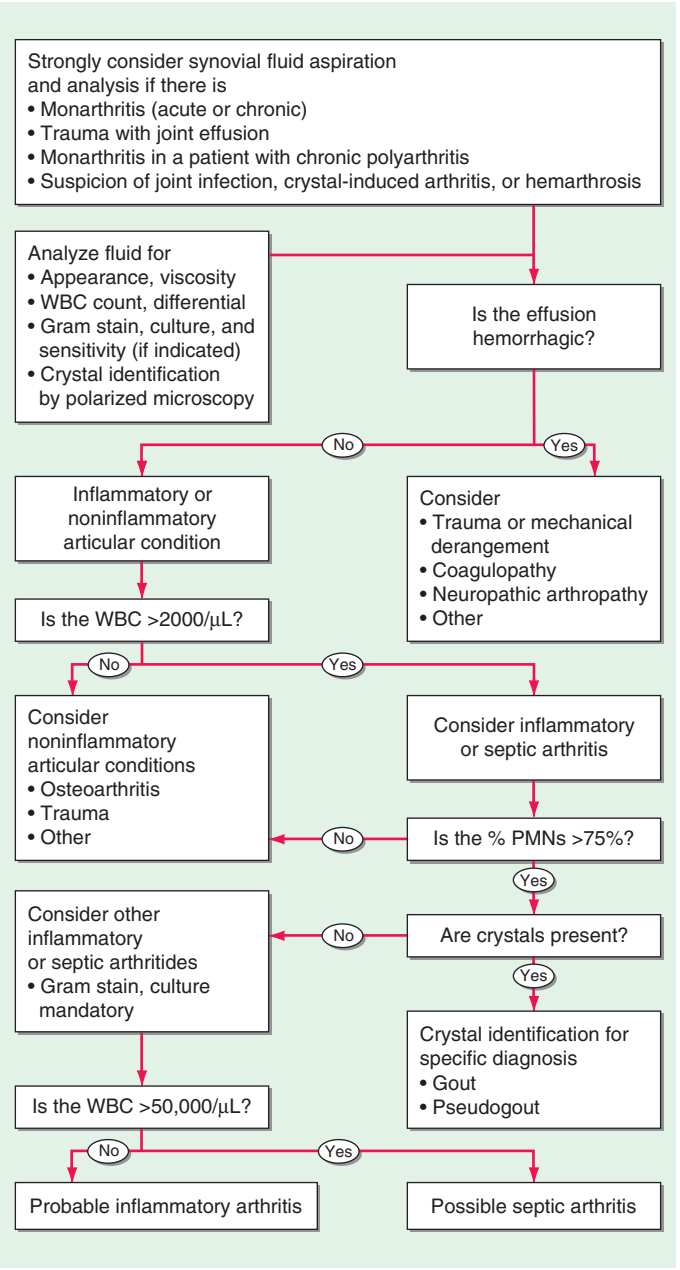

FIGURE 370-6 Algorithmic approach to the use and interpretation of synovial fluid aspiration and analysis. PMNs, polymorphonuclear (leukocytes); WBC, white blood cell count.

to detect either *Chlamydia trachomatis* or *N. gonorrhoeae* infection. Synovial fluid from patients with chronic monoarthritis should also be cultured for *M. tuberculosis* and fungi. Last, it should be noted that crystal-induced arthritis and septic arthritis occasionally occur together in the same joint.

DIAGNOSTIC IMAGING IN JOINT DISEASES

Conventional radiography has been a valuable tool in the diagnosis and staging of articular disorders. Plain x-rays are most appropriate and cost effective when there is a history of trauma, suspected chronic infection, progressive disability, or monarticular involvement; when therapeutic alterations are considered; or when a baseline assessment is desired for what appears to be a chronic process. However, in acute inflammatory arthritis, early radiography is rarely helpful in establishing a diagnosis and may only reveal soft tissue swelling or juxtaarticular demineralization. As the disease progresses, calcification (of soft tissues, cartilage, or periarticular bone), joint space narrowing,

erosions, bony ankylosis, new bone formation (sclerosis, osteophytes, or periostitis), or subchondral cysts may develop and suggest specific clinical entities. Consultation with a radiologist will help define the optimal imaging modality, technique, or positioning to optimize interpretation and prevent the need for further studies.

Additional imaging techniques may possess greater diagnostic sensitivity and facilitate early diagnosis in a limited number of articular disorders and in selected circumstances and are indicated when conventional radiography is inadequate or nondiagnostic **(Table 370-5)**. *Ultrasonography* is useful in the detection of soft tissue abnormalities (tendinitis, tenosynovitis, enthesitis, bursitis), crystal deposition, and entrapment neuropathies. Wider use, lower cost, better technology, and enhanced site-specific transducers now allow for wider use and diagnostic specificity, especially when considering synovial (Baker's) cysts, rotator cuff tears, tendinitis and tendon injury, and crystal deposition on cartilage. Use of power Doppler allows for early detection of synovitis and bony erosions. *Radionuclide scintigraphy* is a very sensitive, but poorly specific, means of detecting inflammatory or metabolic alterations in bone or periarticular soft tissue structures (Table 370-5). Scintigraphy is best suited for total-body assessment (extent and distribution) of skeletal involvement (neoplasia, Paget's disease) and the assessment of patients with undiagnosed polyarthralgias, looking for occult arthritis. The use of scintigraphy has declined with greater use and declining cost of ultrasound and MRI. MRI has largely replaced scintigraphy in diagnosing osseous infection, neoplasia, inflammation, increased blood flow, bone remodeling, heterotopic bone formation, or avascular necrosis. Gallium scanning uses ^{67}Ga, which binds serum and cellular transferrin and lactoferrin and is preferentially taken up by neutrophils, macrophages, bacteria, and tumor tissue (e.g., lymphoma). As such, it is primarily used in the identification of occult infection or malignancy. Scanning with ^{111}In-labeled WBCs has been used to detect osteomyelitis and infectious or inflammatory arthritis. Despite their utility, ^{111}In-labeled WBC and ^{67}Ga scanning have largely been replaced by MRI, except when there is a suspicion of septic joint or prosthetic joint infections.

TABLE 370-5 Diagnostic Imaging Techniques for Musculoskeletal Disorders

METHOD	IMAGING TIME, H	COST[a]	CURRENT INDICATIONS
Ultrasound	<1	++	Synovial (Baker's) cysts Rotator cuff tears Bursitis, tendinitis, tendon injury Enthesitis Carpal tunnel syndrome Urate or calcium pyrophosphate deposition on cartilage Early detection of synovial inflammation or erosions Ultrasound-guided injection/ arthrocentesis

[a]Relative cost for imaging study.

Abbreviations: NA, not commercially available; WBC, white blood cell.

Computed tomography (*CT*) provides detailed visualization of the axial skeleton. Articulations previously considered difficult to visualize by radiography (e.g., zygapophyseal, sacroiliac, sternoclavicular, hip joints) can be evaluated using CT. CT has been demonstrated to be useful in the diagnosis of low back pain (e.g., spinal stenosis vs herniated disk), sacroiliitis, osteoid osteoma, and stress fractures. Helical or spiral CT (with or without contrast angiography) is a novel technique that is rapid, cost effective, and sensitive in diagnosing pulmonary embolism or obscure fractures, often in the setting of initially equivocal findings. High-resolution CT can be advocated in the evaluation of suspected or established infiltrative lung disease (e.g., scleroderma or rheumatoid lung). The recent use of hybrid (positron emission tomography [PET] or single-photon emission CT [SPECT]) CT scans in metastatic evaluations has incorporated CT to provide better anatomic localization of scintigraphic abnormalities.

^{18}F-Fluorodeoxyglucose (FDG) is the most commonly used radiopharmaceutical in PET scanning. FDG-PET/CT scans are rarely indicated in septic or inflammatory arthritis but have been useful in the evaluation of patients with fever of unknown origin or suspected large vessel vasculitis. For instance, while FDG-PET is useful in assessing vascular inflammation/activity, MRI angiography can best define the extent of vascular damage. Dual-energy CT (DECT) scanning, developed in urology to identify urinary calculi, has been a highly sensitive and specific method used to identify and quantify uric acid deposition in tissues **(Fig. 370-7)**.

MRI has significantly advanced the ability to image musculoskeletal structures. MRI has the advantages of providing multiplanar images with fine anatomic detail and contrast resolution **(Fig. 370-8)** that allows for the superior ability to visualize bone marrow and soft tissue periarticular structures. Although more costly with a longer procedural time than CT, the MRI has become the preferred technique when evaluating complex musculoskeletal disorders.

MRI can image fascia, vessels, nerve, muscle, cartilage, ligaments, tendons, pannus, synovial effusions, and bone marrow. Visualization of particular structures can be enhanced by altering the pulse sequence to produce either T1- or T2-weighted spin echo, gradient echo, or inversion recovery (including short tau inversion recovery [STIR]) images. Because of its sensitivity to changes in marrow fat, MRI is a sensitive but nonspecific means of detecting osteonecrosis, osteomyelitis, and marrow inflammation indicating overlying synovitis or osteitis (Fig. 363-8). Because of its enhanced soft tissue resolution, MRI is more sensitive than arthrography or CT in the diagnosis of soft tissue injuries (e.g., meniscal and rotator cuff tears); intraarticular derangements; marrow abnormalities (osteonecrosis, myeloma); and spinal cord or nerve root damage, synovitis, or cartilage damage or loss.

371 Osteoarthritis

David T. Felson, Tuhina Neogi

Osteoarthritis (OA) is the most common type of arthritis. Its high prevalence, especially in the elderly, and its negative impact on physical function make it a leading cause of disability in the elderly. Because of the aging of Western populations and because obesity, a major risk factor, is increasing in prevalence, the occurrence of OA is on the rise.

OA affects certain joints, yet spares others **(Fig. 371-1)**. Commonly affected joints include the hip, knee, and first metatarsal phalangeal

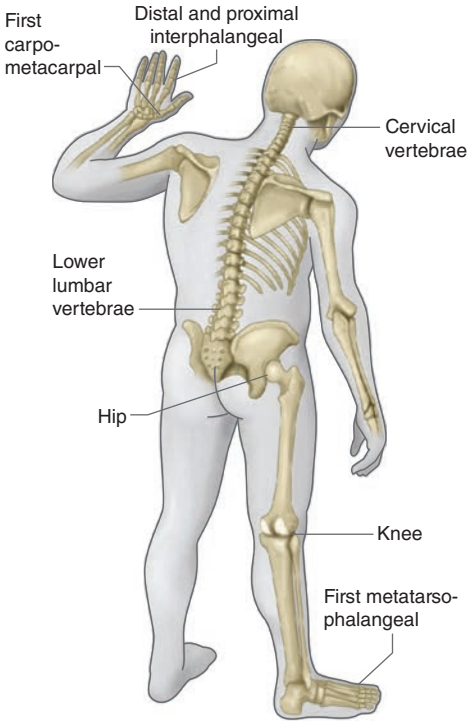

FIGURE 371-1 Joints commonly affected by osteoarthritis.

FIGURE 371-2 Severe osteoarthritis of the hands affecting the distal interphalangeal joints (Heberden's nodes) and the proximal interphalangeal joints (Bouchard's nodes). There is no clear bony enlargement of the other common site in the hands, the thumb base.

joint (MTP) and cervical and lumbosacral spine. In the hands, the distal and proximal interphalangeal joints and the base of the thumb are often affected. Usually spared are the wrist, elbow, and ankle. Our joints were designed, in an evolutionary sense, for brachiating apes, animals that still walked on four limbs. We thus develop OA in joints that were ill designed for human tasks such as pincer grip (OA in the thumb base) and walking upright (OA in knees and hips). Some joints, like the ankles, may be spared because their articular cartilage may be uniquely resistant to loading stresses.

OA can be diagnosed based on structural abnormalities or on the symptoms these abnormalities evoke. According to cadaveric studies, by elderly years, structural changes of OA are nearly universal. These include cartilage loss (seen as joint space loss on x-rays) and osteophytes. Many persons with x-ray evidence of OA have no joint symptoms, and although the prevalence of structural abnormalities is of interest in understanding disease pathogenesis, what matters more from a clinical perspective is the prevalence of symptomatic OA. Symptoms, usually joint pain, determine disability, visits to clinicians, and disease costs.

Symptomatic OA of the knee (pain on most days of a recent month plus x-ray evidence of OA in that knee) occurs in ~12% of persons age ≥60 in the United States and 6% of all adults age ≥30. Symptomatic hip OA is roughly one-third as common as disease in the knee. Although radiographic hand OA and the appearance of bony enlargement in affected hand joints **(Fig. 371-2)** are extremely common in older persons, most affected persons have no pain. Even so, painful hand OA occurs in ~10% of elderly individuals and often produces measurable limitation in function.

The prevalence of OA rises strikingly with age, being uncommon in adults aged <40 and highly prevalent in those aged >60. It is also a disease that, at least in middle-aged and elderly persons, is much more common in women than in men.

X-ray evidence of OA is common in the lower back and neck, but back pain and neck pain have not been tied to findings of OA on x-ray. Thus, back pain and neck pain are treated separately **(Chap. 17)**.

GLOBAL CONSIDERATIONS

With the aging of the populations, both the prevalence of OA and the amount of disability worldwide related to OA have been increasing, especially in developed countries where many are living into old age. Hip OA is rare in China and in immigrants from China to the United States. However, OA in the knees is at least as common, if not more so, in Chinese as in whites from the United States, and knee OA represents a major cause of disability in China, especially in rural areas. Anatomic differences between Chinese and white hips may account for much of the difference in hip OA prevalence, with white hips having a higher prevalence of anatomic predispositions to the development of OA.

DEFINITION

OA is joint failure, a disease in which all structures of the joint have undergone pathologic change, often in concert. The pathologic sine qua non of disease is hyaline articular cartilage loss, present in a focal and, initially, nonuniform manner. This is accompanied by increasing thickness and sclerosis of the subchondral bony plate, by outgrowth of osteophytes at the joint margin, by stretching of the articular capsule, by variable degrees of synovitis, and by weakness of muscles bridging the joint. In knees, meniscal degeneration is part of the disease. There are numerous pathways that lead to joint failure, but the initial step is often joint injury in the setting of a failure of protective mechanisms.

JOINT PROTECTIVE MECHANISMS AND THEIR FAILURE

Joint protectors include joint capsule and ligaments, muscle, sensory afferents, and underlying bone. Joint capsule and ligaments serve as joint protectors by providing a limit to excursion, thereby fixing the range of joint motion.

Synovial fluid reduces friction between articulating cartilage surfaces, thereby serving as a protector against friction-induced cartilage wear. This lubrication function depends on *hyaluronic acid* and on *lubricin*, a mucinous glycoprotein secreted by synovial fibroblasts whose concentration diminishes after joint injury and in the face of synovial inflammation.

The ligaments, along with overlying skin and tendons, contain mechanoreceptor sensory nerves. These mechanoreceptors fire at different frequencies throughout a joint's range of motion, providing feedback by way of the spinal cord to muscles and tendons. As a consequence, these muscles and tendons can assume the right tension at appropriate points in joint excursion to act as optimal joint protectors, anticipating joint loading.

Muscles and tendons that bridge the joint are key joint protectors. Focal stress across the joint is minimized by muscle contraction that decelerates the joint before impact and assures that when joint impact arrives, it is distributed broadly across the joint surface.

Failure of these joint protectors increases the risk of joint injury and OA. For example, in animals, OA develops rapidly when a sensory nerve to the joint is sectioned and joint injury induced. Similarly, in humans, Charcot's arthropathy, a severe and rapidly progressive OA, develops when minor joint injury occurs in the presence of posterior column

peripheral neuropathy. Another example of joint protector failure is rupture of ligaments, a well-known cause of the early development of OA.

CARTILAGE AND ITS ROLE IN JOINT FAILURE

In addition to being a primary target tissue for disease, cartilage also functions as a joint protector. A thin rim of tissue at the ends of two opposing bones, cartilage is lubricated by synovial fluid to provide an almost frictionless surface across which these two bones move. The compressible stiffness of cartilage compared to bone provides the joint with impact-absorbing capacity.

The earliest changes of OA may occur in cartilage, and abnormalities there can accelerate disease development. The two major macromolecules in cartilage are type 2 collagen, which provides cartilage its tensile strength, and aggrecan, a proteoglycan macromolecule linked with hyaluronic acid, which consists of highly negatively charged glycosaminoglycans. In normal cartilage, type 2 collagen is woven tightly, constraining the aggrecan molecules in the interstices between collagen strands, forcing these highly negatively charged molecules into close proximity. The aggrecan molecule, through electrostatic repulsion of its negative charges, gives cartilage its compressive stiffness. Chondrocytes, the cells within this avascular tissue, synthesize all elements of the matrix and produce enzymes that break it down **(Fig. 371-3)**. Cartilage matrix synthesis and catabolism are in a dynamic equilibrium influenced by the cytokine and growth factor environment. Mechanical and osmotic stress on chondrocytes induces these cells to alter gene expression and increase production of inflammatory cytokines and matrix-degrading enzymes. While chondrocytes synthesize numerous enzymes, matrix metalloproteinases (MMPs; especially collagenases and ADAMTS-5) are critical enzymes in the breakdown of cartilage matrix.

Local inflammation accelerates the development and progression of osteoarthritis and increases the likelihood that an osteoarthritic joint will be painful. Some of this inflammation may be induced by mechanical stimuli, so called mechanoinflammation. The synovium, cartilage, and bone all influence disease development through cytokines, chemokines, and even complement activation (Fig. 371-3). These act on chondrocyte cell-surface receptors and ultimately have transcriptional effects. Matrix fragments released from cartilage stimulate synovitis. Inflammatory cytokines such as interleukin 1β (IL-1β) and tumor necrosis factor α (TNF-α) induce chondrocytes to synthesize prostaglandin E_2 and nitric oxide. At early stages in the matrix response to injury, the net effect of cytokine stimulation may be matrix synthesis, but ultimately, the combination of effects on chondrocytes triggers matrix degradation. Enzymes in the matrix are held in check by activation inhibitors, including tissue inhibitor of metalloproteinase (TIMP). Growth factors are also part of this complex network, with bone morphogenetic protein 2 (BMP-2) and transforming growth factor β (TGF-β) playing prominent roles in stimulating the development of osteophytes. Whereas healthy articular cartilage is avascular in part due to angiogenesis inhibitors present in cartilage, disease is characterized by the invasion of blood vessels into cartilage from underlying bone. This is influenced by vascular endothelial growth factor (VEGF) synthesis in the cartilage and bone. With these blood vessels come nerves that may bring nociceptive innervation.

With aging, articular chondrocytes exhibit a decline in synthetic capacity, but they produce proinflammatory mediators and matrix-degrading enzymes, findings characteristic of a senescent secretory phenotype. These chondrocytes are unable to maintain tissue homeostasis (such as after insults of a mechanical or inflammatory nature). Thus, with age, cartilage is easily damaged by minor sometimes unnoticed injuries, including those that are part of daily activities.

OA cartilage is characterized by gradual depletion of aggrecan, an unfurling of the tightly woven collagen matrix, and loss of type 2 collagen. With these changes comes increasing vulnerability of cartilage, which loses its compressive stiffness.

RISK FACTORS

Joint vulnerability and joint loading are the two major factors contributing to the development of OA. On the one hand, a vulnerable joint whose protectors are dysfunctional can develop OA with minimal levels of loading, perhaps even levels encountered during everyday activities. On the other hand, in a young joint with competent protectors, a major acute injury or long-term overloading is necessary to precipitate disease. Risk factors for OA can be understood in terms of their effect either on joint vulnerability or on loading **(Fig. 371-4)**.

SYSTEMIC RISK FACTORS THAT AFFECT JOINT VULNERABILITY

Age is the most potent risk factor for OA. Radiographic evidence of OA is rare in individuals aged <40; however, in some joints, such as the hands, OA occurs in >50% of persons aged >70. Aging increases joint vulnerability through several mechanisms. Whereas dynamic loading of joints stimulates matrix synthesis by chondrocytes in young cartilage, aged cartilage is less responsive to these stimuli. Partly because of this failure to synthesize matrix with loading, cartilage thins with age, and thinner cartilage experiences higher shear stress and is at greater risk of cartilage damage. Also, joint protectors fail more often with age. Muscles that bridge the joint become weaker with age and respond less quickly to oncoming impulses. Sensory nerve input slows with age, retarding the feedback loop of mechanoreceptors to muscles and

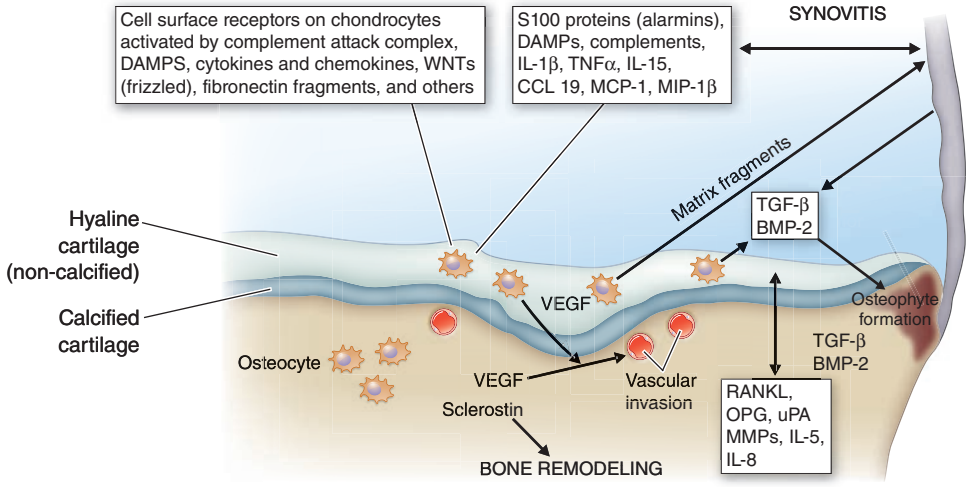

FIGURE 371-3 Selected factors involved in the osteoarthritic process including chondrocytes, bone, and synovium. Synovitis causes release of cytokines, alarmins, damage-associated molecular pattern (DAMP) molecules, and complement, which activate chondrocytes through cell-surface receptors. Chondrocytes produce matrix molecules (collagen type 2, aggrecan) and the enzymes responsible for the degradation of the matrix (e.g., ADAMTS-5 and matrix metalloproteinases [MMPs]). Bone invasion occurs through the calcified cartilage, triggered by vascular endothelial growth factor (VEGF) and other molecules. IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor. *(Reproduced with permission from RF Loeser et al: Osteoarthritis: a disease of the joint as an organ. Arthritis Rheum 64:1697, 2012.)*

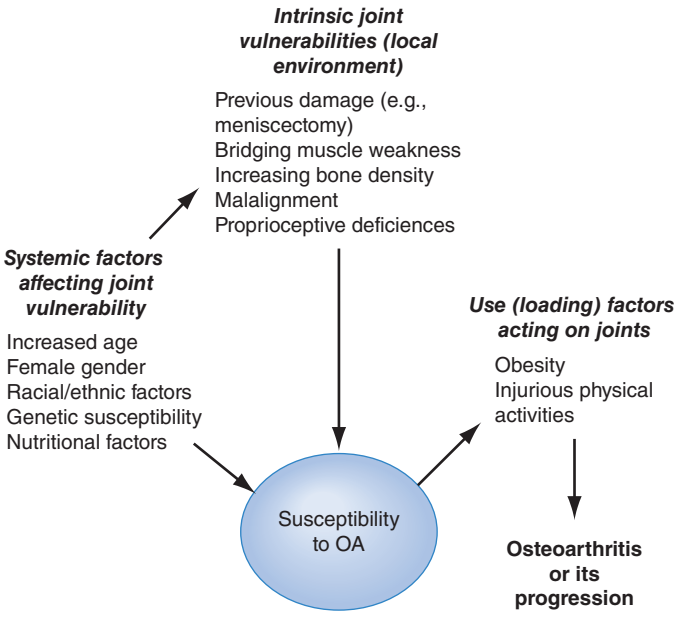

FIGURE 371-4 Risk factors for osteoarthritis (OA) either contribute to the susceptibility of the joint (systemic factors or factors in the local joint environment) or increase risk by the load they put on the joint. Usually, a combination of loading and susceptibility factors is required to cause disease or its progression.

tendons related to their tension and position. Ligaments stretch with age, making them less able to absorb impulses. These factors work in concert to increase the vulnerability of older joints to OA.

Older women are at high risk of OA in all joints, a risk that increases as women reach their sixth decade. Although hormone loss with menopause may contribute to this risk, there is little understanding of the unique vulnerability of older women versus men.

HERITABILITY AND GENETICS AND THEIR RELATION TO JOINT VULNERABILITY

OA is a highly heritable disease, but its heritability is joint specific. Fifty percent of the hand and hip OA in the community is attributable to inheritance, that is, to disease present in other members of the family. However, the heritable proportion of knee OA is at most 30%, with some studies suggesting no heritability at all. Whereas many people with OA have disease in multiple joints, this "generalized OA" phenotype is rarely inherited and is more often a consequence of aging.

Emerging evidence has identified genetic mutations that confer a high risk of OA. The best replicated is a polymorphism within the growth differentiation factor 5 (GDF5) gene whose effect is to diminish the quantity of GDF5. GDF5 affects joint shape, which is likely to be the mechanism by which genes predisposing to OA increase risk of disease. Minor abnormalities in joint shape can make a joint vulnerable to damage if focal stresses across the joint increase.

RISK FACTORS IN THE JOINT ENVIRONMENT

Some risk factors increase vulnerability of the joint through local effects on the joint environment. With changes in joint anatomy, for example, load across the joint is no longer distributed evenly across the joint surface, but rather shows an increase in focal stress. In the hip, three uncommon developmental abnormalities occurring in utero or in childhood—congenital dysplasia, Legg-Perthes disease, and slipped capital femoral epiphysis—leave a child with distortions of hip joint anatomy that often lead to OA later in life. Girls are predominantly affected by acetabular dysplasia, a mild form of congenital dislocation, whereas the other abnormalities more often affect boys. Depending on the severity of the anatomic abnormalities, hip OA occurs either in young adulthood (severe abnormalities) or middle age (mild abnormalities). Femoroacetabular impingement can develop during adolescence. It is a clinical syndrome in which an outgrowth of bone at the femur's head/neck junction thought to develop during closure of

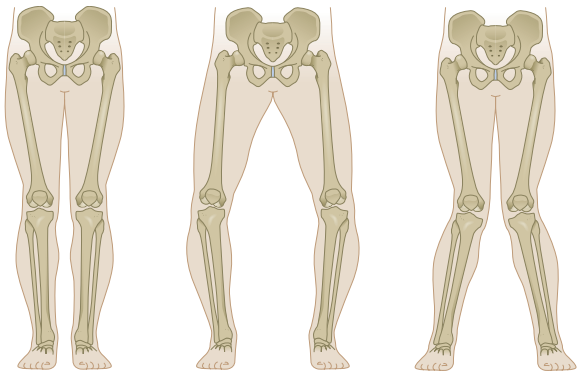

FIGURE 371-5 The two types of limb malalignment in the frontal plane: varus, in which the stress is placed across the medial compartment of the knee joint, and valgus, which places excess stress across the lateral compartment of the knee.

the growth plate results in abnormal contact between the femur and acetabulum, especially during hip flexion and rotation. This leads to cartilage and labral damage, to hip pain, and ultimately in later life, to an increased risk of hip OA.

Major injuries to a joint also can produce anatomic abnormalities that leave the joint susceptible to OA. For example, a fracture through the joint surface often causes OA in joints in which the disease is otherwise rare such as the ankle and the wrist. Avascular necrosis can lead to collapse of dead bone at the articular surface, producing anatomic irregularities and subsequent OA.

Tears of ligamentous and fibrocartilaginous structures that protect the joints, such as the meniscus in the knee and the labrum in the hip, can lead to premature OA. Meniscal tears increase with age and when chronic are often asymptomatic but lead to adjacent cartilage damage and accelerated OA. Even injuries in which the affected person never received a diagnosis may increase risk of OA. For example, in the Framingham Study subjects, men with a history of major knee injury, but no surgery, had a 3.5-fold increased risk for subsequent knee OA.

Another source of anatomic abnormality is malalignment across the joint **(Fig. 371-5)**. This factor has been best studied in the knee. Varus (bowlegged) knees with OA are at exceedingly high risk of cartilage loss in the medial or inner compartment of the knee, whereas valgus (knock-kneed) malalignment predisposes to rapid cartilage loss in the lateral compartment. Malalignment causes this effect by increasing stress on a focal area of cartilage, which then breaks down; it also causes damage to bone underlying the cartilage, producing bone marrow lesions seen on magnetic resonance imaging (MRI). Malalignment in the knee often produces such a substantial increase in focal stress within the knee (as evidenced by its destructive effects on subchondral bone) that severely malaligned knees may be destined to progress regardless of the status of other risk factors.

Weakness in the quadriceps muscles bridging the knee increases the risk of the development of painful OA in the knee.

The role of bone in serving as a shock absorber for impact load is not well understood, but persons with increased bone density are at high risk of OA. Those with high bone density have an increased risk of osteophytes at the joint margin.

LOADING FACTORS

Obesity Three to six times body weight is transmitted across the knee during single-leg stance. Any increase in weight may be multiplied by this factor to reveal the excess force across the knee in overweight persons during walking. Obesity is a well-recognized and potent risk factor for the development of knee OA and, less so, for hip OA. Obesity precedes the development of disease and is not just a consequence of the inactivity present in those with disease. It is a stronger risk factor for disease in women than in men, and for women, the relationship of weight to the risk of disease is linear, so that with each pound increase in weight, there is a commensurate increase in risk. Weight loss in women lowers the risk of developing symptomatic disease. Not only is

obesity a risk factor for OA in weight-bearing joints, but obese persons have more worse pain from the disease.

Obesity's effect on the development and progression of disease is mediated mostly through the increased loading in weight-bearing joints that occurs in overweight persons and more severe joint pain in obese persons.

Repeated Use of Joint and Exercise There are two categories of repetitive joint use: occupational use and leisure time physical activities. Workers performing repetitive tasks as part of their occupations for many years are at high risk of developing OA in the joints they use repeatedly. For example, farmers are at high risk for hip OA, and miners have high rates of OA in knees and spine. Workers whose jobs require regular knee bending or lifting or carrying heavy loads have a high rate of knee OA. One reason why workers may get disease is that during long days at work, their muscles may gradually become exhausted, no longer serving as effective joint protectors.

It is widely recommended for people to adopt an exercise-filled lifestyle, and long-term studies of exercise suggest no consistent association of exercise with OA risk in most persons. However, persons who already have injured joints may put themselves at greater risk by engaging in certain types of exercise. For example, persons who have already sustained major knee injuries are at increased risk of progressive knee OA as a consequence of running. In addition, compared to nonrunners, elite runners (professional runners and those on Olympic teams) have high risks of both knee and hip OA. Lastly, although recreational runners are not at increased risk of knee OA, studies suggest that they have a modest increased risk of disease in the hip.

PATHOLOGY

The pathology of OA provides evidence of the involvement of many joint structures in disease. Cartilage initially shows surface fibrillation and irregularity. As disease progresses, focal erosions develop there, and these eventually extend to the subjacent bone. With further progression, cartilage erosion down to bone expands to involve a larger proportion of the joint surface, even though OA remains a focal disease with nonuniform loss of cartilage.

After an injury to cartilage, chondrocytes undergo mitosis and clustering. Although the metabolic activity of these chondrocyte clusters is high, the net effect of this activity is to promote proteoglycan depletion in the matrix surrounding the chondrocytes. This is because the catabolic activity is greater than the synthetic activity. As disease develops, collagen matrix becomes damaged, the negative charges of proteoglycans get exposed, and cartilage swells from ionic attraction to water molecules. Because in damaged cartilage proteoglycans are no longer forced into close proximity, cartilage does not bounce back after loading as it did when healthy, and cartilage becomes vulnerable to further injury. Chondrocytes at the basal level of cartilage undergo apoptosis.

With loss of cartilage comes alteration in subchondral bone. Stimulated by growth factors and cytokines, osteoclasts and osteoblasts in the bony plate just underneath cartilage become activated. Bone formation produces a thickening of the subchondral plate that occurs even before cartilage ulcerates. Trauma to bone during joint loading may be the primary factor driving this bone response, with healing from injury (including microcracks) inducing remodeling. Small areas of osteonecrosis usually exist in joints with advanced disease. Bone death may also be caused by bone trauma with shearing of microvasculature, leading to a cutoff of vascular supply to some bone areas.

At the margin of the joint, near areas of cartilage loss, osteophytes form. These start as outgrowths of new cartilage, and with neurovascular invasion from the bone, this cartilage ossifies. Osteophytes are an important radiographic hallmark of OA.

The synovium produces lubricating fluids that minimize shear stress during motion. In healthy joints, the synovium consists of a single discontinuous layer filled with fat and containing two types of cells, macrophages and fibroblasts, but in OA, it can sometimes become edematous and inflamed. There is a migration of macrophages from the periphery into the tissue, and cells lining the synovium proliferate. Inflammatory cytokines and alarmins secreted by the synovium activate chondrocytes to produce enzymes that accelerate destruction of matrix.

Additional pathologic changes occur in the capsule, which stretches, becomes edematous, and can become fibrotic.

The pathology of OA is not identical across joints. In hand joints with severe OA, for example, there are often cartilage erosions in the center of the joint probably produced by bony pressure from the opposite side of the joint.

Basic calcium phosphate and calcium pyrophosphate dihydrate crystals are present microscopically in most joints with end-stage OA. Their role in osteoarthritic cartilage is unclear, but their release from cartilage into the joint space and joint fluid likely triggers synovial inflammation, which can, in turn, produce release of cytokines and trigger nociceptive stimulation.

SOURCES OF PAIN

Because healthy cartilage is aneural, cartilage loss alone in a joint is not accompanied by pain. Thus, pain in OA likely arises from structures outside the cartilage. Innervated structures in the joint include the synovium, ligaments, joint capsule, muscles, and subchondral bone. Most of these are not visualized by x-ray, and the severity of x-ray changes in OA correlates poorly with pain severity. However, in later stages of OA, loss of cartilage integrity accompanied by neurovascular invasion may contribute to pain.

Based on MRI studies in osteoarthritic knees comparing those with and without pain and on studies mapping tenderness in unanesthetized joints, likely sources of pain include synovial inflammation, joint effusions, and bone marrow edema. Modest synovitis develops in many but not all osteoarthritic joints. The presence of synovitis on MRI is correlated with the presence and severity of knee pain, and potentially with pain sensitization. Capsular stretching from fluid in the joint stimulates nociceptive fibers there, inducing pain. Increased focal loading as part of the disease not only damages cartilage but probably also injures the underlying bone. As a consequence, bone marrow edema appears on the MRI; histologically, this edema signals the presence of microcracks and scar, which are the consequences of trauma. These lesions may stimulate bone nociceptive fibers. Pain may arise from outside the joint also, including bursae near the joints. Common sources of pain near the knee are anserine bursitis and iliotibial band syndrome.

Much of the pain experienced in OA occurs when nociceptors in the joint are stimulated during weight-bearing activities. However, the pain may eventually become more constant and present at rest, and this suggests other mechanisms contribute to the pain experience. The pathologic changes of OA may lead to alterations in nervous system signaling (Chap. 17). Specifically, peripheral nociceptors can become more responsive to sensory input, known as peripheral sensitization, and there can also be an increase in facilitated central ascending nociceptive signaling, known as central sensitization. Individuals with OA may also have insufficient descending inhibitory modulation. Some individuals may be genetically predisposed to becoming sensitized; however, regardless of the etiology, these nervous system alterations are associated with more severe pain severity, contribute to the presence of allodynia and hyperalgesia in patients with OA, and may predispose to development of chronic pain. Obesity increases the severity of joint pain. This is probably because adipose tissue produces adipokines and other hormones which act on the nervous system to enhance pain sensitivity.

CLINICAL FEATURES

Joint pain from OA is primarily activity-related in the early stages of the disease. Pain comes on either during or just after joint use and then gradually resolves. Examples include knee or hip pain with going up or down stairs, pain in weight-bearing joints when walking, and, for hand OA, pain when cooking. Early in disease, pain is episodic, triggered often by overactive use of a diseased joint, such as a person with knee OA taking a long run and noticing a few days of pain thereafter. As disease progresses, the pain becomes continuous and even begins to be bothersome at night. Stiffness of the affected joint may be prominent, but morning stiffness is usually brief (<30 min).

In knees, buckling may occur, in part, from weakness of muscles crossing the joint. Mechanical symptoms, such as buckling, catching, or locking, could also signify internal derangement, like an anterior cruciate ligament or meniscal tear; however, these symptoms, which

are common in persons with knee OA, need to be further evaluated only if they develop after an acute knee injury. In the knee, pain with activities requiring knee flexion, such as stair climbing and arising from a chair, often emanates from the patellofemoral compartment of the knee, which does not actively articulate until the knee is bent ~35°.

OA is the most common cause of chronic knee pain in persons aged >45, but the differential diagnosis is long. Inflammatory arthritis is likely if there is prolonged morning stiffness and many other joints are affected. Bursitis occurs commonly around knees and hips. A physical examination should focus on whether tenderness is over the joint line (at the junction of the two bones around which the joint is articulating) or outside of it. Anserine bursitis, medial and distal to the knee, is an extremely common cause of chronic knee pain that may respond to a glucocorticoid injection. Prominent nocturnal pain in the absence of end-stage OA merits a distinct workup. For hip pain, OA can be detected by loss of internal rotation on passive movement, and pain isolated to an area lateral to the hip joint usually reflects the presence of trochanteric bursitis.

No blood tests are routinely indicated for workup of patients with OA unless symptoms and signs suggest inflammatory arthritis. Examination of the synovial fluid is often more helpful diagnostically than an x-ray. If the synovial fluid white count is >1000/μL, inflammatory arthritis or gout or pseudogout is likely, the latter two being also identified by the presence of crystals.

Neither x-rays nor magnetic resonance imaging are indicated in the workup of OA. They should be ordered only when joint pain and physical findings are not typical of OA or if pain persists after inauguration of treatment effective for OA. In OA, imaging findings **(Fig. 371-6)** correlate poorly with the presence and severity of pain. Further, in both

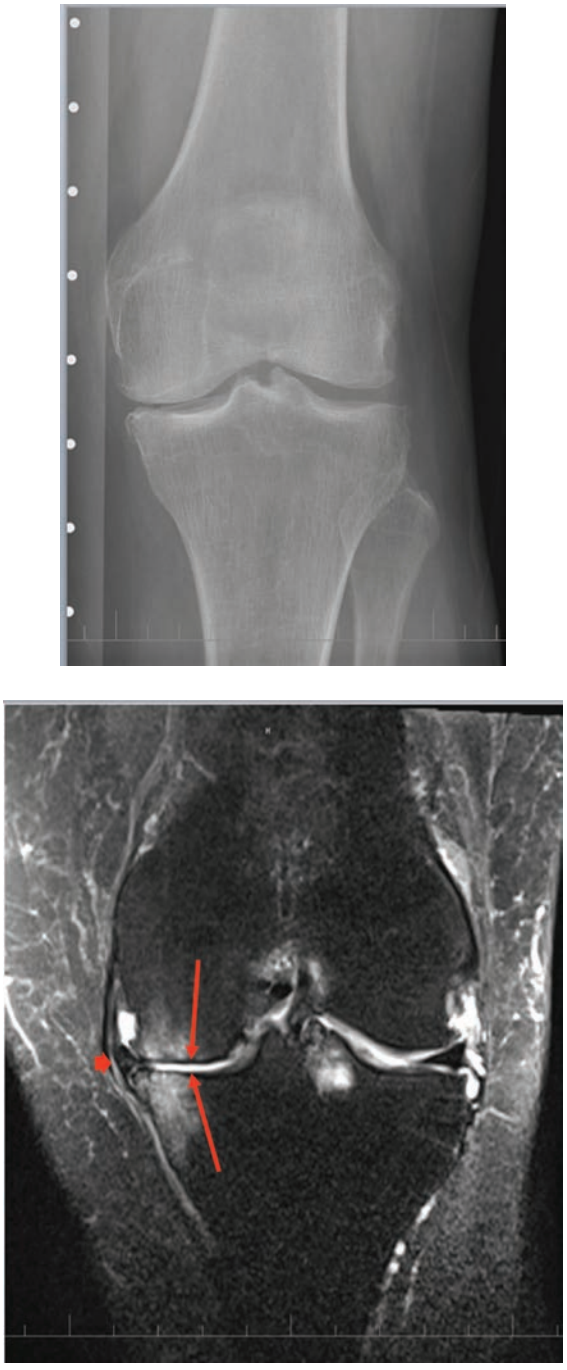

FIGURE 371-6 X-ray and MRI of knee with medial osteoarthritis. X-ray shows osteophytes at the medial and lateral tibia and femur and joint space narrowing of the medial tibiofemoral joint. Coronal intermediate-weighted fat-suppressed MRI confirms the presence of medial and lateral osteophytes and the medial tibiofemoral joint space narrowing. There is diffuse denuded area with no cartilage remaining at the weight-bearing medial tibiofemoral joint (*arrows*). There is also a severe medial meniscus extrusion (*arrowhead*). Bone marrow lesions, which provide evidence of bone injury, are present at medial tibia, medial femur, and intraspinous tibial region. Cartilage focal defects are also seen at the lateral weight-bearing femur and tibia.

knees and hips, radiographs may be normal in early disease as they are insensitive to cartilage loss and other early findings.

Although MRI may reveal the extent of pathology in an osteoarthritic joint, it is not indicated as part of the diagnostic workup. Findings such as meniscal tears and cartilage and bone lesions occur not only in most patients with OA in the knee, but also in most older persons without joint pain. MRI findings almost never warrant a change in therapy.

TREATMENT

Osteoarthritis

The goals of the treatment of OA are to alleviate pain and minimize loss of physical function. To the extent that pain and loss of function are consequences of inflammation, of weakness across the joint, and of laxity and instability, the treatment of OA involves addressing each of these impairments. Comprehensive therapy consists of a multimodality approach including physical modalities and pharmacologic elements.

Patients with mild and intermittent symptoms may need only symptomatic management and/or treatments aimed at weight loss, physical activity, exercise, and self-management strategies. Patients with ongoing, disabling pain are likely to need both physical modalities and pharmacotherapy.

Treatments for knee OA have been more completely evaluated than those for hip and hand OA or for disease in other joints. Thus, although the principles of treatment are identical for OA in all joints, we shall focus below on the treatment of knee OA, noting specific recommendations for disease in other joints, especially when they differ from those for the knee.

PHYSICAL MANAGEMENT MODALITIES

Because OA is a mechanically driven disease, the mainstay of treatment involves altering loading across the painful joint and improving the function of joint protectors, so they can better distribute load across the joint. Ways of lessening focal load across the joint include:

1. Avoiding painful activities as these are usually activities that overload the joint
2. Improving the strength and conditioning of muscles that bridge the joint to optimize their function
3. Unloading the joint, either by redistributing load within the joint with a brace or a splint or by unloading the joint during weight bearing with a cane or a crutch

The simplest treatment for many patients is to avoid activities that precipitate pain. For example, for the middle-aged patient whose long-distance running brings on symptoms of knee OA, a less demanding form of weight-bearing activity may alleviate all symptoms. For an older person whose daily walks up and down hills bring on knee pain, routing these away from hills might eliminate symptoms.

Weight loss is a central strategy, particularly for knee OA. Each pound of weight loss may have a multiplier effect, unloading both knees and hips and probably relieving pain in those joints.

In hand joints affected by OA, splinting, by limiting motion, often minimizes pain for patients with involvement especially in the base of the thumb. Weight-bearing joints such as knees and hips can be unloaded by using a cane in the hand opposite the affected joint for partial weight bearing. A physical therapist can help teach the patient how to use the cane optimally, including ensuring that its height is optimal for unloading. Crutches or walkers can serve a similar beneficial function.

Exercise Osteoarthritic pain in knees or hips during weight bearing results in lack of activity and poor mobility, and because OA is so common, the inactivity that results increases the risk of cardiovascular disease and obesity. Aerobic capacity is poor in most elders with symptomatic knee OA, worse than others of the same age.

Weakness in muscles that bridge osteoarthritic joints is multifactorial in etiology. First, there is a decline in strength with age. Second, with limited mobility comes disuse muscle atrophy. Third, patients with painful knee or hip OA alter their gait to lessen loading across the affected joint, and this further diminishes muscle use. Fourth, "arthrogenous inhibition" may occur, whereby contraction of muscles bridging the joint is inhibited by a nerve afferent feedback loop emanating in a swollen and stretched joint capsule; this prevents attainment of voluntary maximal strength. Because adequate muscle strength and conditioning are critical to joint protection, weakness in a muscle that bridges a diseased joint makes the joint more susceptible to further damage and pain. The degree of weakness correlates strongly with the severity of joint pain and the degree of physical limitation. One of the cardinal elements of the treatment of OA is to improve the functioning of muscles surrounding the joint.

Trials in knee and hip OA have shown that exercise lessens pain and improves physical function. Most effective exercise regimens consist of aerobic and/or resistance training, the latter of which focuses on strengthening muscles across the joint. Exercises are likely to be effective especially if they train muscles for the activities a person performs daily. Activities that increase pain in the joint should be avoided, and the exercise regimen needs to be individualized to optimize effectiveness. Range-of-motion exercises, which do not strengthen muscles, and isometric exercises that strengthen muscles, but not through range of motion, are unlikely to be effective by themselves. Low-impact exercises, including water aerobics and water resistance training, are often better tolerated by patients than exercises involving impact loading, such as running or treadmill exercises. A patient should be referred to an exercise class or to a therapist who can create an individualized regimen. In addition to conventional exercise regimens, tai chi may be effective for knee OA. However, there is no strong evidence that patients with hand OA benefit from therapeutic exercise.

Adherence over the long term is the major challenge to an exercise prescription. In trials involving patients with knee OA who were engaged in exercise treatment, from a third to over half of patients stopped exercising by 6 months. Less than 50% continued regular exercise at 1 year. The strongest predictor of a patient's continued exercise is a previous personal history of successful exercise. Physicians should reinforce the exercise prescription at each clinic visit, help the patient recognize barriers to ongoing exercise, and identify convenient times for exercise to be done routinely. Mobile health and wearable technologies are increasingly being used to encourage adherence to exercise. The combination of exercise with calorie restriction and weight loss is especially effective in lessening pain.

Correction of Malalignment Malalignment in the frontal plane (varus-valgus) markedly increases the stress across the joint, which can lead to progression of disease and to pain and disability (Fig. 371-5). Correcting varus-valgus malalignment, either surgically or with bracing, may relieve pain in persons whose knees are malaligned. However, correcting malalignment is often very challenging. Fitted braces that straighten varus knees by putting valgus stress across the knee can be effective. Unfortunately, many patients are unwilling to wear a realigning knee brace; in addition, in patients with obese legs, braces may slip with usage and lose their realigning effect. Braces are indicated for willing patients who can learn to put them on correctly and on whom they do not slip. Shoes modified with rubber hemispheres on the sole that alter alignment of the proximal knee have shown efficacy in trials especially if used over several months.

Pain from the patellofemoral compartment of the knee can be caused by tilting of the patella or patellar malalignment with the patella riding laterally in the femoral trochlear groove. Using a patellar brace to realign the patella, or tape to pull the patella back into the trochlear sulcus or reduce its tilt, has been shown in controlled trials to lessen patellofemoral pain. However, patients may

find it difficult to apply tape, and skin irritation from the tape is common, and like realigning braces, patellar braces may slip.

Although their effect on malalignment is questionable, neoprene sleeves pulled up to cover the knee lessen pain and are easy to use and popular among patients. The explanation for their therapeutic effect on pain is unclear.

In patients with knee OA, acupuncture produces modest pain relief compared to placebo needles and may be an adjunctive treatment, though placebo effect is likely high. In patients with refractory joint pain from OA, radiofrequency ablation of the nerves innervating the joint has been shown to provide prolonged pain relief, although long-term safety is unknown.

PHARMACOTHERAPY

Although approaches involving physical modalities constitute its mainstay, pharmacotherapy serves an important adjunctive role in OA treatment for symptom management. Available drugs are administered using oral, topical, and intraarticular routes. To date, there are no available drugs that alter the disease process itself.

Acetaminophen, Nonsteroidal Anti-Inflammatory Drugs (NSAIDs), and Cyclooxygenase-2 (COX-2) Inhibitors NSAIDs are the most popular drugs to treat osteoarthritic pain. They can be administered either topically or orally. In clinical trials, oral NSAIDs produce ~30% greater improvement in pain than high-dose acetaminophen. Occasional patients treated with NSAIDs experience dramatic pain relief, whereas others experience little improvement. Initially, NSAIDs should be administered topically or taken orally on an "as-needed" basis because side effects are less frequent with low intermittent doses. If occasional medication use is insufficiently effective, then daily treatment may be indicated, with an anti-inflammatory dose selected (Table 371-1). Patients should be reminded to take low-dose aspirin and ibuprofen or naproxen at different times to eliminate a drug interaction.

NSAIDs taken orally have substantial and frequent side effects, the most common of which is upper gastrointestinal (GI) toxicity, including dyspepsia, nausea, bloating, GI bleeding, and ulcer disease. Thirty to forty percent of patients experience upper GI side effects so severe as to require discontinuation of medication. To minimize the risk of nonsteroidal-related GI side effects, patients should take NSAIDs after food; if risk is high, patients should take a gastroprotective agent, such as a proton pump inhibitor. Certain oral agents are safer to the stomach than others, including nonacetylated salicylates and nabumetone. Major NSAID-related GI side effects can occur in patients who do not complain of upper GI symptoms. In one study of patients hospitalized for GI bleeding, 81% had no premonitory symptoms.

Because of the increased rates of cardiovascular events associated with conventional NSAIDs such as diclofenac, many of these drugs are not appropriate long-term treatment choices for older persons with OA, especially those at high risk of heart disease or stroke. The American Heart Association has identified COX-2 inhibitors as putting patients at high risk, although low doses of celecoxib (≤200 mg/d) are not associated with an elevation of risk. The only conventional NSAIDs that appear safe from a cardiovascular perspective are naproxen and low-dose celecoxib, but they do have GI toxicity.

There are other common side effects of NSAIDs, including the tendency to develop edema because of prostaglandin inhibition of afferent blood supply to glomeruli in the kidneys and, for similar reasons, a predilection toward reversible renal insufficiency. Blood pressure may increase modestly in some NSAID-treated patients. Oral NSAIDs should not be used in patients with stage IV or V renal disease and should be used with caution in those with stage III disease.

NSAIDs can be placed into a gel or topical solution with another chemical modality that enhances penetration of the skin barrier creating a topical NSAID. When absorbed through the skin, plasma concentrations are an order of magnitude lower than with the same amount of drug administered orally or parenterally. However, when these drugs are administered topically in proximity to a superficial joint (knees, hands, but not hips), the drug can be found in joint tissues such as the synovium and cartilage. Trial results have varied but generally have found that topical NSAIDs are slightly less efficacious than oral agents, but have far fewer GI and systemic side effects. Unfortunately, topical NSAIDs often cause local skin irritation where the medication is applied, inducing redness, burning, or itching (see Table 371-1).

TABLE 371-1 Pharmacologic Treatment for Osteoarthritis

TREATMENT	DOSAGE	COMMENTS
Oral NSAIDs and COX-2 inhibitors		Take with food. Increased risk of myocardial infarction and stroke for some NSAIDs. High rates of gastrointestinal side effects, including ulcers and bleeding, occur. Patients at high risk for gastrointestinal side effects should also take either a proton pump inhibitor or misoprostol.[a] There is an increase in gastrointestinal side effects or bleeding when taken with acetylsalicylic acid. Can also cause edema and renal insufficiency.
Naproxen	375–500 mg bid	
Salsalate	1500 mg bid	
Ibuprofen	600–800 mg 3–4 times a day	
Celecoxib	100–200 mg qd	
Topical NSAIDs		Rub onto joint. Few systemic side effects. Skin irritation common.
Diclofenac Na 1% gel	4 g qid (for knees, hands)	
Acetaminophen	Up to 1 g tid	Of limited efficacy and only conditionally recommended
Opiates	Various	Common side effects include dizziness, sedation, nausea or vomiting, dry mouth, constipation, urinary retention, and pruritus. Addiction risk. Less efficacious than oral NSAIDs
Capsaicin	0.025–0.075% cream 3–4 times a day	Can irritate mucous membranes.
Intraarticular injections		
Steroids		
Hyaluronans	Varies from 3 to 5 weekly injections depending on preparation	Mild to moderate pain at injection site. Controversy exists regarding efficacy.

[a]Patients at high risk include those with previous gastrointestinal events, persons ≥60 years, and persons taking glucocorticoids. Trials have shown the efficacy of proton pump inhibitors and misoprostol in the prevention of ulcers and bleeding. Misoprostol is associated with a high rate of diarrhea and cramping; therefore, proton pump inhibitors are more widely used to reduce NSAID-related gastrointestinal symptoms.

The treatment effect of acetaminophen (paracetamol) in OA is small and not considered clinically meaningful **(Table 371-1)**. However, for a minority of patients, it is adequate to control symptoms, in which case more toxic drugs such as NSAIDs can be avoided.

Intraarticular Injections: Glucocorticoids and Hyaluronic Acid Because synovial inflammation is likely to be a major cause of pain in patients with OA, local anti-inflammatory treatments administered intraarticularly may be effective in ameliorating pain, for up to 3 months. Glucocorticoid injections provide such efficacy, but response is variable. While some patients having little relief of pain, most experience pain relief lasting up to several months. Synovitis, a major cause of joint pain in OA, may abate after an injection, and this correlates with the reduction in knee pain severity. Glucocorticoid injections are useful to get patients over acute flares of pain. Repeated injections may cause minor amounts of cartilage loss with probably unimportant clinical consequences.

Hyaluronic acid injections can be given for treatment of symptoms in knee and hip OA, but most evidence suggests no efficacy versus placebo (Table 371-1).

Other Classes of Drugs and Nutraceuticals Opioids have only modest short-term efficacy in treating pain in hip or knee OA with unclear benefit over the long-term and, given concerns about opioid dependency, should be avoided. If NSAIDs are ineffective, one option is the use of duloxetine, which has modest efficacy in OA and may be efficacious especially when knee pain is part of a syndrome of widespread pain.

Recent guidelines recommend against the use of glucosamine or chondroitin for OA. Large publicly supported trials have failed to show that, compared with placebo, these compounds relieve pain in persons with disease.

Optimal pharmacologic therapy for OA is often achieved by trial and error, with each patient having idiosyncratic responses to specific treatments. Placebo (or contextual) effects may account for 50% of more of treatment effects in OA, and certain modes of treatment delivery including intraarticular injections have greater contextual effects than others such as pills. When medical therapies have failed and the patient has an unacceptable reduction in their quality of life and ongoing pain and disability, then at least for knee and hip OA, total joint arthroplasty is indicated.

SURGERY

Based on data from randomized trials, the efficacy of arthroscopic debridement and lavage in persons with OA is no greater than that of sham surgery for relief of pain or disability. Further, if a meniscal tear is present, as is often the case in persons with knee OA, trials have shown that arthroscopic meniscectomies do not relieve knee pain or improve function long-term nor do they reduce catching or locking symptoms.

On the other hand, for patients with knee OA isolated to the medial compartment, operations to realign the knee to lessen medial loading can relieve pain. These include a high tibial osteotomy, in which the tibia is broken just below the tibial plateau and realigned to load the lateral, nondiseased compartment, or a unicompartmental replacement with realignment. Each surgery may provide the patient with years of pain relief before a total knee replacement is required.

Ultimately, when the patient with knee or hip OA has failed nonsurgical treatments with limitations of pain or function that compromise their quality of life, patients with reasonable expectations and readiness for surgery should be referred for total knee or hip arthroplasty. These are highly efficacious operations that relieve pain and improve function in the vast majority of patients, although pain elimination occurs in almost all patients getting a hip replacement but only ~80% of those undergoing knee replacement. Currently, failure rates from loosening or infection for both are ~1% per year, with higher rates in obese patients. The chance of surgical success is greater in centers where at least 25 such operations are performed yearly or with surgeons who perform multiple operations annually. The timing of knee or hip replacement is critical. If the patient suffers for many years until their functional status has declined substantially, with considerable muscle weakness, postoperative functional status may not improve to a level achieved by others who underwent operation earlier in their disease course.

Cartilage Regeneration Chondrocyte transplantation has not been found to be efficacious in OA, perhaps because OA includes pathology of joint mechanics, which is not corrected by chondrocyte transplants. Similarly, abrasion arthroplasty (chondroplasty) has not been well studied for efficacy in OA, but it produces fibrocartilage in place of damaged hyaline cartilage. Both surgical attempts to regenerate and reconstitute articular cartilage are more likely to be efficacious early in disease when joint malalignment and many of the other noncartilage abnormalities that characterize OA have not yet developed.

372 Gout and Other Crystal-Associated Arthropathies

Hyon K. Choi

The use of polarizing light microscopy during synovial fluid analysis in 1961 by McCarty and Hollander and the subsequent application of other crystallographic techniques, such as electron microscopy, energy-dispersive elemental analysis, and x-ray diffraction, have allowed investigators to identify the pathogenic roles of different microcrystals, including monosodium urate (MSU), calcium pyrophosphate (CPP), calcium apatite (apatite), and calcium oxalate (CaOx), in inducing acute or chronic arthritis or periarthritis **(Table 372-1)**. The clinical manifestations that result from these crystals have substantial similarities but also have notable differences. Given their therapeutic implications, the need to perform synovial fluid analysis to distinguish the type of crystal involved should be emphasized. Polarized light microscopy alone can identify most typical crystals, except for apatite. Aspiration and analysis of effusions are also important to assess the possibility of infection. Crystal shedding from inert deposits triggered by certain factors is considered a key process behind episodic manifestation of acute inflammation (gout or pseudogout) involving activation of inflammasome and potent proinflammatory cytokines such as interleukin (IL) 1β. Furthermore, physical, inflammatory, and catalytic effects (involving metalloproteinase, collagenase, or prostaglandin E_2) of crystal deposits on the cartilage and other joint structures can lead to chronic erosive or destructive changes in the articular structures.

GOUT

PATHOGENESIS

Gout is a hyperuricemic metabolic condition, typically manifested by episodic inflammatory arthritis with disabling pain, among middle-aged to elderly men and postmenopausal women. It stems from an increased

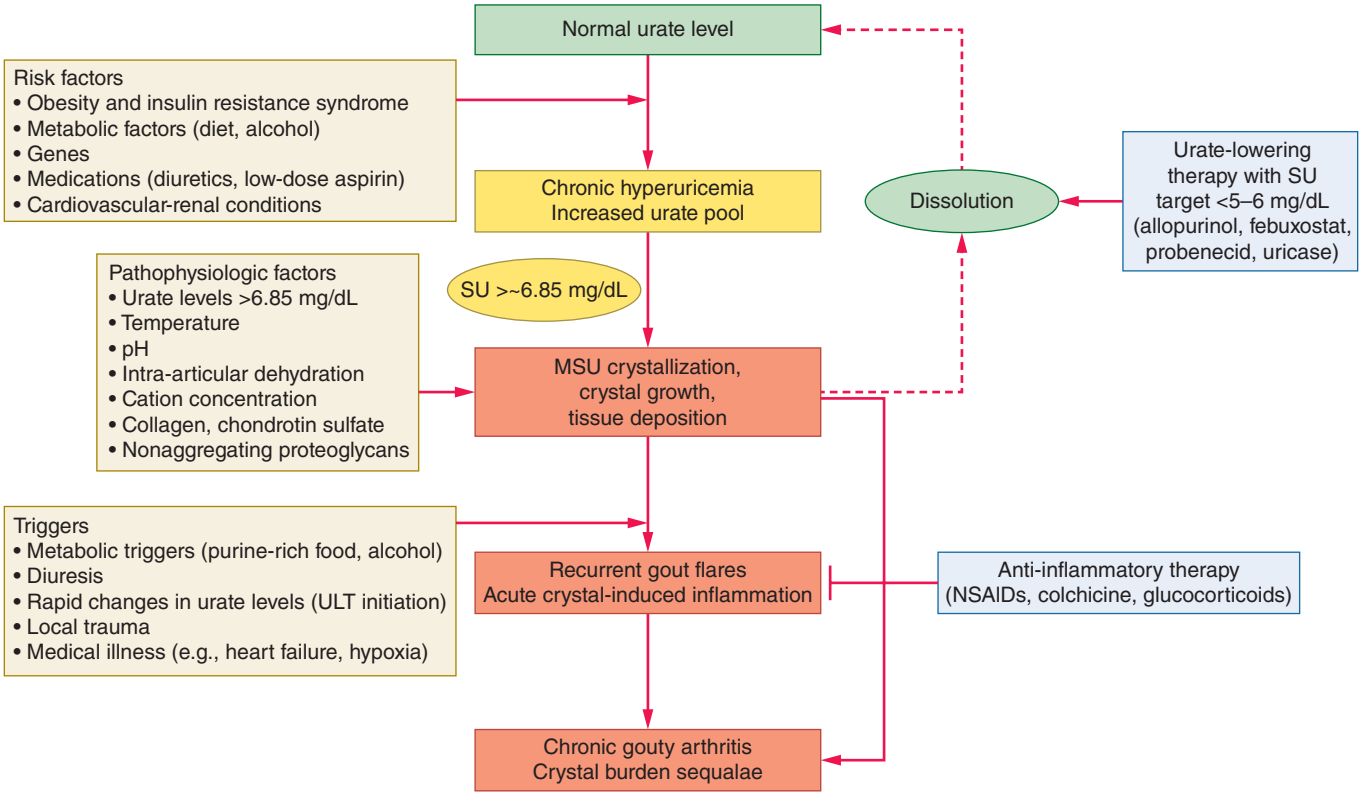

FIGURE 372-1 Pathogenesis of gout and therapeutic targets. Metabolic and some genetic factors contribute to the development of chronic hyperuricemia. Gout stems from an increased body pool of urate due to chronic hyperuricemia, leading to supersaturation and crystal formation and deposition of monosodium urate (MSU; tophi) within the joints and connective tissue. Synovial tophi are usually walled off, but certain triggers may loosen them from the organic matrix, leading to crystal shedding and interaction with synovial cell lining and residential inflammatory cells, initiating an acute gout flare. In some individuals, growing MSU crystal deposition leads to chronic gouty arthritis with subcutaneous tophi. Anti-inflammatory therapy targets the downstream process of crystal-induced inflammation, whereas ultimate control of gout requires correction of the underlying central cause, chronic hyperuricemia with increased urate pool. NSAIDs, nonsteroidal anti-inflammatory drugs; SU, sodium urate; ULT, urate-lowering therapy.

body pool of urate due to chronic hyperuricemia, leading to supersaturation and crystal formation and deposition of MSU within the joints and connective tissue **(Fig. 372-1)**. If left untreated, gout can progress to chronic gouty arthritis, frequently with low-grade persistent synovitis and erosive deformities due to growing deposition of MSU crystals. Humans are the only mammals known to develop gout spontaneously as they often develop hyperuricemia with their evolutionary species-wide loss of uricase, which converts urate into the highly water-soluble compound allantoin. Although chronic hyperuricemia is a prerequisite for the development of gout, other factors influence MSU deposition and pathogenic reactions to the crystals (Fig. 372-1); a minority of hyperuricemic individuals develop gout during their lifetime. At physiologic pH, uric acid exists largely as urate, the ionized form, given its weak acidic property (pKa, 5.8). Considered as a part of the insulin resistance syndrome, hyperuricemia and gout are associated with multiple cardiovascular-metabolic comorbidities, including obesity, hypertension, type 2 diabetes, myocardial infarction, stroke, and urate nephrolithiasis **(Chap. 417)**; modifiable risk factors include obesity, Western diet, alcohol, sedentary lifestyle, and diuretics (Fig. 372-1).

CLINICAL MANIFESTATIONS

Early clinical manifestation of gout is characterized by acute recurrent gout flares. Usually, only one joint is affected initially, although oligo- and polyarticular gout flares can develop over time. The metatarsophalangeal joint of the first toe is involved in 70–90% of cases (podagra), followed by tarsal joints, ankles, and knees. Finger, wrist, and elbow joints can also be involved, although more often in elderly patients or in advanced disease. The gout flares often begin at night to early morning, constituting one of the most painful conditions experienced by humans. The affected joints rapidly become warm, red, tender, and substantially swollen with a clinical appearance that often mimics that of cellulitis (pseudocellulitis). Typical flares tend to subside spontaneously within 1–2 weeks, and most patients have intervals of varying length with no residual symptoms until the next episode (intercritical gout). Triggers of gout flares include purine-rich food, alcohol, diuretic use, initial introduction of urate-lowering therapy, local trauma, and medical illnesses such as congestive heart failure and respiratory hypoxic conditions (Fig. 372-1).

Usually after years of gout flares without treatment, chronic gouty arthritis can develop, often associated with ongoing synovitis, subcutaneous tophi, deformity, and bony destruction. Less commonly, chronic gouty arthritis will be the only manifestation, and more rarely, gout can manifest only as tophi. Women represent only 5–20% of all patients with gout. Most women with gout are postmenopausal and elderly; tend to have osteoarthritis, hypertension, or mild renal insufficiency; and usually are receiving diuretics. Premenopausal gout is rare, although kindreds of precocious gout in young women caused by decreased renal urate clearance and renal insufficiency have been described.

DIAGNOSIS

Laboratory Diagnosis Even if characteristic clinical features strongly suggest gout, the presumptive diagnosis ideally should be confirmed by needle aspiration of involved joints or tophaceous deposits. Acute septic arthritis, other crystal-associated arthropathies, palindromic rheumatism, and psoriatic arthritis can mimic clinical presentations of gout. During acute gout flares, needle-shaped MSU crystals typically are present both intracellularly and extracellularly **(Fig. 372-2)**. Under compensated polarized light, these crystals show bright, negative birefringence. Synovial fluid appears cloudy due to the increased numbers of leukocytes (e.g., from 5000–75,000/μL). Large amounts of crystals occasionally produce a thick, pasty, chalky joint fluid or drainage from distended tophus. Because bacterial infection

can coexist with MSU crystals in synovial fluid, joint fluid is often stained and cultured for potential septic arthritis. MSU crystals also can often be demonstrated in the first metatarsophalangeal joint and in knees not acutely involved with gout, making arthrocentesis of these joints useful for the diagnosis of gout between flares.

While chronic hyperuricemia is a prerequisite in the pathogenesis of gout, serum urate levels can be normal or low at the time of an acute flare, as inflammatory cytokines' uricosuric property (e.g., IL-6) can lower the level by ~2 mg/dL. This tends to limit the value of serum urate testing in the setting of an acute flare. Nevertheless, serum urate levels are almost always elevated at some time in a gout patient's lifetime, and thus, it is important to seek historical or postflare serum urate values as a diagnostic clue or therapeutic target to urate-lowering therapy. Serum creatinine, liver function tests, hemoglobin, white blood cell (WBC) count, hemoglobin A_{1c}, and serum lipids are usually obtained at baseline to assess possible risk factor and comorbidities requiring treatment or monitored for potential adverse effects of gout treatments.

Radiographic Features In plain radiography, cystic changes, well-defined erosions with sclerotic margins (often with overhanging bony edges), and soft tissue masses are characteristic features of advanced gout with tophaceous deposits, although these findings are typically absent in earlier stages of gout. Musculoskeletal ultrasound can timely aid earlier diagnosis by revealing a double-contour sign overlying the articular cartilage (signifying MSU deposition). Similarly, dual-energy computed tomography (CT) that utilizes two different energy beams and identifies MSU based on its chemical composition can indicate specific presence of MSU crystals.

TREATMENT

Acute Gout Care

Although nonpharmacologic measures, such as ice pack application and rest of the involved joints, can be helpful, the mainstay of acute gout care is the administration of anti-inflammatory drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, and glucocorticoids (Fig. 372-1). The choice of these options largely depends on the patients' comorbidities, concurrent medications, and previous response if recurrent flares. Early initiation of anti-inflammatories helps abort or reduce the severity of flares. Thus, for recurrent flares in established gout patients, patients can be provided a supply of their medications ready to start at the first sign of a flare. NSAIDs are used most often in individuals without complicating comorbidities; NSAIDs given in full anti-inflammatory doses are effective in the vast majority of patients (e.g., indomethacin, 25–50 mg tid; naproxen, 500 mg bid; ibuprofen, 800 mg tid; and celecoxib, 800 mg followed by 400 mg 12 h later, then 400 mg bid). Oral colchicine is also effective, particularly if used early in a gout flare. A low-dose regimen (1.2 mg with the first sign of a flare, followed by 0.6 mg in 1 h and subsequent-day dosing depending on response) is as effective as, and better tolerated than, the formerly used higher-dose regimens. Colchicine is eliminated from the body through P-glycoprotein (also known as MDR1) in the liver, small intestine, and kidneys as well as via enteric and hepatic cytochrome P450 3E4 (CYP3A4). As such, the dose, particularly for prolonged use, is reduced among patients with renal disease or when used with P-glycoprotein or CYP3A4 inhibitors such as clarithromycin or tacrolimus; additional caution is warranted among patients with hepatorenal impairment.

Glucocorticoids given as an intramuscular injection or orally (e.g., prednisone, 30–50 mg/d as the initial dose and gradually tapered with the resolution of the attack) can be effective even in polyarticular gout. For a single joint or a few involved joints, intraarticular glucocorticoid injection is effective and well tolerated. With the central role of the inflammasome and IL-1β in gout flares, anakinra is a useful option when other treatments are contraindicated or have failed.

URATE-LOWERING THERAPY

Ultimate control of gout requires correction of the underlying chronic hyperuricemia, the central cause for gout. Attempts to normalize serum urate to a subsaturation point (typically, <300–360 μmol/L [5.0–6.0 mg/dL]) to prevent recurrent gout flares and eliminate tophi are critical and entail a commitment to urate-lowering regimens that are required usually for life (Fig. 372-1). Urate-lowering drug therapy should be considered when, as in most patients, the hyperuricemia cannot be corrected by risk factor interventions (control of body weight, healthy diet, limitation of alcohol use, decreased consumption of fructose-rich foods and beverages, and avoidance of thiazide and loop diuretics). The decision to initiate urate-lowering drug therapy usually is made considering the number of gout flares (urate lowering may be cost-effective with more than two attacks yearly), severity and duration of flares, quality of life, or the patient's willingness to commit to lifelong therapy. Urate-lowering therapy should be initiated in any patient who already has subcutaneous tophi or chronic gouty arthritis or known uric acid stones.

Allopurinol, a xanthine oxidase inhibitor, is the first-line urate-lowering drug among gout patients. Allopurinol can be given in a single morning dose, starting at 100 mg daily or less and titrating up (to 800 mg daily) to achieve a target serum urate level <5–6 mg/dL (i.e., a subsaturation point of MSU crystals). In patients with chronic kidney disease (CKD), the starting allopurinol dose should be lowered depending on the CKD levels; for example, with an estimated glomerular filtration rate of 30–45 mL/min, one would start at 50 mg daily and titrate up slowly. Starting at a low dose and titrating up reduces the risk of severe cutaneous adverse reactions (SCARs), including Stevens-Johnson syndrome and toxic epidermal necrolysis, as well as the risk of gout flares associated with rapid serum urate reduction due to introduction of urate-lowering therapy (Fig. 372-1). Allopurinol is generally well tolerated, but mild cutaneous reactions can develop in ~2% of users. SCARs to allopurinol are rare but can be life-threatening, and thus, appropriate precaution is advised. Presence of CKD, higher allopurinol initial dosing (e.g., >100 mg daily in CKD patients), and *HLA-B*5801* carriage are important risk factors; older age and female sex are also associated with a higher risk of SCARs. As the *HLA-B*5801* carriage rate is substantially higher among Southeast Asians (except for Japanese descendants), Pacific Islanders/Native Hawaiians, and blacks than whites or Hispanics (leading to racial disparity in the risk of SCARs), screening for *HLA-B*5801* should be performed before starting allopurinol in those Asians and blacks. If patients carry the *HLA-B*5801* allele, an alternative urate-lowering agent should be administered. Febuxostat is a newer xanthine oxidase inhibitor that is predominantly metabolized by glucuronide formation and oxidation in the liver and considered to not require dose adjustment in moderate to severe chronic kidney disease. It has also been used in patients who carry the *HLA-B*5801* allele.

Uricosuric agents such as probenecid are considered second-line urate-lowering therapies for gout and can be used in patients with good renal function either alone or in combination with xanthine oxidase inhibitors such as allopurinol. Probenecid can be started at a dose of 250 mg twice daily and increased gradually as needed up to 3 g/d to achieve and maintain a target serum urate level. Probenecid is generally not effective in patients with serum creatinine levels >177 μmol/L (2 mg/dL). Benzbromarone (not available in the United States) is another uricosuric drug that is more effective in patients with CKD. In contrast to thiazide and loop diuretics, which increase serum urate levels and trigger gout attacks, other drugs used to treat common comorbidities of gout can also help lower serum urate levels, including losartan, amlodipine, fenofibrate, and sodium-glucose cotransporter-2 inhibitors. Pegloticase is a pegylated uricase that is available for patients who do not tolerate or fail full doses of other treatments.

Urate-lowering drugs are generally not initiated during active ongoing gout flares, given the potential worsening of the flare by acutely lowering serum urate levels. However, urate-lowering therapy can be started during the resolution phase of or after a gout flare, together with anti-inflammatory prophylaxis (e.g., colchicine 0.6 mg one to two times daily or naproxen 250 mg twice daily) to reduce the risk of the flares that often occur with the initiation of urate-lowering therapy. These paradoxical flares are presumed to be inflammatory reactions to MSU crystals shed from dissolution of organized MSU deposits (synovial tophi) induced by rapid serum urate reduction (Fig. 372-1). As such, faster urate reduction has been associated with higher risk of flares in clinical trials of urate-lowering drugs. Continuing concomitant anti-inflammatory prophylaxis is usually recommended until the patient is normouricemic and without gouty attacks for 3–6 months or tophi disappear.

CALCIUM PYROPHOSPHATE DEPOSITION DISEASE

CPP deposition (CPPD) predominately affects the elderly, with a doubling prevalence of CPPD in articular tissues with each decade >60 years of age (e.g., prevalence of nearly 50% for those >85 years old).

TABLE 372-2 Factors and Conditions Associated with Calcium Pyrophosphate Crystal Deposition Disease

Aging
Osteoarthritis
Postmeniscectomy or joint trauma
Familial-genetic
Endocrine-metabolic conditions
Primary hyperparathyroidism
Hemochromatosis
Hypophosphatasia
Hypomagnesemia
Certain drugs: thiazide and loop diuretics, potentially proton pump inhibitors
Malabsorption
Gitelman's syndrome
Gout
X-linked hypophosphatemic rickets
Familial hypocalciuric hypercalcemia

In most cases, this process is asymptomatic with uncertain underlying etiology, although it is likely that biochemical changes in aging or diseased cartilage favor CPP crystal nucleation. Increased levels of inorganic pyrophosphate in cartilage matrix are thought to be a central pathogenic process in patients with CPPD arthritis, analogous to hyperuricemia in gout. This pyrophosphate can combine with calcium to form CPP crystals in cartilage matrix vesicles or on collagen fibers. Most inorganic pyrophosphate in cartilage matrix originates from breakdown of extracellular ATP. The ATP efflux (and thus the levels of inorganic pyrophosphate) is tightly regulated by a multipass membrane protein, ANKH. As such, mutations in the *ANKH* gene, as described in both familial and sporadic cases, have been found to increase elaboration and extracellular transport of pyrophosphate. The increase in pyrophosphate production is also related to enhanced activity of ATP pyrophosphohydrolase and 5′-nucleotidase, which catalyze the reaction of ATP to adenosine and pyrophosphate. Decreased levels of cartilage glycosaminoglycans and increased activities of transglutaminase enzymes may contribute to the deposition of CPP crystals.

Similar to MSU crystals, release of CPP crystals into the joint space is followed by the phagocytosis of those crystals by monocyte-macrophages and neutrophils, which respond by releasing chemotactic and inflammatory substances and activating the inflammasome.

A minority of patients with CPPD arthropathy have metabolic abnormalities or hereditary CPPD **(Table 372-2)**. As such, the presence of CPPD arthritis in individuals aged <50 years should lead to consideration of these metabolic disorders and inherited forms of disease, including those identified in a variety of ethnic groups. Included among endocrine-metabolic conditions are hyperparathyroidism, hemochromatosis, hypophosphatasia, and hypomagnesemia. These associations suggest that a variety of different metabolic products may enhance CPP crystal deposition either by directly altering cartilage or by inhibiting inorganic pyrophosphatases. Investigation of younger patients with CPPD should include inquiry for evidence of familial aggregation and evaluation of serum calcium, phosphorus, alkaline phosphatase, magnesium, iron, and transferrin.

CLINICAL MANIFESTATIONS

Acute CPP crystal arthritis, originally termed *pseudogout* by McCarty and co-workers, often mimics acute gout flares with similar articular findings of substantial inflammation. There are several clinical clues that suggest CPP crystal arthritis. The knee is the joint most commonly affected, followed by the wrist, while the first metatarsophalangeal joint (podagra) is rarely affected. Other affected joints include the shoulder, ankle, elbow, and hands. Also, initial episodes of acute attacks tend to last longer than typical gout flares, even up to weeks to months. Acute attacks present sometimes with systemic signs such as fever, chills, and elevated acute-phase reactants. Acute CPP crystal arthritis may be precipitated by trauma, severe medical illness, or surgery, especially

parathyroidectomy, as it leads to rapid diminution of serum calcium and magnesium levels, causing dissolution and shedding of crystal.

Chronic CPP crystal arthritis has several patterns; the most common form is a polyarticular arthritis resembling osteoarthritis (pseudoosteoarthritis). The clinical picture mimics that of progressive osteoarthritis, characterized by unusually severe joint damage in atypical joints for osteoarthritis, such as metacarpophalangeal, wrist, elbow, shoulder, or ankle joints. Other less common forms include chronic symmetric synovitis that is clinically similar to rheumatoid arthritis, severe destructive disease that may radiographically mimic neuropathic arthritis, intervertebral disk and ligament calcification with restriction of spine mobility, the crowned dens syndrome, spinal stenosis (most commonly seen in the elderly), and rarely, tumoral deposits of CPP crystals in soft tissues.

If radiographs or ultrasound reveal punctate and/or linear radiodense deposits within fibrocartilaginous joint menisci or articular hyaline cartilage (*chondrocalcinosis*), the diagnostic likelihood of CPPD disease is further increased. *Definitive diagnosis* requires demonstration of typical rhomboid or rodlike crystals (generally weakly positively birefringent or nonbirefringent with polarized light) in synovial fluid or articular tissue (Fig. 372-2). In the absence of joint effusion or indications to obtain a synovial biopsy, chondrocalcinosis is presumptive of CPPD. One exception is chondrocalcinosis due to CaOx in some patients with chronic renal failure.

In as many as 50% of cases, episodes of CPP crystal-induced inflammation are associated with low-grade fever and, on occasion, temperatures as high as 40°C (104°F). In such cases, synovial fluid analysis with microbial cultures is essential to rule out the possibility of infection. In fact, infection in a joint with any microcrystalline deposition process can lead to crystal shedding and subsequent synovitis from both crystals and microorganisms. The leukocyte count in synovial fluid in acute CPPD can range from several thousand cells to 100,000 cells/μL, with the mean being ~24,000 cells/μL and the predominant cell being the neutrophil. CPP crystals may be seen inside tissue fragments and fibrin clots and in neutrophils (Fig. 372-2). CPP crystals may coexist with MSU and apatite in some cases.

TREATMENT

CPPD Disease

Anti-inflammatory treatment for acute CPP crystal arthritis is largely adapted from that for gout flares, including ice pack applications with rest, joint fluid aspiration and glucocorticoid injection, oral colchicine, NSAIDs, and systemic glucocorticoids. Severe polyarticular attacks can also be treated with the IL-1β antagonist anakinra. For patients with frequent recurrent attacks, prophylactic treatment with daily colchicine can be helpful. For chronic CPP crystal arthritis, there is no effective way to remove CPP crystal deposits from cartilage and synovium (unlike urate-lowering agents in gout). Limited studies suggest that NSAIDs (with a gastric protective agent if required), colchicine, low-dose glucocorticoids, hydroxychloroquine, or methotrexate may be helpful for chronic synovitis. Patients with progressive destructive large-joint arthropathy may require joint replacement.

CALCIUM APATITE DEPOSITION DISEASE

PATHOGENESIS

Apatite is the primary mineral of normal bone and teeth. Abnormal accumulation of basic calcium phosphates, largely carbonate substituted apatite, can occur in areas of tissue damage (dystrophic calcification), hypercalcemic or hyperparathyroid states (metastatic calcification), connective tissue diseases (calcinosis), and other conditions (Table 372-3). In chronic renal failure, hyperphosphatemia can contribute to extensive apatite deposition both in and around joints (tumoral calcinosis, calciphylaxis). Familial aggregation is rarely seen. Synovial lining cell or fibroblast cultures exposed to apatite (or CPP) crystals can undergo mitosis and markedly increase the release of prostaglandin E_2, various cytokines, and collagenases and neutral proteases, underscoring the destructive potential of abnormally stimulated synovial lining cells.

Although the true incidence of apatite arthritis is not known, 30–50% of patients with osteoarthritis have apatite microcrystals in their synovial fluid. Such crystals frequently can be identified in clinically stable osteoarthritic joints, but they are more likely to come to attention in persons experiencing acute or subacute worsening of joint pain and swelling.

TABLE 372-3 Clinical Manifestations of Apatite Crystal Deposition

Periarticular
Calcific periarthritis (e.g., supraspinatus tendon apatite deposit rupture)
Bursitis and tendinitis
Hydroxyapatite pseudopodagra
Polyarticular involvement
Asymptomatic deposition
Articular
Hemorrhagic shoulder effusions in the elderly (Milwaukee shoulder)
Chronic destructive arthropathy
Chronic erosive monoarthritis (resembling erosive osteoarthritis)
Acute synovitis
Association with osteoarthritis
Secondary apatite crystal deposition
Tumoral calcinosis
Hyperparathyroidism
Calciphylaxis (renal failure/long-term dialysis)
Connective tissue diseases (e.g., systemic sclerosis, dermatomyositis)
Heterotopic calcification after neurologic catastrophes (e.g., stroke, spinal cord injury)
Fibrodysplasia ossificans progressiva

CLINICAL MANIFESTATIONS

Periarticular or articular deposits can present with acute reversible inflammation and/or chronic damage to the joint capsule, tendons, bursa, or articular surfaces (Table 372-3). The most common sites of apatite deposition include bursae and tendons in and/or around the knees, shoulders, hips, and fingers. These deposits can also be asymptomatic radiographic abnormalities.

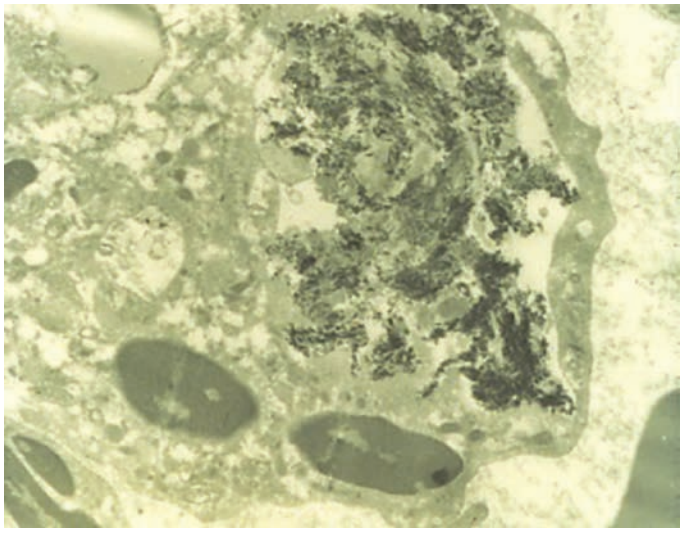
Apatite aggregates are often present in synovial fluid in an extremely destructive chronic arthropathy of the elderly that occurs most often in the shoulders (Milwaukee shoulder) and in a similar process in hips, knees, and erosive osteoarthritis of fingers (Table 372-3). Joint destruction is associated with damage to cartilage and supporting structures, leading to instability and deformity. Progression tends to be indolent. Symptoms range from minimal to severe pain and disability that may lead to joint replacement surgery.

DIAGNOSIS

Intra- and/or periarticular calcifications with or without erosive, destructive, or hypertrophic changes may be seen on radiographs (Fig. 372-3). They should be distinguished from the linear calcifications typical of CPPD.

The synovial fluid leukocyte count in apatite arthritis is usually low (<2000/μL) despite dramatic symptoms, with predominance of mononuclear cells. Definitive diagnosis of apatite arthropathy, also called basic calcium phosphate disease, depends on identification of crystals from synovial fluid or tissue (Fig. 372-3). Individual crystals are very small and can be seen only by electron microscopy. Clumps of crystals may appear as 1- to 20-μm shiny intra- or extracellular nonbirefringent globules or aggregates that stain purplish with Wright's stain and bright red with alizarin red S. Absolute identification depends on electron microscopy with energy-dispersive elemental analysis, x-ray diffraction, infrared spectroscopy, or Raman microspectroscopy, but these techniques usually are not required in clinical diagnosis.

A



B

FIGURE 372-3 ***A.*** Radiograph showing calcification due to apatite crystals surrounding an eroded joint. ***B.*** An electron micrograph demonstrates dark needle-shaped apatite crystals within a vacuole of a synovial fluid mononuclear cell (30,000×).

TREATMENT

Calcium Apatite Deposition Disease

Treatment of apatite arthritis or periarthritis is nonspecific. Acute attacks of bursitis or synovitis may be self-limiting, resolving in days to several weeks. Aspiration of effusions and the use of either NSAIDs or oral colchicine for 2 weeks or intra- or periarticular injection of a depot glucocorticoid appear to shorten the duration and intensity of symptoms. Periarticular apatite deposits may be resorbed with resolution of attacks. Agents to lower serum phosphate levels may lead to resorption of deposits in renal failure patients receiving hemodialysis. In patients with underlying severe destructive articular changes, response to medical therapy is usually less rewarding.

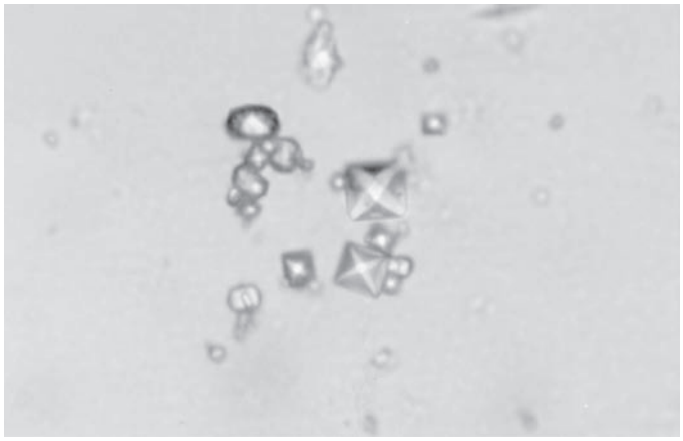


FIGURE 372-4 Bipyramidal and small polymorphic calcium oxalate crystals from synovial fluid are a classic finding in calcium oxalate arthropathy (ordinary light microscopy; 400×).

CaOx DEPOSITION DISEASE

PATHOGENESIS

In chronic renal disease, CaOx deposits have long been recognized in visceral organs, blood vessels, bones, and cartilage and are now known to be one of the causes of arthritis in chronic renal failure. Thus far, reported patients have been dependent on long-term hemodialysis or peritoneal dialysis **(Chap. 312)**, and many had received ascorbic acid supplements. Ascorbic acid is metabolized to oxalate, which is inadequately cleared in uremia and by dialysis. Such supplements and foods high in oxalate content usually are avoided in dialysis programs because of the risk of enhancing hyperoxalosis and its sequelae.

CaOx aggregates can be found in bone, articular cartilage, synovium, and periarticular tissues. From these sites, crystals may be shed, causing acute synovitis. Persistent aggregates of CaOx can, like apatite and CPP crystals, stimulate synovial cell proliferation and enzyme release, resulting in progressive articular destruction. *Primary oxalosis* is a rare hereditary metabolic disorder **(Chap. 420)** that can lead to acute or chronic CaOx arthritis, periarthritis, and bone disease during later years of illness.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical features of acute CaOx arthritis may not be distinguishable from those due to MSU, CPP, or apatite. Deposits have been documented in fingers, wrists, elbows, knees, ankles, and feet. Radiographs may reveal chondrocalcinosis or soft tissue calcifications. CaOx-induced synovial effusions are usually noninflammatory, with <2000 leukocytes/μL, or mildly inflammatory. Neutrophils or mononuclear cells can predominate. CaOx crystals have a variable shape and variable birefringence to polarized light. The most easily recognized forms are bipyramidal, have strong birefringence **(Fig. 372-4)**, and stain with alizarin red S.

TREATMENT

Calcium Oxalate Deposition Disease

Treatment of CaOx arthropathy with NSAIDs, colchicine, intraarticular glucocorticoids, and/or an increased frequency of dialysis has produced only slight improvement. In primary oxalosis, liver transplantation has induced a significant reduction in crystal deposits **(Chap. 420)**.

373 Fibromyalgia

Leslie J. Crofford

DEFINITION

Fibromyalgia (FM) is characterized by chronic widespread musculoskeletal pain and tenderness. Although FM is defined primarily as a pain syndrome, patients also commonly report associated neuropsychological symptoms of fatigue, unrefreshing sleep, cognitive dysfunction, anxiety, and depression. Patients with FM have an increased prevalence of other syndromes associated with pain and fatigue, including myalgic encephalitis/chronic fatigue syndrome **(Chap. 450)**, temporomandibular disorder, chronic headaches, irritable bowel syndrome, interstitial cystitis/painful bladder syndrome, and other pelvic pain syndromes. Available evidence implicates the central nervous system as key to maintaining pain and other core symptoms of FM and related conditions. The presence of FM is associated with substantial negative consequences for physical and social functioning.

EPIDEMIOLOGY

Worldwide prevalence is ~2%, with a prevalence of ~4% in women and <1% in men. There is some variability depending on the method of ascertainment; however, the prevalence data are similar across world regions and socioeconomic classes. Cultural factors may play a role in determining whether patients with FM symptoms seek medical attention; however, even in cultures in which secondary gain is not expected to play a significant role, the prevalence of FM remains in this range. In clinical settings, a diagnosis of FM is far more common in women than in men, with a ratio of ~9:1.

CLINICAL MANIFESTATIONS

Pain and Tenderness At presentation, patients with FM most commonly report "pain all over." These patients have pain that is typically both above and below the waist on both sides of the body and involves the axial skeleton (neck, back, or chest). The pain attributable to FM is poorly localized, difficult to ignore, severe in its intensity, and associated with a reduced functional capacity. For a diagnosis of FM, pain should have been present most of the day on most days for at least 3 months.

The pain of FM is associated with tenderness and increased evoked pain sensitivity. In clinical practice, this elevated sensitivity may be identified by pain induced by the pressure of a blood pressure cuff or skin roll tenderness. More formally, an examiner may complete a tender-point examination in which the examiner uses the thumbnail to exert pressure of ~4 kg/m^2 (or the amount of pressure leading to blanching of the tip of the thumbnail) on well-defined musculotendinous sites **(Fig. 373-1)**. Previously, the classification criteria of the American College of Rheumatology required that 11 of 18 sites be perceived as painful for a diagnosis of FM. In practice, tenderness is a continuous variable, and strict application of a categorical threshold for diagnostic specifics is not necessary. Newer criteria eliminate the need for identification of tender points and focus instead on clinical symptoms of widespread or multisite pain and neuropsychological symptoms. The newer criteria perform well in a clinical setting in comparison to the older, tender-point criteria. However, it appears that when the new criteria are applied to populations, the result is an increase in prevalence of FM and a change in the sex ratio (see "Epidemiology," earlier).

Patients with FM often have peripheral pain generators that are thought to serve as triggers for the more widespread pain attributed to central nervous system factors. Potential pain generators such as arthritis, bursitis, tendinitis, neuropathies, and other inflammatory or degenerative conditions should be identified by history and physical examination. More subtle pain generators may include joint hypermobility and scoliosis. In addition, patients may have chronic myalgias triggered by infectious, metabolic, or psychiatric conditions that can serve as triggers for the development of FM. These conditions are often identified in the differential diagnosis of patients with FM, and a major challenge is to distinguish the ongoing activity of a triggering condition from FM that is occurring as a consequence of a comorbid condition and that should itself be treated.

Neuropsychological Symptoms In addition to widespread pain, FM patients typically report fatigue, stiffness, sleep disturbance, cognitive dysfunction, anxiety, and depression. These symptoms are present to varying degrees in most FM patients but are not present in every patient or at all times in a given patient. Relative to pain,

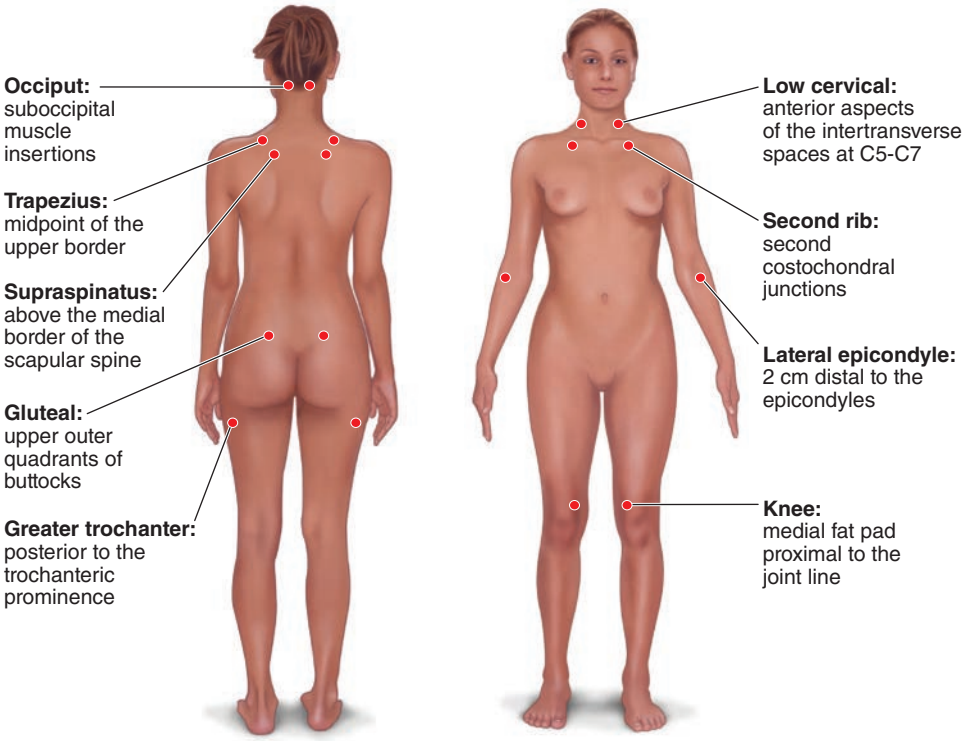

FIGURE 373-1 Tender-point assessment in patients with fibromyalgia. *(Figure created using data from F Wolfe et al: Arthritis Care Res 62:600, 2010.)*

such symptoms may, however, have an equal or even greater impact on function and quality of life. Fatigue is highly prevalent in patients under primary care who ultimately are diagnosed with FM. Pain, stiffness, and fatigue often are worsened by exercise or unaccustomed activity. The sleep complaints include difficulty falling asleep, difficulty staying asleep, and early-morning awakening. Regardless of the specific complaint, patients awake feeling unrefreshed. Patients with FM may meet criteria for restless legs syndrome and sleep-disordered breathing; frank sleep apnea can also be documented. Cognitive issues are characterized as difficulties with attention or concentration, problems with word retrieval, and short-term memory loss. Studies have demonstrated altered cognitive function in these domains in patients with FM, although speed of processing is age appropriate. Symptoms of anxiety and depression are common, and the lifetime prevalence of mood disorders in patients with FM approaches 80%. Although depression is neither necessary nor sufficient for the diagnosis of FM, it is important to screen for major depressive disorders by querying for depressed mood and anhedonia. Analysis of genetic factors that are likely to predispose to FM reveals shared neurobiologic pathways with mood disorders, providing the basis for comorbidity (see later in this chapter).

Overlapping Syndromes FM is considered as part of a group of conditions called "chronic overlapping pain syndromes" because of the propensity to coexist with other syndromes that may share underlying mechanisms. Review of systems often reveals headaches, facial/jaw pain, regional myofascial pain particularly involving the neck or back, and arthritis. Visceral pain involving the gastrointestinal tract, bladder, and pelvic or perineal region is often present as well. It is important for patients to understand that shared pathways may mediate symptoms and treatment strategies effective for one condition may help with global symptom management.

Comorbid Conditions FM is often comorbid with chronic musculoskeletal, infectious, metabolic, or psychiatric conditions. Whereas FM affects only ~2% of the general population, it occurs in ~10–30% of patients with degenerative or inflammatory rheumatic disorders, likely because these conditions serve as peripheral pain generators to alter central pain-processing pathways. Similarly, chronic infectious, metabolic, or psychiatric diseases associated with musculoskeletal pain can mimic FM and/or serve as a trigger for the development of FM. It is particularly important for clinicians to be sensitive to pain management of these comorbid conditions so that when FM emerges—characterized by pain outside the boundaries of what could reasonably be explained by the triggering condition, development of neuropsychological symptoms, or tenderness on physical examination—treatment of central pain processes will be undertaken as opposed to a continued focus on treatment of peripheral or inflammatory causes of pain.

Psychosocial Considerations Symptoms of FM often have their onset and are exacerbated during periods of perceived stress. This pattern may reflect an interaction among central stress physiology, vigilance or anxiety, and central pain-processing pathways. An understanding of current psychosocial stressors will aid in patient management, as many factors that exacerbate symptoms cannot be addressed by pharmacologic approaches. Furthermore, there is a high prevalence of exposure to previous interpersonal and other forms of violence in patients with FM and related conditions. If posttraumatic stress disorder is an issue, the clinician should be aware of it and consider treatment options.

Functional Impairment It is crucial to evaluate the impact of FM symptoms on function and role fulfillment. In defining the success of a management strategy, improved function is a key measure. Functional assessment should include physical, mental, and social domains. Recognition of the ways in which role functioning falls short will be helpful in establishing treatment goals.

DIFFERENTIAL DIAGNOSIS

Because musculoskeletal pain is such a common complaint, the differential diagnosis of FM is broad. Table 373-1 lists some of the more common conditions that should be considered. Patients with inflammatory causes for widespread pain should be identifiable on the basis of specific history, physical findings, and laboratory or radiographic tests.

TABLE 373-1 Common Conditions in the Differential Diagnosis of Fibromyalgia

Inflammatory
Polymyalgia rheumatica
Inflammatory arthritis: rheumatoid arthritis, spondyloarthritides
Connective tissue diseases: systemic lupus erythematosus, Sjögren's syndrome
Infectious
Hepatitis C
HIV infection
Lyme disease
Parvovirus B19 infection
Epstein-Barr virus infection
Noninflammatory
Degenerative joint/spine/disk disease
Myofascial pain syndromes
Bursitis, tendinitis, repetitive strain injuries
Endocrine
Hypo- or hyperthyroidism
Hyperparathyroidism
Neurologic Diseases
Multiple sclerosis
Neuropathic pain syndromes
Psychiatric Disease
Major depressive disorder
Drugs
Statins
Aromatase inhibitors

LABORATORY OR RADIOGRAPHIC TESTING

Routine laboratory and radiographic tests yield normal results in FM without comorbidities. Thus, diagnostic testing is focused on identification of other diagnoses and evaluation for pain generators or comorbid conditions (Table 373-2). Most patients with new chronic widespread pain should be assessed for the most common entities in the differential diagnosis. Radiographic testing should be used very sparingly and only for diagnosis of inflammatory arthritis. After the patient has been evaluated thoroughly, repeat testing is discouraged unless the symptom complex changes. Particularly to be discouraged is magnetic resonance imaging (MRI) of the spine unless there are features suggesting inflammatory spine disease or neurologic symptoms.

TABLE 373-2 Laboratory and Radiographic Testing in Patients with Fibromyalgia Symptoms

Routine
Erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP)
Complete blood count (CBC)
Thyroid-stimulating hormone (TSH)
Guided by History and Physical Examination
Complete metabolic panel
Antinuclear antibody (ANA)
Anti-SSA (anti–Sjögren's syndrome A) and anti-SSB
Rheumatoid factor and anti–cyclic citrullinated peptide (anti-CCP)
Creatine phosphokinase (CPK)
Viral (e.g., hepatitis C, HIV) and bacterial (e.g., Lyme) serologies
Spine and joint radiographs

GENETICS AND PHYSIOLOGY

As in most complex diseases, it is likely that a number of genes contribute to vulnerability to the development of FM. To date, these genes appear to be in pathways controlling pain and stress responses. Some of the genetic underpinnings of FM are shared across other chronic pain conditions. Genes associated with metabolism, transport, and receptors of serotonin and other monoamines have been implicated in FM and overlapping conditions. Genes associated with other pathways involved in pain transmission have also been described as vulnerability factors for FM. Taken together, the pathways in which polymorphisms have been identified in FM patients further implicate central factors in mediation of the physiology that leads to the clinical manifestations of FM.

Psychophysical testing of patients with FM has demonstrated altered sensory afferent pain processing and impaired descending noxious inhibitory control leading to hyperalgesia and allodynia. Functional MRI and other research imaging procedures clearly demonstrate activation of the brain regions involved in the experience of pain in response to stimuli that are innocuous in study participants without FM. Pain perception in FM patients is influenced by the emotional and cognitive dimensions, such as catastrophizing and perceptions of control, providing a solid basis for recommendations for cognitive and behavioral treatment strategies.

Studies have indicated that some patients meeting criteria for FM may have a small fiber neuropathy. Other studies have identified alterations in expressed gene or metabolic signatures in peripheral blood. These early studies raise the possibility that confirmatory diagnostic testing could be developed in the future to assist in the diagnosis of FM.

APPROACH TO THE PATIENT

Fibromyalgia

FM is common and has an extraordinary impact on the patient's function and health-related quality of life. Optimal management requires prompt diagnosis and assessment of pain, function, and psychosocial context. Physicians and other health professionals can be helpful in managing some of the symptoms and impact of FM. Developing a partnership with patients is essential for improving the outcome of FM, with a goal of understanding the factors involved, implementing a treatment strategy, and choosing appropriate nonpharmacologic and pharmacologic treatments.

TREATMENT

Fibromyalgia

NONPHARMACOLOGIC TREATMENT

Patients with chronic pain, fatigue, and other neuropsychological symptoms require a framework for understanding the symptoms that have such an important impact on their function and quality of life. Explaining the genetics, triggers, and physiology of FM can be an important adjunct in relieving associated anxiety and in reducing the overall cost of health care resources. In addition, patients must be educated regarding expectations for treatment. The physician should focus on improved function and quality of life rather than elimination of pain. Illness behaviors, such as frequent physician visits, should be discouraged and behaviors that focus on improved function strongly encouraged.

Treatment strategies should include physical conditioning, with encouragement to begin at low levels of aerobic exercise and to proceed with slow but consistent advancement. Physical activity and exercise are consistently found to be the most helpful strategies.

TABLE 373-3 Pharmacologic Agents Effective for Treatment of Fibromyalgia

Muscle relaxant
Cyclobenzaprine
Antidepressants: balanced serotonin–norepinephrine reuptake inhibitors
Amitryptiline[a]
Duloxetine[b,c]
Milnacipran[b,c]
Anticonvulsants: ligand of the alpha-2-delta subunit of voltage-gated calcium channels
Pregabalin[b]
Analgesic
Tramadol

[a]RA Moore et al: Cochrane Database Syst Rev 12:CD008242, 2012. [b]Approved by the U.S. Food and Drug Administration. [c]W Hauser et al: Cochrane Database Syst Rev 1: CD010292, 2013.

Source: GJ Macfarlane et al: EULAR revised recommendations for the management of fibromyalgia. Ann Rheum Dis 76:318, 2017.

Patients who have been physically inactive may do best in supervised or water-based programs at the start. Strength training may be recommended after patients reach their aerobic goals. Transcutaneous electric nerve stimulation (TENS) reduces movement-evoked pain and fatigue. Meditative movement therapies, such as qigong, yoga, or Tai Chi, may also be helpful. Other defined physical therapies such as acupuncture or hydrotherapy may also be considered. Exercise programs are helpful in reducing tenderness and enhancing self-efficacy. Cognitive-behavioral strategies to improve sleep hygiene and reduce illness behaviors can also be helpful in management.

PHARMACOLOGIC APPROACHES

It is essential for the clinician to treat any comorbid triggering condition and to clearly delineate for the patient the treatment goals for each medication. For example, glucocorticoids or nonsteroidal anti-inflammatory drugs may be useful for management of inflammatory triggers but are not effective against FM-related symptoms. At present, the treatment approaches that have proved most successful in FM patients target afferent or descending pain pathways. **Table 373-3** lists the drugs with demonstrated effectiveness. It should be emphasized that strong opioid analgesics are to be avoided in patients with FM. These agents have no demonstrated efficacy in FM and are associated with adverse effects that can worsen both symptoms and function. Tramadol, an opioid with mild serotonin-noradrenaline reuptake inhibitor activity, has been studied in this population with indication of efficacy. Use of single agents to treat multiple symptom domains is strongly encouraged. For example, if a patient's symptom complex is dominated by pain and sleep disturbance, use of an agent that exerts both analgesic and sleep-promoting effects is desirable. These agents include cyclobenzaprine, sedating antidepressants such as amitriptyline, and alpha-2-delta ligands such as gabapentin and pregabalin. For patients whose pain is associated with fatigue, anxiety, or depression, drugs that have both analgesic and antidepressant/anxiolytic effects, such as duloxetine or milnacipran, may be the best first choice.

374 Arthritis Associated with Systemic Disease, and Other Arthritides

Carol A. Langford, Brian F. Mandell

ARTHRITIS ASSOCIATED WITH SYSTEMIC DISEASE

ARTHROPATHY OF ACROMEGALY

Acromegaly is the result of excessive production of growth hormone by an adenoma in the anterior pituitary gland (Chap. 383). The excess of growth hormone along with insulin-like growth factor I stimulates proliferation of cartilage, periarticular connective tissue, and bone, resulting in several musculoskeletal problems, including osteoarthritis, back pain, muscle weakness, and carpal tunnel syndrome.

Osteoarthritis is a common feature, most often affecting the knees, shoulders, hips, and hands. Single or multiple joints may be affected. Hypertrophy of cartilage initially produces radiographic widening of the joint space. The newly synthesized cartilage is abnormally susceptible to fissuring, ulceration, and destruction. Ligamental laxity of joints further contributes to the development of articular discomfort and osteoarthritis. Cartilage degrades, the joint space narrows, and subchondral sclerosis and osteophytes may develop. Joint examination reveals crepitus and laxity. Joint fluid is noninflammatory. Calcium pyrophosphate dihydrate crystals are found in the cartilage in some cases of acromegaly arthropathy and, when shed into the joint, can elicit attacks of pseudogout (calcium pyrophosphate arthropathy). Chondrocalcinosis may be observed on radiographs. Back pain is extremely common, perhaps as a result of spine hypermobility. Spine radiographs show normal or widened intervertebral disk spaces, hypertrophic anterior osteophytes, and ligamental calcification. The latter changes are similar to those observed in patients with diffuse idiopathic skeletal hyperostosis. Dorsal kyphosis in conjunction with elongation of the ribs contributes to the development of the barrel chest seen in acromegalic patients. The hands and feet become enlarged as a result of soft tissue proliferation. The fingers are thickened and have spadelike distal tufts. One-third of patients have a thickened heel pad. Approximately 25% of patients exhibit Raynaud's phenomenon. Carpal tunnel syndrome occurs in about half of patients. The median nerve may become compressed by excess connective tissue in the carpal tunnel. Patients with acromegaly may develop proximal muscle weakness, which is thought to be caused by the effect of growth hormone on muscle. Serum muscle enzyme levels and electromyographic findings are normal. Muscle biopsy specimens contain muscle fibers of varying size without inflammation.

ARTHROPATHY OF HEMOCHROMATOSIS

Hemochromatosis is a disorder of iron storage. Absorption of excessive amounts of iron from the intestine leads to iron deposition in parenchymal cells, which results in impairment of organ function (Chap. 414). Symptoms of hemochromatosis usually begin between the ages of 40 and 60 but can appear earlier. Arthropathy, which occurs in 20–40% of patients, usually begins after the age of 50 and may be the first clinical feature of hemochromatosis. The arthropathy is an osteoarthritis-like disorder affecting the small joints of the hands and later the larger joints, such as knees, ankles, shoulders, and hips. The second and third metacarpophalangeal joints of both hands are often the first and most prominent joints affected; this clinical picture may provide an important clue to the possibility of hemochromatosis because these joints are not predominantly affected by primary osteoarthritis. Patients experience some morning stiffness and pain with use of involved joints. The affected joints are enlarged and mildly tender. Hand pain in patients with hemochromatosis generally is milder, starts at an earlier age, and causes less disability than in patients with primary osteoarthritis. Radiographs show narrowing of the joint space, subchondral sclerosis, subchondral cysts, and juxtaarticular proliferation of bone. Hook-like osteophytes are seen in up to 20% of patients; although they are regarded as a characteristic feature of hemochromatosis, they are not disease specific. However, dominant radiographic and clinical findings in the second and third metacarpophalangeal joints, even if modest in degree, warrants evaluation of ferritin and iron/total iron-binding capacity levels. The more typical radiographic changes of primary osteoarthritis in the proximal interphalangeal, distal interphalangeal, and first carpometacarpal joint are often not present. The synovial fluid is noninflammatory. The synovium shows mild to moderate proliferation of iron-containing lining cells, fibrosis, and some mononuclear cell infiltration. In approximately half of patients, there is evidence of calcium pyrophosphate deposition disease, and some patients late in the course of disease experience episodes of acute calcium pyrophosphate arthritis (Chap. 372). An early diagnosis is suggested by high serum transferrin saturation, which is more sensitive than ferritin elevation.

Iron may damage the articular cartilage in several ways. Iron catalyzes superoxide-dependent lipid peroxidation, which may play a role in joint damage. In animal models, ferric iron has been shown to interfere with collagen formation and increase the release of lysosomal enzymes from cells in the synovial membrane. Iron inhibits synovial tissue pyrophosphatase in vitro and therefore may inhibit pyrophosphatase in vivo, resulting in chondrocalcinosis.

TREATMENT

Arthropathy of Hemochromatosis

The treatment of hemochromatosis is repeated phlebotomy. Unfortunately, this treatment has little effect on established arthritis, which, along with chondrocalcinosis, may progress. Symptom-based treatment of the arthritis consists of administration of acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs), as tolerated. Acute calcium pyrophosphate arthropathy flares are treated with high doses of an NSAID or a short course of glucocorticoids. Low-dose colchicine may have efficacy in limiting the number of flares. Hip or knee total joint replacement has been successful in advanced disease.

HEMOPHILIC ARTHROPATHY

Hemophilia is a sex-linked recessive genetic disorder characterized by the absence or deficiency of factor VIII (hemophilia A, or classic hemophilia) or factor IX (hemophilia B, or Christmas disease) (Chap. 116). Hemophilia A constitutes 85% of cases. Spontaneous hemarthrosis is a common problem with both types of hemophilia and can lead to a deforming arthritis. The frequency and severity of hemarthrosis are related to the degree of clotting factor deficiency. Hemarthrosis is not common in other disorders of coagulation such as von Willebrand disease, factor V deficiency, warfarin therapy, or thrombocytopenia.

Hemarthrosis occurs after 1 year of age, when a child begins to walk and run. In order of frequency, the joints most commonly affected are the knees, ankles, elbows, shoulders, and hips. Small joints of the hands and feet are occasionally involved.

In the initial stage of arthropathy, hemarthrosis produces a warm, tensely swollen, and painful joint. The patient holds the affected joint in flexion and guards against any movement. Blood in the joint remains liquid because of the absence of intrinsic clotting factors and the absence of tissue thromboplastin in the synovium. The synovial blood is resorbed over a period of ≥1 week, with the precise interval depending on the size of the hemarthrosis. Joint function usually returns to normal or baseline in ~2 weeks. Low-grade temperature elevation may accompany hemarthrosis, but a fever >38.3°C (101°F) warrants concern about infection.

Recurrent hemarthrosis may result in chronic, noninflammatory, fibrotic arthropathy. The involved joints remain swollen, and flexion deformities impacting function develop. Restricted joint motion or laxity with subluxation is a feature of end-stage disease.

Bleeding into muscle and soft tissue also causes musculoskeletal dysfunction. When bleeding into the iliopsoas muscle occurs, the hip is held in flexion because of the pain, resulting in a hip flexion contracture. Rotation of the hip is preserved, which distinguishes this problem from hemarthrosis or other causes of hip synovitis. Expansion of the hematoma may place pressure on the femoral nerve, resulting in femoral neuropathy. Hemorrhage into a closed compartment space, such as the calf or the volar compartment in the forearm, can result in muscle necrosis, neuropathy, and flexion deformities of the ankles, wrists, and fingers. When bleeding involves periosteum or bone, a painful pseudotumor forms. These pseudotumors occur distal to the elbows or knees in children and improve with treatment of hemophilia. Surgical removal is indicated if the pseudotumor continues to enlarge. In adults, pseudotumors develop in the femur and pelvis and are usually refractory to treatment. When bleeding occurs in muscle, cysts may develop within the muscle. Needle aspiration of a cyst is contraindicated because this procedure can induce further bleeding; however, if the cyst becomes secondarily infected, drainage may be necessary (after factor repletion).

Septic arthritis is rare in hemophilia but is difficult to distinguish from acute hemarthrosis on physical examination. If there is serious suspicion of an infected joint, the joint should be aspirated immediately, the fluid cultured, and treatment with broad-spectrum antibiotics administered, with coverage for microorganisms including *Staphylococcus*, until culture results become available. Clotting factor deficiency should be corrected before arthrocentesis to minimize the risk of traumatic bleeding. Notably, low-grade fever can occur in the setting of acute hemarthrosis.

Radiographs of joints reflect the stage of disease. In early stages, there is capsule distention; later, juxtaarticular osteopenia, marginal erosions, and subchondral cysts develop. Late in the disease, the joint space is narrowed, and there is bony overgrowth similar to that in osteoarthritis.

TREATMENT

Hemarthrosis

The treatment of musculoskeletal bleeding is initiated with the immediate infusion of factor VIII or IX at the first sign of joint or muscle hemorrhage. Patients who have developed factor inhibitors are at elevated risk for joint damage and may benefit from receiving recombinant activated factor VII or activated prothrombin complex concentrate. The joint should be rested in a position of forced extension, as tolerated, to avoid contracture. Analgesia should be provided; nonselective NSAIDs, which can diminish platelet function, should be avoided. Selective cyclooxygenase-2 inhibitors do not interfere with platelet function, although cardiovascular and gastrointestinal risks must still be weighed. Synovectomy—open or arthroscopic—may be attempted in patients with chronic symptomatic synovial proliferation and recurrent hemarthrosis, although hypertrophied synovium is highly vascular and subject to bleeding. Both types of synovectomy reduce the number of hemarthroses. Open surgical synovectomy, however, is associated with some loss of range of motion. Both require aggressive prophylaxis against bleeding. Radiosynovectomy with either yttrium-90 silicate or phosphorus-31 colloid has been effective and may be attempted when surgical synovectomy is not practical. Total joint replacement is indicated for severe joint destruction and incapacitating pain.

ARTHROPATHIES ASSOCIATED WITH HEMOGLOBINOPATHIES

Sickle Cell Disease Sickle cell disease **(Chap. 98)** is associated with several musculoskeletal abnormalities **(Table 374-1)**. Children aged <5 years may develop diffuse swelling, tenderness, and warmth of the hands and feet lasting 1–3 weeks. This condition, referred to as *sickle cell dactylitis* or *hand-foot syndrome*, has also been observed in sickle cell thalassemia. Dactylitis is believed to result from infarction of the bone marrow and cortical bone leading to periostitis and soft tissue swelling. Radiographs show periosteal elevation, subperiosteal new bone formation, and areas of radiolucency and increased density involving the metacarpals, metatarsals, and proximal phalanges. These bone changes disappear after several months. The syndrome leaves little or no residual damage. Because hematopoiesis ceases in the small bones of the hands and feet with age, the syndrome is rarely seen after age 5.

TABLE 374-1 Musculoskeletal Abnormalities in Sickle Cell Disease

Sickle cell dactylitis	Avascular necrosis
Joint effusions in sickle cell crises	Bone changes secondary to marrow hyperplasia
Osteomyelitis	Septic arthritis
Infarction of bone	Gouty arthritis
Infarction of bone marrow	Synovial infarction

Sickle cell crisis is associated with periarticular pain and occasionally with joint effusions. The joint and periarticular area are warm and tender. Knees and elbows are most often affected, but other joints can be involved. Joint effusions are usually noninflammatory. Acute synovial infarction can cause a sterile effusion with high neutrophil counts in synovial fluid. Synovial biopsies have shown mild lining-cell proliferation and microvascular thrombosis with infarctions. Scintigraphic studies have shown decreased marrow uptake adjacent to the involved joint. The treatment for sickle cell crisis is detailed in **Chap. 98**.

Patients with sickle cell disease are predisposed to osteomyelitis, which commonly involves the long tubular bones **(Chap. 131)**; *Salmonella* is a particularly common cause **(Chap. 165)**. Radiographs of the involved site initially show periosteal elevation, with subsequent disruption of the cortex. Treatment of the infection results in healing of the bone lesion. In addition, bone infarction resulting from vasoocclusion secondary to the sickling of red cells can occur and is the cause of the bone pain in sickle cell crisis. Bone infarction also occurs in hemoglobin sickle cell disease and sickle cell thalassemia **(Chap. 98)**. In children, infarction of the epiphyseal growth plate interferes with normal growth of the affected extremity. Radiographically, infarction of the bone cortex results in periosteal elevation and irregular thickening of the bone cortex. Infarction in the bone marrow leads to lysis, fibrosis, and new bone formation. Clinical distinction between osteomyelitis and bone infarctions can be difficult; imaging can be helpful.

Avascular necrosis of the head of the femur occurs in ~5% of patients. It also occurs in the humeral head and less commonly in the distal femur, tibial condyles, distal radius, vertebral bodies, and other juxtaarticular sites. Irregularity of the femoral head and other articular surfaces often results in degenerative joint disease. Radiographs may show patchy radiolucency and density followed by flattening of the bone. MRI is a sensitive technique for detecting early avascular necrosis as well as bone infarction elsewhere. Total hip replacement and placement of prostheses in other joints may improve function and relieve joint pain in these patients.

Septic arthritis is occasionally encountered in sickle cell disease **(Chap. 130)**. Multiple joints may be infected. Joint infection may result from bacteremia due to splenic dysfunction or from contiguous osteomyelitis. The more common microorganisms include *Staphylococcus aureus*, *Streptococcus*, and *Salmonella*. *Salmonella* does not cause septic arthritis as frequently as it causes osteomyelitis. Acute gouty arthritis is uncommon in sickle cell disease, even though 40% of patients are hyperuricemic. However, it may occur in patients generally not expected to get gout (young patients, female patients). Hyperuricemia is due to overproduction of uric acid secondary to increased red cell turnover as well as suboptimal renal excretion. Attacks may be polyarticular, and diagnostic arthrocentesis should be performed to distinguish infection from gout or synovial infarction.

The bone marrow hyperplasia in sickle cell disease results in widening of the medullary cavities, thinning of the cortices, and coarse trabeculations and central cupping of the vertebral bodies. These changes are also seen to a lesser degree in hemoglobin sickle cell disease and sickle cell thalassemia. In normal individuals, red marrow is located

mostly in the axial skeleton, but in sickle cell disease, red marrow is found in the bones of the extremities and even in the tarsal and carpal bones. Vertebral compression may lead to dorsal kyphosis, and softening of the bone in the acetabulum may result in protrusio acetabuli.

Thalassemia A congenital disorder of hemoglobin synthesis, β thalassemia is characterized by impaired production of β chains (Chap. 98). Bone and joint abnormalities occur in β thalassemia, being most common in the major and intermedia groups. In one study, ~50% of patients with β thalassemia had evidence of symmetric ankle arthropathy with onset in the second or third decade of life. The degree of ankle pain in these patients varied. Some patients experienced self-limited ankle pain that occurred only after strenuous physical activity and lasted several days or weeks, while others had chronic ankle pain that became worse with walking. Compression of the ankle, calcaneus, or forefoot was painful in some patients. Synovial fluid from two patients was noninflammatory. Radiographs of the ankle showed osteopenia, widened medullary spaces, thin cortices, and coarse trabeculations as a result of bone marrow expansion. The joint space was preserved. Specimens of bone from three patients revealed osteomalacia, osteopenia, and microfractures. Increased numbers of osteoblasts as well as increased foci of bone resorption were present on the bone surface. Iron staining was found in the bone trabeculae, in osteoid, and in the cement line. Synovium showed hyperplasia of lining cells, which contained deposits of hemosiderin. This arthropathy was considered to be related to the underlying bone pathology. The role of iron overload or abnormal bone metabolism in the pathogenesis of this arthropathy is not known. The arthropathy was treated with analgesics and splints. Patients also received transfusions to decrease hematopoiesis and bone marrow expansion.

In patients with β-thalassemia major and β-thalassemia intermedia, other joints are also involved, including the knees, hips, and shoulders. Acquired hemochromatosis with arthropathy has been described in a patient with thalassemia. Gouty arthritis and septic arthritis can occur. Avascular necrosis is not a feature of thalassemia because there is no sickling of red cells leading to thrombosis and infarction.

β Thalassemia minor (also known as *β thalassemia trait*) is likewise associated with joint manifestations. Chronic seronegative oligoarthritis affecting predominantly ankles, wrists, and elbows has been described; the affected patients had mild persistent synovitis without large effusions or joint erosions. Recurrent episodes of acute asymmetric arthritis have also been reported; episodes last <1 week and may affect the knees, ankles, shoulders, elbows, wrists, and metacarpophalangeal joints. The mechanism underlying this arthropathy is unknown. Treatment with NSAIDs is not particularly effective.

MUSCULOSKELETAL DISORDERS ASSOCIATED WITH HYPERLIPIDEMIA

(See also Chap. 407) Musculoskeletal or cutaneous manifestations may be the first clinical indication of a specific hereditary disorder of lipoprotein metabolism. Patients with familial hypercholesterolemia (previously referred to as *type II hyperlipoproteinemia*) may have recurrent migratory polyarthritis involving the knees and other large peripheral joints and, to a lesser degree, peripheral small joints. Pain ranges from moderate to incapacitating. The involved joints can be warm, erythematous, swollen, and tender. Arthritis usually has a sudden onset, lasts from a few days to 2 weeks, and does not cause joint damage. Synovial fluid from involved joints is not inflammatory and contains few white cells and no crystals. Joint involvement may actually represent inflammatory periarthritis or peritendinitis and not true arthritis. The recurrent, transient nature of the arthritis may suggest acute gout or rheumatic fever, especially because patients with hyperlipoproteinemia may have an elevated erythrocyte sedimentation rate and elevated antistreptolysin O titers (the latter being quite common). Attacks of tendinitis, including the large Achilles and patellar tendons, may come on gradually and last only a few days or may be acute, as described above. Patients may be asymptomatic between attacks. Achilles tendinitis and other joint manifestations often precede the appearance of xanthomas and may be the first clinical indication of hyperlipoproteinemia. Attacks of tendinitis may follow treatment with a lipid-lowering drug. Over time, patients may develop tendinous xanthomas in the Achilles, patellar, and extensor tendons of the hands and feet. Xanthomas have also been reported in the peroneal tendon, the plantar aponeurosis, and the periosteum overlying the distal tibia where they are located within tendon fibers. Tuberous xanthomas are soft subcutaneous masses located over the extensor surfaces of the elbows, knees, and hands as well as on the buttocks. They appear during childhood in homozygous patients and after the age of 30 in heterozygous patients. Patients with elevated plasma levels of very-low-density lipoprotein (VLDL) and triglycerides (previously referred to as *type IV hyperlipoproteinemia*) may also have a mild inflammatory arthritis affecting large and small peripheral joints, usually in an asymmetric pattern, with only a few joints involved at a time. The onset of arthritis is typically between the age of 40 and 65 years. Arthritis may be persistent or recurrent, with episodes lasting a few days or weeks. Severe joint pain and tenderness, morning stiffness, and periarticular hyperesthesia may also be present, as may synovial thickening. Joint fluid is usually noninflammatory and without crystals but may have increased white blood cell counts with predominantly mononuclear cells. Radiographs may show juxtaarticular osteopenia and cystic lesions. Large bone cysts have been noted in a few patients. Xanthoma and bone cysts are also observed in other lipoprotein disorders. The pathogenesis of arthritis in patients with familial hypercholesterolemia or with elevated levels of VLDL and triglycerides is not well understood. NSAIDs or analgesics usually provide adequate relief of symptoms when used on an as-needed basis.

Patients may improve clinically as they are treated with lipid-lowering agents; however, patients treated with an HMG-CoA reductase inhibitor may experience myalgias, and a few patients develop myopathy, myositis, or even rhabdomyolysis. Patients who develop myositis during statin therapy may be susceptible to this adverse effect because of an underlying muscle disorder and should be reevaluated after discontinuation of the drug. Testing for anti–3-hydroxy-3-methylglutaryl-CoA reductase (HMGCR) autoantibodies in patients with elevated muscle enzymes on treatment may identify patients with statin-induced necrotizing autoimmune myopathy. Myositis has also been reported with the use of niacin (Chap. 365) but is less common than myalgias.

Musculoskeletal syndromes have not clearly been associated with the more common mixed hyperlipidemias seen in general practice.

OTHER ARTHRITIDES

NEUROPATHIC JOINT DISEASE

Neuropathic joint disease (Charcot joint) is a progressive destructive arthritis associated with loss of pain sensation, proprioception, or both. Normal muscular reflexes that modulate joint movement are impaired. Without these protective mechanisms, joints are subjected to repeated trauma, resulting in progressive cartilage and bone damage. Today, diabetes mellitus is the most frequent cause of neuropathic joint disease (Fig. 374-1). A variety of other disorders are associated with neuropathic arthritis, including tabes dorsalis, leprosy, yaws, syringomyelia, meningomyelocele, congenital indifference to pain, peroneal muscular atrophy (Charcot-Marie-Tooth disease), and amyloidosis. An arthritis resembling neuropathic joint disease has been reported in patients who have received intraarticular glucocorticoid injections, but this is a rare complication and was not observed in one series of patients with knee osteoarthritis who received intraarticular glucocorticoid injections every 3 months for 2 years. The distribution of joint involvement depends on the underlying neurologic disorder (Table 374-2). In tabes dorsalis, the knees, hips, and ankles are most commonly affected; in syringomyelia, the glenohumeral joint, elbow, and wrist; and in diabetes mellitus, the tarsal and tarsometatarsal joints.

PATHOLOGY AND PATHOPHYSIOLOGY

The pathologic changes in the neuropathic joint are similar to those found in the severe osteoarthritic joint. There is fragmentation and eventual loss of articular cartilage with eburnation of the underlying bone. Osteophytes are found at the joint margins. With more advanced

FIGURE 374-1 Charcot arthropathy associated with diabetes mellitus. Lateral foot radiograph demonstrating complete loss of the arch due to bony fragmentation and dislocation in the midfoot. *(Courtesy of Andrew Neckers, MD, and Jean Schils, MD; with permission.)*

disease, erosions are present on the joint surface. Fractures, devitalized bone, intraarticular loose bodies, and microscopic fragments of cartilage and bone may be present.

At least two underlying mechanisms are believed to be involved in the pathogenesis of neuropathic arthritis. An abnormal autonomic nervous system is thought to be responsible for the dysregulated blood flow to the joint with subsequent resorption of bone. Loss of bone, particularly in the diabetic foot, may be the initial finding. With the loss of deep pain, proprioception, and protective neuromuscular reflexes, the joint is subjected to repeated microtrauma, resulting in ligamental tears and bone fractures. The injury that follows frequent intraarticular glucocorticoid injections is thought to be due to the analgesic effect of glucocorticoids, leading to overuse of an already damaged joint; the result is accelerated cartilage damage, although steroid-induced cartilage damage is more common in some other animal species than in humans. It is not understood why only a few patients with neuropathy develop clinically evident neuropathic arthritis.

CLINICAL MANIFESTATIONS

Neuropathic joint disease usually begins in a single joint and then becomes apparent in other joints, depending on the underlying neurologic disorder. The involved joint becomes progressively enlarged as a result of bony overgrowth and synovial effusion. Loose bodies may be palpated in the joint cavity. Joint instability, subluxation, and crepitus occur as the disease progresses. Neuropathic joints may develop rapidly, and a totally disorganized joint with multiple bony fragments may evolve within weeks or months. The amount of pain experienced by the patient is less than would be anticipated from the degree of joint damage. Patients may experience sudden joint pain from intraarticular fractures of osteophytes or condyles.

Neuropathic arthritis is encountered most often in patients with diabetes mellitus, with an incidence of ~0.5%. The onset of disease usually comes at an age of ≥50 years in a patient who has had diabetes for several years, but exceptions occur. The tarsal and tarsometatarsal joints are most often affected, with the metatarsophalangeal and talotibial joints next most commonly involved. The knees and spine are occasionally involved. Patients often attribute the onset of foot pain to antecedent trauma such as twisting of the foot. Neuropathic changes may develop rapidly after a foot fracture or dislocation. The foot and ankle are often swollen. Downward collapse of the tarsal bones leads to convexity of the sole, referred to as a "rocker foot." Large osteophytes may protrude from the top of the foot. Calluses frequently form over the metatarsal heads and may lead to infected ulcers and osteomyelitis. The value of protective inserts and orthotics, as well as regular foot examination, cannot be overstated. Radiographs may show resorption and tapering of the distal metatarsal bones. The term *Lisfranc fracture-dislocation* is sometimes used to describe the destructive changes at the tarsometatarsal joints.

TABLE 374-2 Disorders Associated with Neuropathic Joint Disease

Diabetes mellitus	Amyloidosis
Tabes dorsalis	Leprosy
Meningomyelocele	Congenital indifference to pain
Syringomyelia	Peroneal muscular atrophy

DIAGNOSIS

The diagnosis of neuropathic arthritis is based on the clinical features and characteristic radiographic findings in a patient with underlying sensory neuropathy. The differential diagnosis of neuropathic arthritis depends upon the severity of the process and includes osteomyelitis, avascular necrosis, advanced osteoarthritis, stress fractures, and calcium pyrophosphate deposition disease. Radiographs in neuropathic arthritis initially show changes of osteoarthritis with joint space narrowing, subchondral bone sclerosis, osteophytes, and joint effusions; marked destructive and hypertrophic changes follow later. The radiographic findings of neuropathic arthritis may be difficult to differentiate from those of osteomyelitis, especially in the diabetic foot. The joint margins in a neuropathic joint tend to be distinct, while in osteomyelitis, they are blurred. Imaging studies may be helpful, but cultures of tissue from the joint are often required to exclude osteomyelitis. MRI and bone scans using indium-111–labeled white blood cells or indium-111–labeled immunoglobulin G, which will show increased uptake in osteomyelitis but not in a neuropathic joint, may be useful. A technetium bone scan will not distinguish osteomyelitis from neuropathic arthritis, as increased uptake is observed in both. The joint fluid in neuropathic arthritis is noninflammatory; it may be xanthochromic or even bloody and may contain fragments of synovium, cartilage, and bone. The finding of calcium pyrophosphate dihydrate crystals supports the diagnosis of crystal-associated arthropathy. In the absence of such crystals, an increased number of leukocytes may indicate osteomyelitis.

TREATMENT

Neuropathic Joint Disease

The primary focus of treatment is to stabilize the joint. Treatment of the underlying disorder, even if successful, does not usually affect established joint disease. Braces and splints are helpful. Their use requires close surveillance, because patients may be unable to appreciate pressure from a poorly adjusted brace. In the diabetic patient, early recognition of Charcot foot and its treatment—prohibition of weight bearing by the foot for at least 8 weeks—may possibly prevent severe disease from developing. Fusion of an unstable joint may improve function and reduce pain, but nonunion is frequent, especially when immobilization of the joint is inadequate.

HYPERTROPHIC OSTEOARTHROPATHY AND CLUBBING

Hypertrophic osteoarthropathy (HOA) is characterized by clubbing of digits and, in more advanced stages, by periosteal new bone formation and synovial effusions. HOA may be primary or familial and may begin in childhood. Secondary HOA is associated with intrathoracic malignancies, suppurative and some hypoxemic lung diseases, congenital heart disease, and a variety of other disorders. Clubbing is almost always a feature of HOA but can also occur as an isolated finding (Fig. 374-2). The presence of clubbing in isolation may be congenital or represent either an early stage or one element in the spectrum of HOA. Isolated acquired clubbing has the same clinical significance as clubbing associated with periostitis.

Pathology and Pathophysiology of Acquired HOA In HOA, bone changes in the distal extremities begin as periostitis followed by new bone formation. At this stage, a radiolucent area may be observed between the new periosteal bone and the subjacent cortex. As the process progresses, multiple layers of new bone are deposited and become contiguous with the cortex, with consequent cortical thickening. The outer portion of the bone is laminated in appearance, with an irregular

FIGURE 374-2 Clubbing of the fingers. *(Photo contributor Alan B. Storrow, MD).*

surface. Initially, the process of periosteal new bone formation involves the proximal and distal diaphyses of the tibia, fibula, radius, and ulna and, less frequently, the femur, humerus, metacarpals, metatarsals, and phalanges. Occasionally, scapulae, clavicles, ribs, and pelvic bones are also affected. The adjacent interosseous membranes may become ossified. The distribution of bone manifestations is usually bilateral and symmetric. The soft tissue overlying the distal third of the arms and legs may be thickened. Proliferation of connective tissue occurs in the nail bed and volar pad of digits, giving the distal phalanges a clubbed appearance. Small blood vessels in the clubbed digits are dilated and have thickened walls. In addition, the number of arteriovenous anastomoses is increased.

Several theories have been suggested for the pathogenesis of HOA, but many have been disproved or have not explained the condition's development in all clinical disorders with which it is associated. Previously proposed neurogenic and humoral theories are no longer considered likely explanations for HOA. Studies have suggested a role for platelets in the development of HOA. It has been observed that megakaryocytes and large platelet particles present in the venous circulation are fragmented in their passage through normal lung. In patients with cyanotic congenital heart disease and in other disorders associated with right-to-left shunts, these large platelet particles bypass the lung and reach the distal extremities, where they can interact with endothelial cells. Platelet–endothelial cell activation in the distal portion of the extremities may result in the release of platelet-derived growth factor (PDGF) and other factors leading to the proliferation of connective tissue and periosteum. Stimulation of fibroblasts by PDGF and transforming growth factor β results in cell growth and collagen synthesis. Elevated plasma levels of von Willebrand factor antigen have been found in patients with both primary and secondary forms of HOA, indicating endothelial activation or damage. Abnormalities of collagen synthesis have been demonstrated in the involved skin of patients with primary HOA. Other factors are undoubtedly involved in the pathogenesis of HOA, and further studies are needed to elucidate this disorder.

Clinical Manifestations Primary or familial HOA, also referred to as *pachydermoperiostitis* or *Touraine-Solente-Golé syndrome*, usually begins insidiously at puberty. In a smaller proportion of patients, the onset comes in the first year of life. The disorder is inherited as an autosomal dominant trait with variable expression and is nine times more common among boys than among girls. Approximately one-third of patients have a family history of primary HOA.

Primary HOA is characterized by clubbing, periostitis, and unusual skin features. A small number of patients with this syndrome do not express clubbing. The skin changes and periostitis are prominent features of this syndrome. The skin becomes thickened and coarse. Deep nasolabial folds develop, and the forehead may become furrowed. Patients may have heavy-appearing eyelids and ptosis. The skin is often greasy, and there may be excessive sweating of the hands and feet. Patients may also experience acne vulgaris, seborrhea, and folliculitis. In a few patients, the skin over the scalp becomes very thick and corrugated, a feature that has been descriptively termed *cutis verticis gyrata*. The distal extremities, particularly the legs, become thickened as a consequence of the proliferation of new bone and soft tissue; when the process is extensive, the distal lower extremities resemble those of an elephant. The periostitis usually is not painful, which it can be in secondary HOA. Clubbing of the fingers may be extensive, producing large, bulbous deformities, and clumsiness. Clubbing also affects the toes. Patients may experience articular and periarticular pain, especially in the ankles and knees, and joint motion may be mildly restricted by periarticular bone overgrowth. Noninflammatory effusions occur in the wrists, knees, and ankles. Synovial hypertrophy is not found. Associated abnormalities observed in patients with primary HOA include hypertrophic gastropathy, bone marrow failure, female escutcheon, gynecomastia, and cranial suture defects. In patients with primary HOA, the symptoms disappear when adulthood is reached.

HOA secondary to an underlying disease occurs more frequently than primary HOA. It accompanies a variety of disorders and may precede clinical features of the associated disorder by months. Clubbing is more frequent than the full syndrome of HOA in patients with associated illnesses. Because clubbing evolves over months and is usually asymptomatic, it is often recognized first by the physician and not the patient. Patients may experience a burning sensation in their fingertips. Clubbing is characterized by widening of the fingertips, enlargement of the distal volar pad, convexity of the nail contour, and the loss of the normal 15° angle between the proximal nail and cuticle. The thickness of the digit at the base of the nail is greater than the thickness at the distal interphalangeal joint. An objective measurement of finger clubbing can be made by determining the diameter at the base of the nail and at the distal interphalangeal joint of all 10 digits. Clubbing is present when the sum of the individual digit ratios is >10. At the bedside, clubbing can be appreciated by having the patient place the dorsal surface of the distal phalanges of the fourth fingers together with the nails opposing each other. Normally, an open area is visible between the bases of the opposing fingernails; when clubbing is present, this open space is no longer visible. The base of the nail feels spongy when compressed, and the nail can be easily rocked on its bed. When clubbing is advanced, the finger may have a drumstick appearance, and the distal interphalangeal joint can be hyperextended. Periosteal involvement in the distal extremities may produce a burning or deep-seated aching pain. The pain, which can be quite incapacitating, is aggravated by dependency and relieved by elevation of the affected limbs. Pressure applied over the distal forearms and legs or gentle percussion of distal long bones like the tibia may be quite painful.

Patients may experience joint pain, most often in the ankles, wrists, and knees. Joint effusions may be present but are usually noninflammatory. The small joints of the hands are rarely affected. Severe joint or long bone pain may be the presenting symptom of an underlying lung malignancy and may precede the appearance of clubbing. In addition, the progression of HOA tends to be more rapid when associated with malignancies, most notably bronchogenic carcinoma. Noninflammatory but variably painful knee effusions may occur prior to the onset of clubbing and symptoms of distal periostitis. Unlike primary HOA, secondary HOA does not commonly include excessive sweating and oiliness of the skin or thickening of the facial skin.

HOA occurs in 5–10% of patients with intrathoracic malignancies, the most common being bronchogenic carcinoma and pleural tumors **(Table 374-3)**. Lung metastases infrequently cause HOA. HOA is also seen in patients with intrathoracic infections, including lung abscesses, empyema, and bronchiectasis, but is uncommon in pulmonary tuberculosis. HOA may accompany chronic interstitial pneumonitis, sarcoidosis, and cystic fibrosis. In cystic fibrosis, clubbing is more common than the full syndrome of HOA. Other causes of clubbing include congenital heart disease with right-to-left shunts, bacterial endocarditis, Crohn's disease, ulcerative colitis, sprue, and neoplasms of the esophagus, liver, and small and large bowel. In patients who have congenital heart disease with right-to-left shunts, clubbing alone occurs more often than the full syndrome of HOA.

Unilateral clubbing has been found in association with aneurysms of major extremity arteries, with infected arterial grafts, and with

TABLE 374-3 Disorders Associated with Hypertrophic Osteoarthropathy

Pulmonary
Bronchogenic carcinoma and other neoplasms
Lung abscesses, empyema, bronchiectasis
Chronic interstitial pneumonitis
Cystic fibrosis
Sarcoidosis
Gastrointestinal
Inflammatory bowel disease
Sprue
Neoplasms: esophagus, liver, bowel
Cardiovascular
Cyanotic congenital heart disease
Subacute bacterial endocarditis
Infected arterial grafts[a]
Aortic aneurysm[b]
Aneurysm of major extremity artery[a]
Patent ductus arteriosus[b]
Arteriovenous fistula of major extremity vessel[a]
Thyroid (thyroid acropachy)
Hyperthyroidism (Graves' disease)

[a]Unilateral involvement. [b]Bilateral lower-extremity involvement.

arteriovenous fistulas of brachial vessels. Clubbing of the toes but not the fingers has been associated with an infected abdominal aortic aneurysm and patent ductus arteriosus. Clubbing of a single digit may follow trauma and has been reported in tophaceous gout and sarcoidosis. While clubbing occurs more commonly than the full syndrome in most diseases, periostitis in the absence of clubbing has been observed in the affected limb of patients with infected arterial grafts.

Hyperthyroidism (Graves' disease), treated or untreated, is occasionally associated with clubbing and periostitis of the bones of the hands and feet. This condition is referred to as *thyroid acropachy*. Periostitis may be asymptomatic and occurs in the midshaft and diaphyseal portion of the metacarpal and phalangeal bones. Significant hand-joint pain may occur, which may respond to successful therapy for thyroid dysfunction. The long bones of the extremities are seldom affected. Elevated levels of long-acting thyroid stimulator are found in the sera of these patients.

Laboratory Findings The laboratory abnormalities reflect the underlying disorder. The synovial fluid of involved joints has <500 white cells/μL, and the cells are predominantly mononuclear. Radiographs show a faint radiolucent line beneath the new periosteal bone along the shaft of long bones at their distal end. These changes are observed most frequently at the ankles, wrists, and knees. The ends of the distal phalanges may show osseous resorption. Radionuclide studies show pericortical linear uptake along the cortical margins of long bones that may precede any radiographic changes.

TREATMENT

Hypertrophic Osteoarthropathy

The treatment of HOA aims to identify and treat the associated disorder. The symptoms and signs of HOA may disappear completely with removal of or effective chemotherapy for a tumor or with antibiotic therapy for a chronic pulmonary infection and drainage of the infected site. Vagotomy or percutaneous block of the vagus nerve leads to symptomatic relief in some patients. NSAIDs or analgesics may help control symptoms of HOA.

COMPLEX REGIONAL PAIN SYNDROME
